Memorandum On Arch Dam Developments

BY LARS JORGENSEN*

SYNOPSIS

The intention in the presentation of this paper is to record some of the recent developments in arch dam design and construction in general and in Constant Angle Arch Dam design in particular.

The work described covers the period of the last 16 years. During this period more arch dams have been built than ever before and their design has finally been developed upon as scientific a foundation as that of any other type of dam.

The possibility of obtaining a high factor of safety economically is beginning to become generally recognized by the profession. This was not so 16 years ago.

Actual cost data have been given for the various structures described—covering all kinds of locations—in order to have reliable figures available as a guide for estimating the cost of new work.

Arch Dams can not be called new and untried any longer since the highest dams built and being built are now of that type.

As time goes by, the art of dam building is improving along with other lines of activities. Faith in arch dams is beginning to manifest itself among engineers, especially among the younger set; and the preference shown by many engineers for gravity dams is beginning to give place to a desire for a more economical structure such as an arch dam on sites where this type fits.

An engineering structure must first of all be safe, and secondly it should be economical. It does not require much skill merely to use plenty of material in a structure in order to make it safe; the material should always be placed where it does the most good. The factor of safety may properly vary on various structures, depending upon their importance, but this does not alter the fact

*Consulting Hydro-Electric Engineer, San Francisco.

that whatever material is used, it should be placed as economically as possible.

In a gravity dam it is not possible to utilize the material to the best advantage; half of it is not fully working with reservoir full. Nevertheless, there are cases where this type still remains the best type to use.

In the past, gravity dams have been almost exclusively built on large important projects. At present, however, the arch dam theory has been developed to a stage where it is possible to predetermine the stresses in such a structure with a satisfactory degree of dependability, and with as great accuracy as the stresses in a gravity dam near the foundation. There is no more uncertainty about the behavior of an arch dam than about most any other structure. Enough arch dams have been built and are building to inspire confidence that the principle is right. About the only mystery about arch dams is that no single arch dam has ever failed; there are several freaks existing, almost mysteriously holding a reservoir full of water. (Crowley Creek, Bear Valley Upper Otay.)

Professor Cain put the calculation of arch dams on a better technical basis than it had been before the appearance of his paper "The Circular Arch Under Normal Load."* If his method of calculation is followed, using conservative stresses, a structure of definite safety will result. The lower the stresses are assumed naturally the higher the factor of safety will be. How high it should be depends, as already stated, upon the importance of the work.

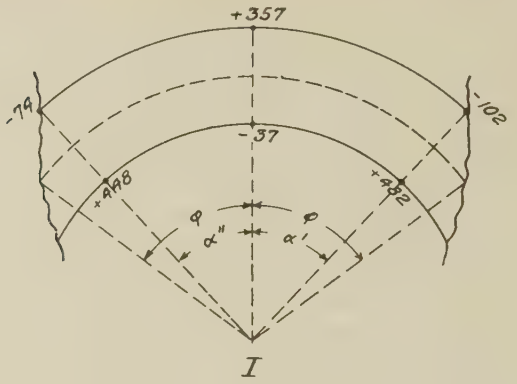
Professor Cain's theory as well as the work of Jakobsen, Noetzli and others is to a great extent responsible for the conversion of many members of the profession from being blind gravity enthusiasts to arch dam considerers or even to arch proponents.

There is hardly a subject to be found in engineering where two factions of engineers have been opposed to one another so definitely, as on the subject of gravity dams versus arch dams. On sites where arch dams do not fit, of course, they have no place. In this connection, the words "do not fit" mean where they are not safer and cheaper.

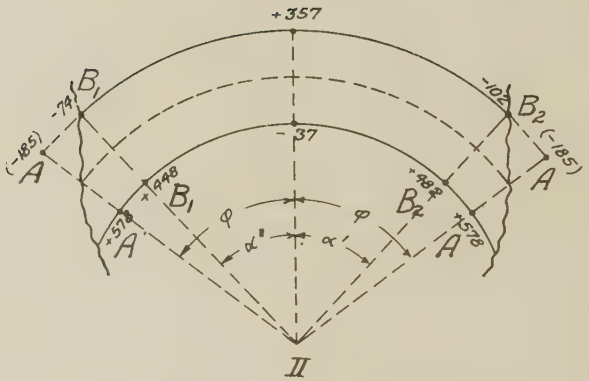
The fact that no single arch dam has ever failed and that to the

*Trans. Am. Soc. Civil Engineers, 1922, page 233.

writer's knowledge 25 gravity dams have failed from one cause or another (19 during the last 30 years),† should be convincing proof that even the most conservative engineers cannot afford to overlook the possibility of the arch dam. The engineer is responsible to his client and should give him the best for his money, regardless of the inconvenience it may cause the engineer to investigate a field new to him.



To choose a gravity dam in any and all cases merely because the engineer has been an advocate of this type of dam all his life is a poor foundation for a choice. A decision should be based upon the results of calculations of safety and cost of structure, and not upon preconceived or inherited ideas.



It has been mentioned above that Cain's formulas for a fixed arch under normal load can be regarded as standard; they are now used in design work done by the Constant Angle Arch Dam Co., San Francisco, with which the writer is connected. Some difference of opinion may exist as to how to apply the formulas in cases where the rock abutments are not radial, and such cases are common.

The three sketches, Figures 1, 2 and 3, illustrate various assumptions possible as to span, length, subtended angle, etc., when the abutments are not radial. When calculating the bending moment at the crown the subtended angle of $2\ \phi$ is used in Fig. 1. This angle subtends the points of intersection of the middle line with the abutments. The middle line is assumed to be equal and generally is equal to the average length of the arch, subject to the elastic deformation. The plane of maximum bending moment is taken to be where a radial line first intersects the rock abutments, either on the up or downstream face, as the case may be. Here the water load is assumed to stop on the arch proper. When calculating the maximum bending moment here the smaller value $2\ \dot{\alpha}$ is used for the subtended angle.

For a thick arch, additional calculations are made assuming the maximum plane of bending to be along the plane A-A, Fig. 2, being a radial plane through the point of intersection of the center line or middle line of the arch ring with the rock abutment. The subtended angle $2\ \phi$ is used for the calculation of the bending

†See "Record of 100 Dam Failures," by Lars Jorgensen, Journal of Electricity, San Francisco, March 15, April 1, 1920.

FIGS. 1 AND 2—PACIOMA DAM. STRESSES IN POUNDS PER SQUARE INCH, ELEVATION 1825

moments both at the crown and at the abutments, A-A in this case.

This gives a check on unit compression at the downstream face in plane A-A. If found too high, the dimension should be increased. No attention is paid to possible tension in the rock along the continuation of the upstream face, as none can actually exist.

In Fig. 3, the third possible assumption as to the location of the planes of maximum bending moments and value of subtended angle 2 ϕ is shown. Here the same subtended angle 2 ϕ is used

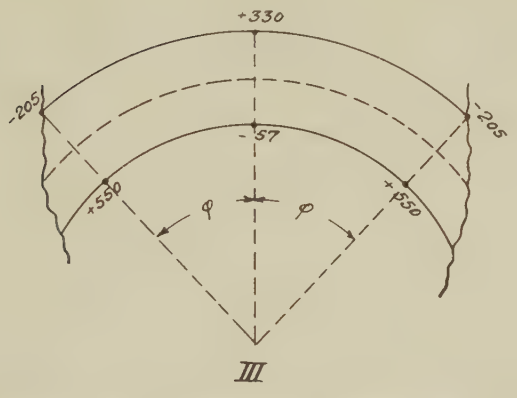


FIG. 3—PACOIMA DAM. STRESSES IN POUNDS PER SQUARE INCH, ELEVATION 1825

for the calculation of both the bending moments at the crown and at the abutments. The influence of using a smaller subtended angle on these bending moments is to the effect of generally lowering the stresses at the crown, at least at the upstream face, and increasing them at the abutments. The stresses at the abutments practically always control the design. On important work it may be well to use all three variations for checking purposes.

When making a design for an arch dam, the simple arch formula (*unit water pressure* $\times$ *length of upstream radius* = *unit stress* $\times$ *thickness*) can most conveniently be used in order to obtain a preliminary section. Then the bending moments and resulting stresses are calculated by means of Cain's formulas. Since the bending moments at the abutments are approximately twice as high as the bending moment at the crown, the thickness at the abutments will not be the same as the thickness at the crown, but will have to be increased towards the abutments to correspond to the increase in stress due to the effect of the larger bending moment. This increase in thickness should commence at a point located between 15 and 18 per cent of the length of the arch out from each abutment. The addition of material should be placed mostly on the downstream face and should increase in thickness from 0 at $\frac{15}{100}$ to $\frac{18}{100}$ of length of arc from the abutments, to a maximum at the abutments.

TABLE TO ACCOMPANY FIGURES 1, 2 AND 3

			Elev. 1825 I	Elev. 1825 II	Elev. 1825 III
t_o thickness of dam at crown		ft.	51.0	51.0	51.0

STRESSES IN LBS. PER SQ. INCH, ELEV. 1825

Towards the crest of the dam where excess material is used to provide for a practical thickness the up and downstream faces can be kept concentric. Towards the bottom the shear action predominates, especially in narrow canyons, and the dam is to be investigated for this action in its lower portion.

ALLOWABLE STRESSES

When calculating the bending moments and resulting stresses on actual structures, as shown later, the normal load on the structure is taken to equal the full water pressure; the portion of the water load taken by the cantilever has been neglected. To find the portion of load taken by the cantilever is a difficult problem; the amount taken in the middle of the canyon differs from the amount taken at other points and due to the effect of water soaking the cantilever may not take any load. Therefore, this action has been neglected, which is on the side of safety.

Before deciding upon the maximum stress to use, the ultimate strength of the concrete must be determined and the importance of the structure considered.

The writer first used a concrete mix which would have a crushing strength of 1500 to 2000 lbs. per sq. in. when 28 days old. Recently only the upper limit and above has been considered. The amount of cement is varied in such a manner as to give this strength when mixed with the aggregate at hand at the different locations. Less than a barrel of cement to the cubic yard is never used and more than a barrel of cement per cubic yard of concrete often has to be used in order to bring the strength and water-tightness up to the desired standard. The cement is the only thing that glues the particles together and makes the dam a watertight monolith and to save to the limit on cement is not good economy.

When calculating stresses in accordance with assumptions shown in Fig. 1 on work of average importance a maximum compression of 600 lb. per sq. in. and a maximum tension of 100 lb. per sq. in. are generally used. Maximum tension should not be paired with maximum compression, as in case the dam should crack in the tension side and thereby relieve the tension, more compression may be thrown on the compression side, although not always.

Sometimes a crack in the tension side (relieving the tension) may also relieve the compression on the compression side, depending upon whether the bending moment is created by a large force acting through a small eccentricity or by a small force acting through a large eccentricity. Whenever a large compression exists at the downstream face at the abutments it is safer not to allow a large tension at the upstream side of the abutments. If such a combination should happen, the thickness of the arch ought to be increased. The abutment stresses are the controlling stresses, as here the bending moment is the greatest.

If the simple arch formula were used in order to obtain a preliminary section using between 300 and 350 lbs. per sq. in. for the arch compression, it will generally be found that the section will be ample at the crown and that additions to the thickness only need be made at the abutments in order to satisfy the Cain formulas using the extreme stresses up to 600 lb. compression and 100 lb. tension per sq. in.

Should the assumption shown in Fig. 3 be used, it would be safe to allow somewhat higher unit stresses, since the condition represented by it is more severe than actually is the case.

Even using the assumptions shown in Figures 1 and 2 will indicate higher stresses than actually exist, for several reasons:

1. The cantilever action perhaps takes some of the load.

2. The concrete especially near the upstream face is wet and expands, relieving the tension.

3. In case the stresses are very high (higher than 800 lb. per sq. in. compression) a redistribution may take place due to the action of the time factor in creating "flow."

4. The arch may not be fixed in an extreme sense, hence taken all in all, the assumed designing stresses (600 lb. per sq. in. compression and 100 lb. per sq. in. tension) will not materialize at the abutments where the stresses generally are the highest.

A factor of safety of between 4 and 5 for the structure should therefore be a reality.

During the last 16 years, 40 or more Constant Angle Arch Dams have been built, besides many ordinary arch dams. Several large Constant Angle Arch Dams are being constructed at present, and this type of dam can therefore hardly be called

new and experimental any longer. The Constant Angle Arch design has been previously explained* and a detailed description of two large arch dams—the Lake Spaulding Dam, (California) and the Salmon Lake Dam, (Alaska) given.

Since then improvements in the design of arch dams have been effected partly due to practical experience gained in building numerous dams and partly due to improvements in the theory as recently advanced by different writers on the subject.

In the following the description of several typical Constant Angle Arch Dams recently built will be given indicating the successive improvement in design.

FIG. 4A—BULLARDS BAR DAM UNDER CONSTRUCTION. HEIGHT 183 FT. ABOVE FOUNDATION; SPAN 440 FT.

Figures 4, 5, 5A and 5B show working details of the Bullards Bar Dam built on the North Fork of the Yuba River, California. This dam is 182 ft. high above the foundation (175 ft. above river level) and creates a head of 175 ft. which is utilized in a power

*Trans. Am. Soc. C. E., 1915, v. 78, p. 685.

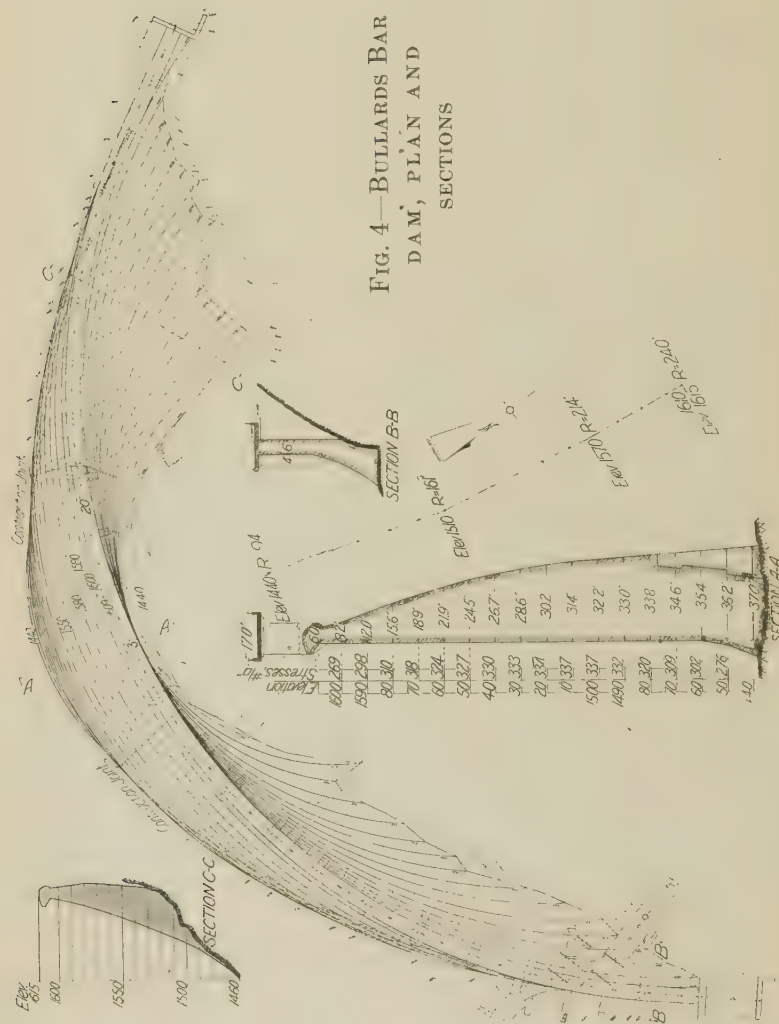

FIG. 4—BULLARDS BAR DAM, PLAN AND SECTIONS

plant located 300 ft. below the dam. The length of the upstream radius varies from 240 ft. at the crest to 94 ft. at the bottom. The development is now operated as part of the Pacific Gas & Electric Company's system. The reservoir space created by this dam is principally to be used for storing debris from gold mines located on the drainage above. Hydraulic gold mining was discontinued on a large scale in the early eighties when dumping of gravel or debris into any tributary to the Sacramento or San Joaquin Rivers was prohibited because these rivers were being rapidly filled up with gravel from the mines. With reservoirs built on the tributaries for storing this gravel, hydraulic mining is again legally possible.

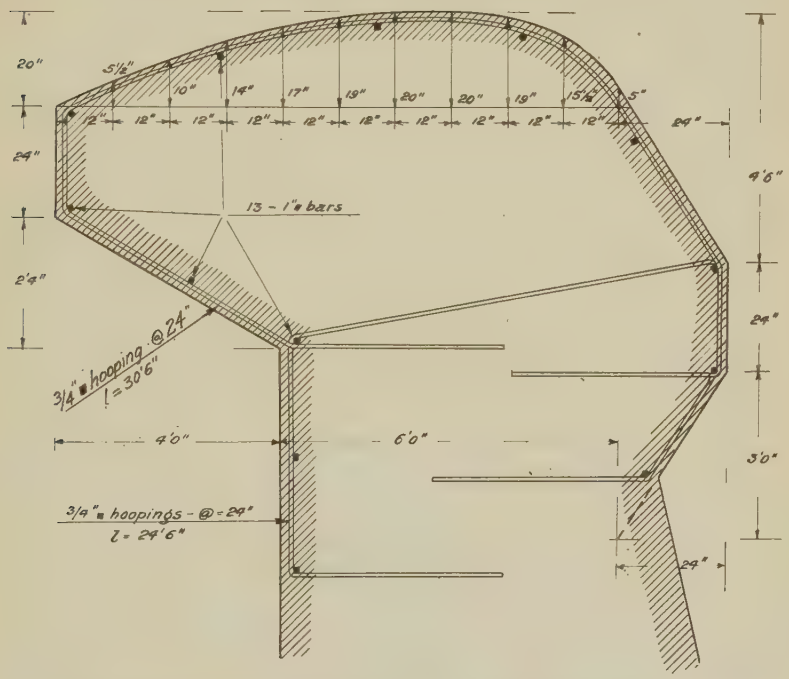

FIG. 5 —SECTION THROUGH SPILLWAY LIP, BULLARDS BAR PROJECT

The Bullards Bar reservoir will store approximately 70 million cu. yds. of debris to within 15 ft. of its crest. This represents also the approximate yardage of gold bearing gravel still remaining to be worked by the hydraulic method above this dam.

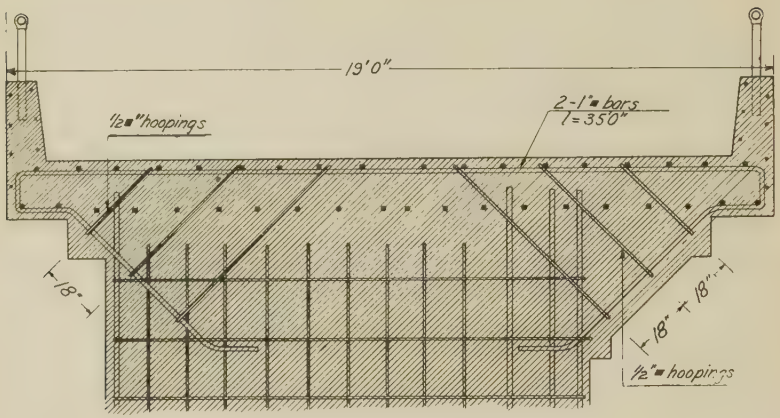

FIG. 5A—SECTION THROUGH ROADWAY, BULLARDS BAR PROJECT

Filling the reservoir with gravel and sand will not seriously interfere with the development of power, and since this dam is designed for a 13 ft. overflow it can be provided with 13-ft. gates along the crest whereby the fluctuating water storage will be increased by 8,000 acre ft.

This dam is designed to pass 65,000 sec. ft. over the crest. The normal winter flow, which is much less, requires only the three middle openings and it is intended to keep the tainter gates along the crest closed except a few in the middle in order to keep the head up to a maximum.

The dam has been in operation four winters without tainter gates and considerable experience has been obtained from watching the action of the overflow. The overflow period has been about 6 months every year, and the greatest depth of water going over the crest has so far been 11 ft. equivalent to 50,000 sec. ft.

In the middle of the dam the sheet of falling water stays clear of the dam and falls on a loose rock fill, if considerable water is flowing a pool is formed automatically.

On the sides however, the water first leaves the crest and then later strikes the concrete lower down under a small angle and finally strikes the rough rock abutment which is very solid.

In the middle no wear and tear can be detected. On the sides there is some wear of the concrete where the water strikes the

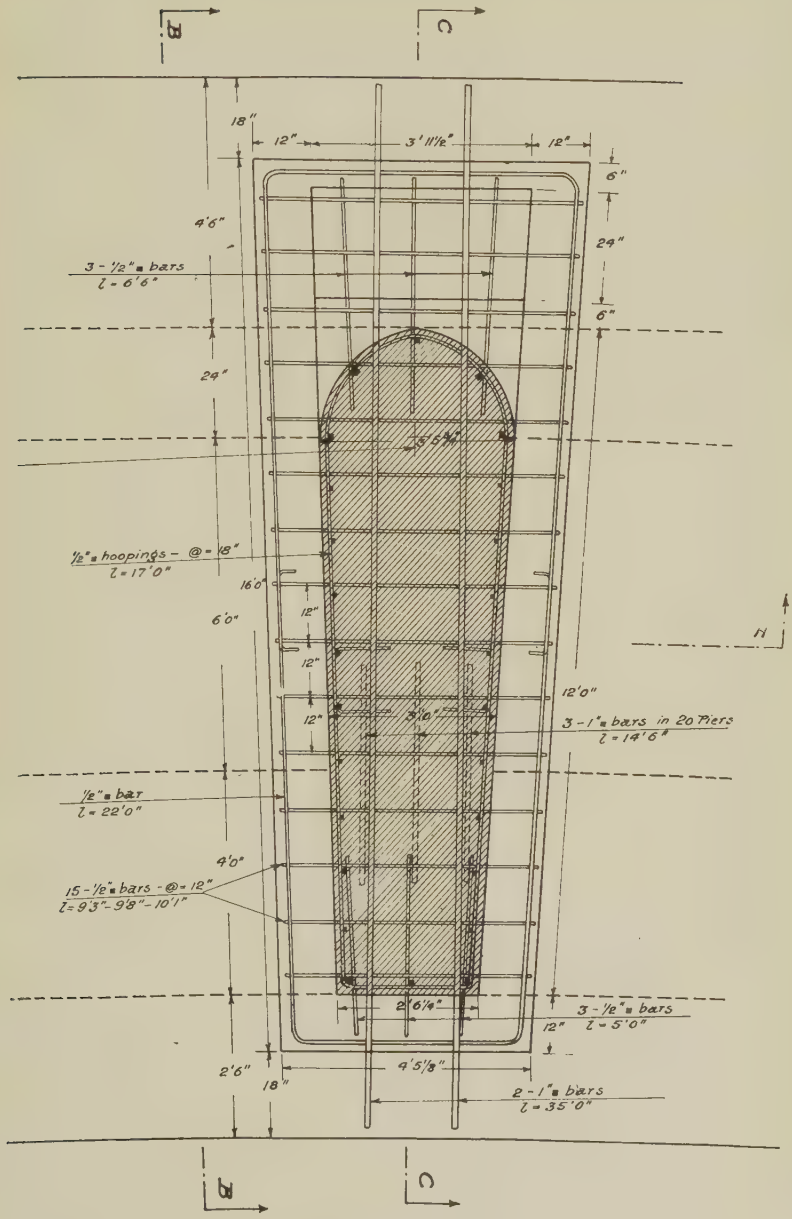

FIG. 5B—PLAN OF PIER, BULLARDS BAR PROJECT

dam body under a small angle. The wear on the rock is considerable however, and in order to prevent further wear tainter gates are now being installed on the sides to prevent the spill from going over the crest at that point and to confine it to the middle portion of the dam where no wear takes place.

In a river which is fairly level the writer has found that a mat of loose rocks (from the excavation) is a very safe bed for the overflow to fall on. The sheet of water striking the fill will split into many little jets whereby the energy will quickly be destroyed. The mat should be about 15 ft. thick under a fall of over 150 ft. During the first overflow period the mat will become two to three feet thinner where the water strikes it due to the pounding it receives, and after that nothing except dynamite can remove the rock.

On the Bullards Bar project a small dam for the purpose of forming a pool and for holding the rock fill back was provided. The secondary dam was about 5 ft. high and was completely buried in the rockfill. The rockfill stayed in place below the dam just as well as above, showing a secondary dam was unnecessary, and none has been provided on 14 free, overflow arch dams with which the writer has been connected.

For calculating the stresses in the dam, the assumption has been made that the reservoir was full of debris to within 15 ft. from the crest with 28 ft. of water on top of the debris. The weight of the debris was taken to equal 90 lb. per cu. ft. A reinforced concrete bridge along the crest of the dam takes the main county road across the canyon. This bridge has been designed for two 15-ton trucks meeting each other on the 20 ft. spans. A small forebay on the west side keeps the debris away from the pressure pipe intake.

The contraction joints are provided with a grout pipe system.

This dam was let by contract to the lowest bidder, Bent Bros., Inc., Los Angeles, and the following are the unit prices paid them on the main items:

Loose dirt excavation—2,500 cu. yd.	@	$ 2.50
Loose rock excavation—2,000 cu. yd.	@	2.50
Solid rock excavation—1,000 cu. yd.	@	5.00
Plain 1:3:6 concrete not including the cement—46,000 cu. yd.	@	6.45

Reinforced concrete 1:2:4 not including the cement—1,800 cu. yd.	@	$19.00
Installation of grout pipes	per ft.	1.00
Cement grouting—50 sacks	@	2.00

The dam is located 40 miles from the nearest railroad station at Marysville, California.

Very good concrete material in the form of river gravel was found in sufficient quantity 1¼ miles from the dam. This gravel was screened and remixed in the proper proportion for maximum density, using 2½-in. rock as the maximum size for best grading. Rocks up to 6 in. were left in the mix, but there were too few for complete grading. The actual mix was, most of the time, 1:2.8:6.5. The mixing plant was located high up on the hillside and the concrete was deposited by gravity through a chuting system of the Insley type. The sand (1:3 mortar) tested 12 per cent better than standard Ottawa sand in tension and 25 per cent better in compression at all ages.

Cylinders of concrete, 8 in. diameter and 16 in. long, were tested regularly, as the construction progressed, at the age of about 30 days. A test result (the average of six cylinders) picked out at random reads: 1673 lb. per sq. in. when 28 days old (Sept. 11th, 1923). The specimens were taken from the concrete in the dam. When fully aged this concrete can be expected to develop a crushing strength around 3000 lb. per sq. in. The weight per cu. ft. was 150 lb. The design of this dam, was made by A. C. Hoff, chief designing engineer for the Constant Angle Arch Dam Co. The testing was in charge of Theodore P. Dresser, Jr., chief engineer of Abbot A. Hanks, Inc., San Francisco, who also was in charge of testing on several of the dams mentioned later. George Ray was resident engineer and B. T. Millard his assistant engineer.

The constant angle arch dam which will pass a great amount of overflow over its crest is the Kerckhoff dam on the San Joaquin River, California, described by B. F. Jakobsen.* The tainter gates are 14 ft high. With a water level 14 ft. above the crest 60,000 sec. ft. will flow over the crest, and 100,000 sec. ft. can go over without interfering with the bridge on top. This dam has been in use for the last ten years. The overflow takes place about four to five months every year. It falls upon a loose rockfill made from the excavation and there is no secondary

*Trans. Am. Soc. C. E., 1921, Vol. 84, p. 106-107.

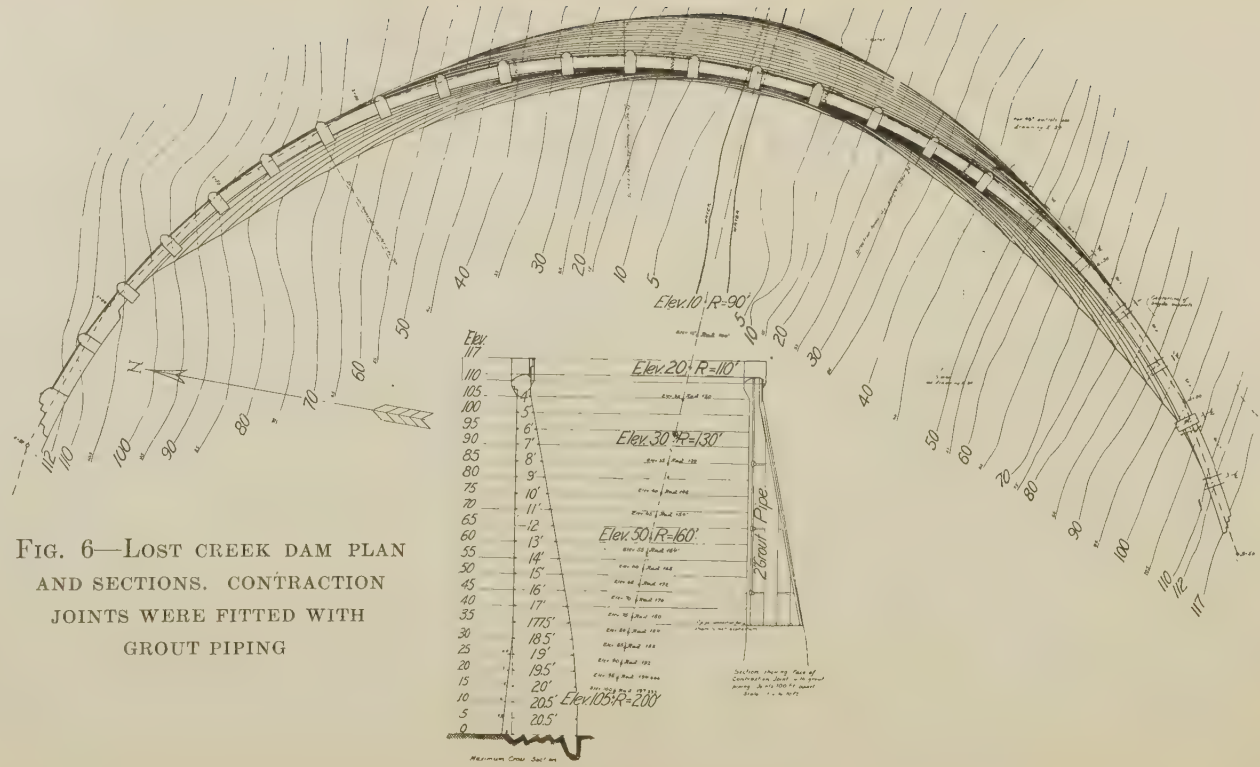

FIG. 6—LOST CREEK DAM PLAN AND SECTIONS. CONTRACTION JOINTS WERE FITTED WITH GROUT PIPING

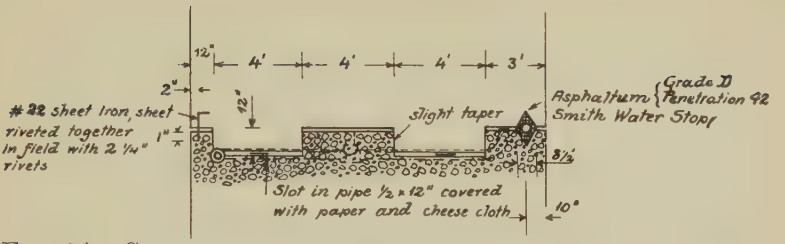

FIG. 6A—SECTION LOST CREEK DAM AT ELEVATION 45 SHOWING GROUT PIPES AND WATER STOP

dam. The Aluminum Co. of America has just fiinished a Constant Angle Arch Dam on the Little Tennessee River 180 ft. high, designed for 200,000 sec. ft. of overflow.

In Figures 6 and 6A, an arch dam 112 ft. high is shown in detail, having a variation in the length of its upstream radius of from 200 ft. at the top to 90 ft. at the bottom. It stores water for the Oroville-Wyandotte Irrigation District, of which S. J. Norris was chief engineer. F. E. Baxter was resident engineer.

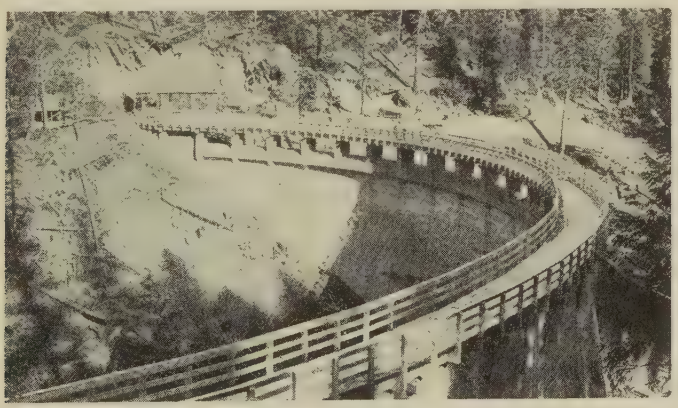

FIG. 6B—LOST CREEK DAM, 112 FT. HIGH, 380 FT. SPAN. THICKNESS AT CREST 4 FT.; AT BOTTOM 235 FT.

It is seen that the canyon is well adapted to a Constant Angle Arch type of dam, being of a quite regular "V" shape. All the centers lie on a straight line which makes it easy to lay out the dam. A wooden bridge on piers along the crest accommodates an unimportant county road. The contraction joints are provided with grout pipes and Smith patented waterstop.

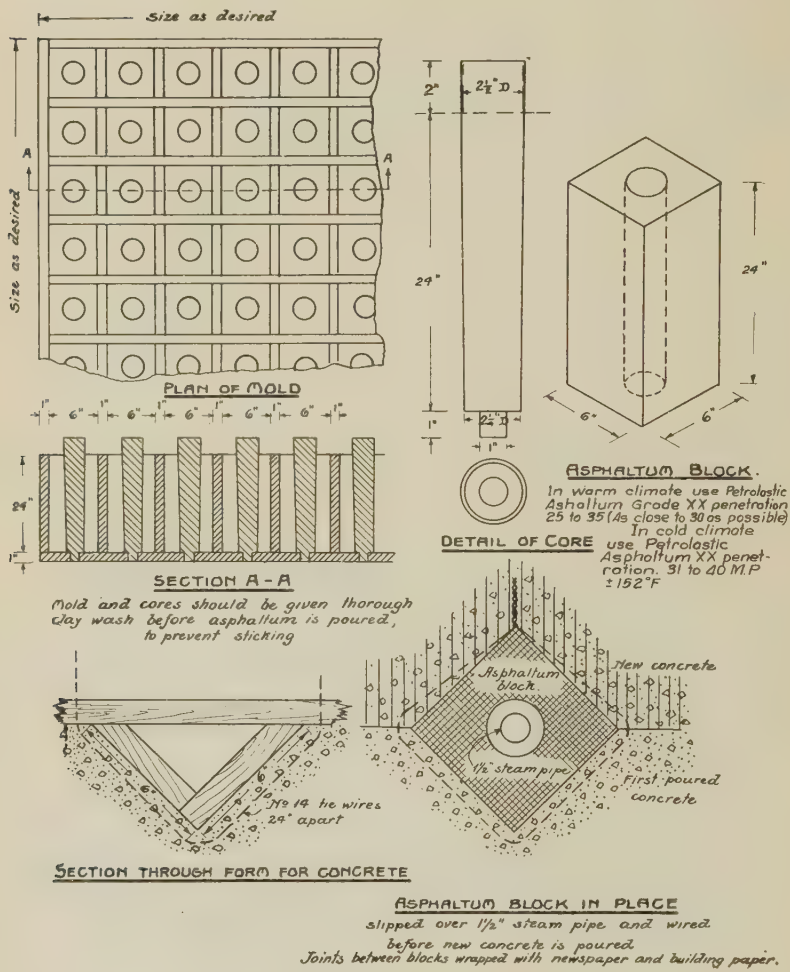

FIG. 7—DETAILS OF SMITH WATER STOP

A detail of the Smith waterstop is shown on Fig. 7. It consists of precast asphaltum blocks strung on an iron pipe and built in across the contraction joints close to the upstream face. The asphaltum may also be poured in around the pipe in say, 5 ft. lifts. Later steam is let through the pipe and the blocks melt

together and fill the diamond shaped hole and any cavity which may exist. This waterstop was first brought out by Francis B. Smith, member, American Society Civil Engineers.

The dam is an overflow dam provided with flashboards 3 ft. high. The normal overflow is confined by means of these flash boards to the middle portion where it falls clear of the dam. With 5 ft. of water going over the entire crest the discharge is 15,000 sec. ft. The dam was built by contract, Messrs. Lord and Bishop of Napa, California, being low bidders and being awarded the contract at the following unit prices on the main items:

570 cu. yd. of loose rock and gravel excavation	@	$ 1.25
2378 cu. yd. of solid rock excavation	@	5.00
11,093 cu. yd. of 1:3:6 concrete, including everything except the cement	@	5.15

The dam is located in rough country, 50 miles from the nearest railroad. The concrete material was found within a mile of the dam and consisted of gravel, which was screened and remixed in the proper proportion. When the work was half completed the

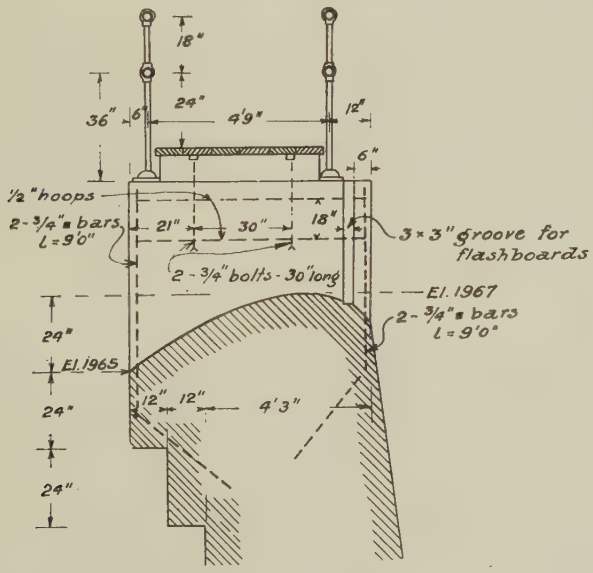

FIG. 8A—CONCOW DAM SECTION OF SPILLWAY AND BRIDGE

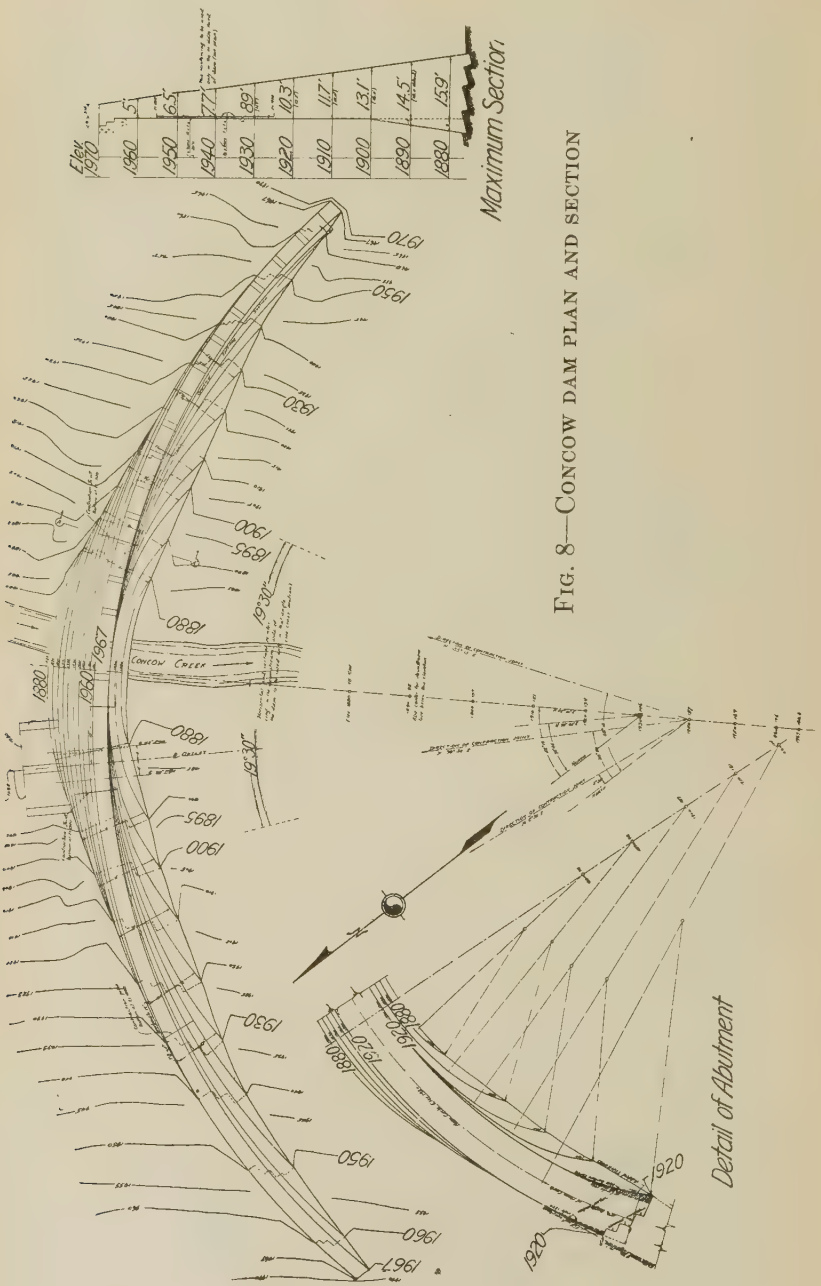

FIG. 8—CONCOW DAM PLAN AND SECTION

deposit became deficient in coarse material. A quarry was then opened up and crushed rock was mixed with the gravel.

The larger sand particles were slightly weak, but the average quality of the sand particles was satisfactory. The sand (1:3 mortar) gave low seven-day strengths (tensile 82 per cent and compression 68 per cent of standard Ottawa sand), but had high 7-day to 28-day gains, giving 28-day tensile and compressive strength 100 per cent and 92.5 per cent respectively of standard Ottawa sand.

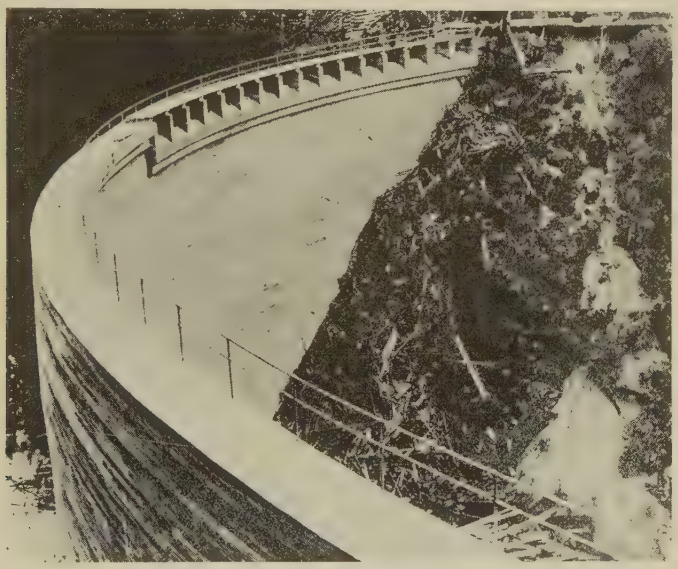

FIG. 8B—CONCOW DAM, 90 FT. HIGH ABOVE STREAM BED. SPAN 275 FT.

Somewhat over 1 barrel (average addition 15 per cent) of cement per cubic yard was necessary to bring the crushing strength of the concrete up to 1500 lb. per sq. in. when 28 days old. Ultimately, this concrete should develop a strength of at least 2500 lb. per sq. in. The concrete was graded to a maximum size of 3 in.; it was mixed for 1¼ minutes after all the ingredients were deposited in the mixer and distributed through a chuting system of the Insley type. This design and also the design of the Bullards Bar dam was made using the simple arch formula.

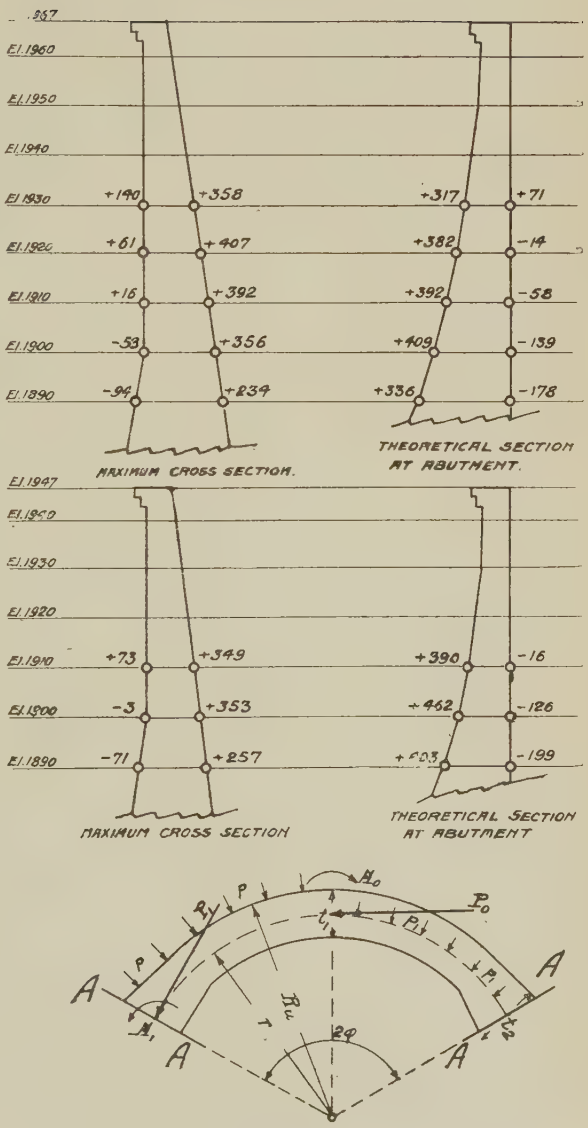

FIG. 9—DIAGRAM FOR CALCULATION OF CONCOW DAM

CONCOW CREEK DAM

In Fig. 8 details are shown on the Concow Creek dam, also called Lake Willenor dam, built for the Thermalito and Table Mountain Irrigation Districts, of which S. J. Norris was chief engineer and F. E. Baxter was resident engineer. The Dam is about 100 ft. high, with length of upstream radius at crest 180.6 ft. and at bottom 78 ft.

In the design of this dam, the method in Fig. 2 was used. When applying the Cain formulas p was taken as the full water pressure. The calculations are shown on Fig. 9 and the accompanying table. It is seen that the tension at the abutments is rather high, but since the method in Fig. 2, plane AA has been used in this particular case, this tension represents the imaginary tension inside the rock.

The dam is thicker at the abutments than further out on the arch to bring the stresses down to a conservative value. This additional thickness is made decreasing from a maximum amount at the rock junction to zero approximately 15 per cent out from the abutments. In this way the material is put where it does the most good. This dam is also an overflow dam, provided with flashboards 3 ft. high so as to keep water level to the maximum elevation possible after the rainy season has passed and to direct the overflow towards the middle.

The dam was let by contract to the lowest bidder, J. S. Greaves, Oroville, California, at the following prices:

905 cu. yd. of loose rock	@	$ 1.50
2,156 cu. yd. of solid rock	@	7.90
6,332 cu. yd. of 1:2½:5 concrete, including everything except cement	@	7.45
Per cu. yd. of reinforced 1:2:4 concrete, exclusive of cement and steel	@	19.50
Per ft. of grout pipe installed (exclusive of pipe)	@	.25

The dam is located 26 miles from the nearest railroad station (Oroville, California). Being a slim structure, a richer concrete mix than usual was used with 1¼ barrels of cement per cu. yd. of concrete. The weight of the concrete was 149 lb. per cu. ft. and the strength at 28 days averaged close to 1900 lb. per sq. in., fluctuating with the variation in the amount of cement used and the season in which the specimen was made, whether in the hot or in the cold. It was not possible to keep the cylinders (6 in. x 9 in. and 10 in. x 15 in.) under constant temperature in the

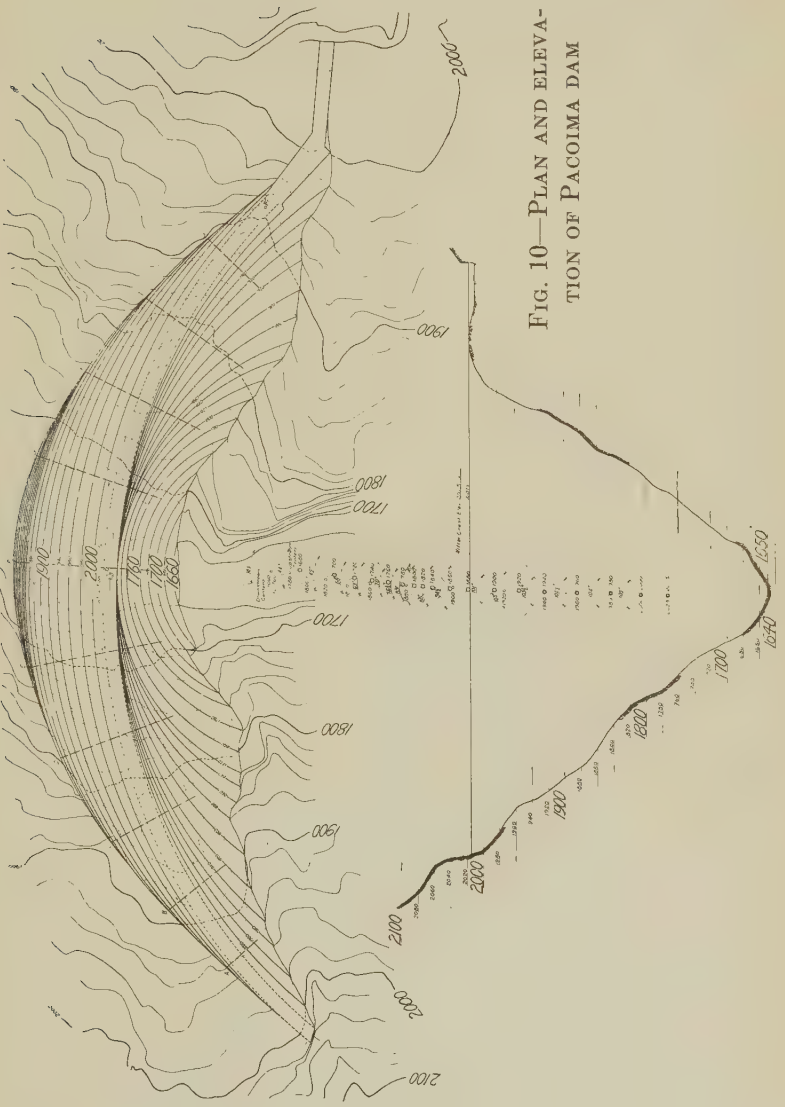

FIG. 10—PLAN AND ELEVATION OF PACOIMA DAM

field. The mixing plant was located at a sufficient elevation above the dam to allow chuting the concrete in place. Sand and gravel of good quality were found very close to the dam site.

PACOIMA DAM

In Figures 10, 10A and 10B, details are shown of the Pacoima Dam, built by the Los Angeles County Flood Control District of which J. W. Reagan was chief engineer until three years

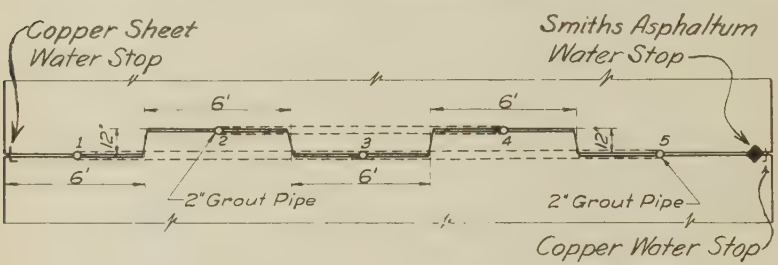

FIG. 10B—PACOIMA DAM. TYPICAL PLAN OF CONTRACTION JOINT

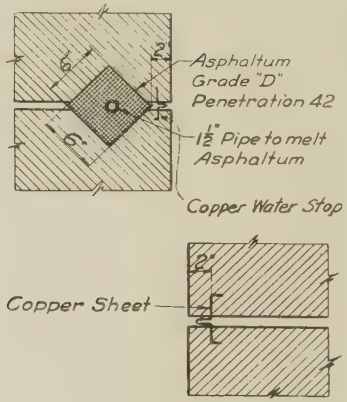

FIG. 10B—DETAIL OF SMITH'S ASPHALTUM WATER STOP, PACOIMA DAM

FIG. 10B—DETAIL OF COPPER SHEET WATER STOP

ago, when he became consulting engineer and E. Court Eaton became chief engineer. As the name implies, the purpose of the reservoir formed by the dam is to take care of flood waters due to torrential rains. The total storage in this reservoir amounts to 12,000 acre feet only, but it is intended to utilize this storage capacity several times per season by alternately emptying and

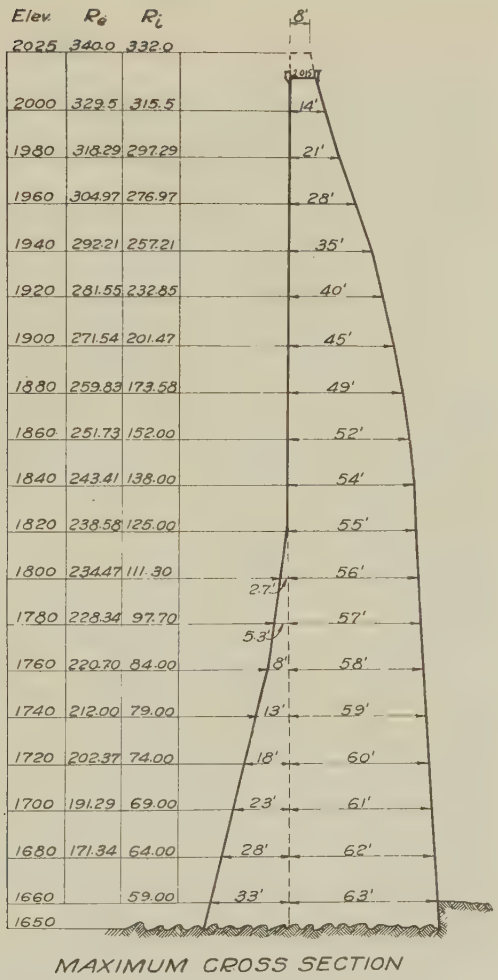

FIG. 10A—PACOIMA DAM. MAXIMUM CROSS SECTION

filling it as many times as the particular season may require. The water from the reservoir is to be let out at a rate slow enough to avoid damage to land below, and if possible to be all absorbed by the so-called gravel cone at the head of the valley, to help supply the irrigation pumping demand during the dry season.

The construction work was let to the lowest bidder, Bent

FIG. 10C'—PACOIMA DAM. HEIGHT ABOVE FOUNDATION 373 FT.; CREST LENGTH 680 FT.; 225,000 CU. YDS. PLAIN CONCRETE

Brothers, Inc., Los Angeles, at the following unit prices on the most important items:

95,000 cu. yd. of mixed excavation	@	$ 4.00
2,000 cu. yd. of rock excavation, no blasting	@	6.00
225,000 cu. yd. of plain concrete, exclusive of cement	@	4.70
620 cu. yd. of reinforced concrete, exclusive of steel and cement	@	11.00
1,200 lin. ft. of 2 in. galvanized iron pipe railing to place	@	.40
1,900 lin. ft. of asphaltum water stop with steampipe—to place	@	.46
1,000 lin. ft., more or less, 3 in. diameter holes into bedrock, placing pipe and pressure grouting under 175 lb. per sq. in. pressure	@	4.00

The concrete material, gravel, was available within a mile of the damsite and the railroad (San Fernando station of the Southern Pacific) is only about four miles away. The crest length is 700 ft. On account of the great height of the dam, 373 ft. above the foundation and 365 ft. above streambed, and the importance of the location 20 miles above the City of Los Angeles, it was decided to use five sacks of cement per cubic yard of concrete, although the sand available is of an excellent quality and grading, testing at least 25 per cent higher than standard Ottawa sand.

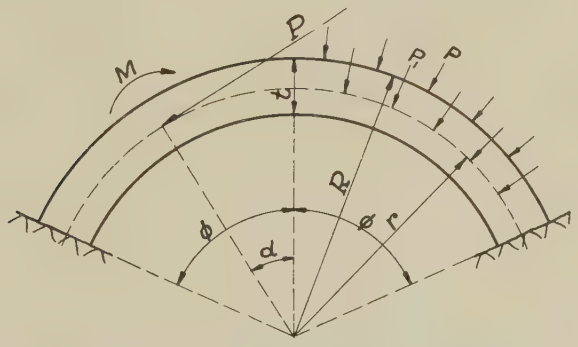

FIG. 11—DERIVATION OF CONSTANTS FOR DESIGN OF ARCH DAMS

TABLE TO ACCOMPANY FIG. 11

EQUATIONS 1 TO 7 INCLUSIVE ARE FROM CAIN'S ANALYSIS

	Number of Formula in Cain's Paper.
① $P = p_1 r - (p_1 r - P_o) \cos \alpha$	④
② $M = (p_1 r - P_o)\, r \left(\frac{\sin \phi}{\phi} - \cos \alpha\right)$	⑬
③ Where $p_1 r = p R$	page 235
④ $p_1 r - P_o = 2 \sin \phi \, \frac{\phi}{D_1} \, \frac{k^2}{r} \, p_1$	⑲

⑤ $D_s = D + 2.88\frac{k^2}{r^2}\,\phi\,(\phi - \tfrac{1}{2}\sin 2\,\phi)$ page 269

⑥ $D = \left(1 + \frac{k^2}{r^2}\right)\phi\,(\phi + \tfrac{1}{2}\sin 2\,\phi) - 2\sin^2\phi$ ⑪

⑦ $k^2 = \frac{1}{12}t^2$ page 236

⑧ Let $A = \left(\frac{r}{t}\right)^2$ then $\left(\frac{k}{r}\right)^2 = \frac{1}{12A}$ ⑨

④ $p_1 r - P_o = 2\sin\phi \times \frac{\phi}{D_s} \times \frac{k^2}{r} \times p_1$ but $\frac{k^2}{r} = \frac{r}{12A}$ and from ③

⑩ We have $p_1 r - P_o = \frac{\sin\phi \times p.R \times \phi}{6AD_s}$

from ⑤ & ⑥ we have

$$D_s = \left[\left(1 + \frac{1}{12A}\right)\phi\,(\phi + \tfrac{1}{2}\sin 2\,\phi) - 2\sin^2\phi\right] + \left[\frac{2.88}{12A}\,\phi\,(\phi - \tfrac{1}{2}\sin 2\,\phi)\right]$$

$$\therefore 6AD_s = \phi\left[6A\left(\phi + \tfrac{1}{2}\sin 2\,\phi - \frac{2\sin^2\phi}{\phi}\right) + \tfrac{1}{2}\,(\phi + \tfrac{1}{2}\sin 2\,\phi) + 1.44\,(\phi - \tfrac{1}{2}\sin 2\,\phi)\right]$$

⑪ $6AD_s = \phi\left[A\left(6\,\phi + 3\sin 2\,\phi - 12\frac{\sin^2\phi}{\phi}\right) + 1.94\,\phi - .47\sin 2\,\phi\right]$

⑫ let $K_1 = 6\,\phi + 3\sin 2\,\phi - 12\frac{\sin^2\phi}{\phi}$

⑬ and $K_2 = 1.94\,\phi - .47\sin 2\phi$
then $6AD_s = \phi\,[AK_1 + K_2]$

$\therefore$ ⑭ $p_1 r - P_o = p\,R - P_o = p\,R\,\frac{\phi\sin\phi}{\phi\,(AK_1 + K_2)}$

from ① & ③ $P = p\,R - (p\,R - P_o)\cos\alpha = p\,R\,\frac{(AK_1 + K_2) - \sin\phi\cos\alpha}{AK_1 + K_2}$

$\therefore$ ⑮ $P = p\,R\,\frac{AK_1 + K_3}{AK_1 + K_2}$

⑯ Where $K_3 = 1.94\,\phi - 0.47\sin 2\,\phi - \sin\phi\cos\alpha$

from ② $M = (p\,R - P_o) \times r \times \left(\frac{\sin\phi}{\phi} - \cos\alpha\right)$

$= p\,R\,\frac{\phi\sin\phi}{\phi\,(AK_1 + K_2)} \times r \times \left(\frac{\sin\phi}{\phi} - \cos\alpha\right)$

⑰ $= p\,R\,r\,\frac{\frac{\sin^2\phi}{\phi} - \sin\phi\cos\alpha}{AK_1 + K_2} = p\,R\,r\,\frac{K_4}{AK_1 + K_2}$

⑱ Where $K_4 = \frac{\sin^2\phi}{\phi} - \sin\phi\cos\alpha$

let $C_1 = \frac{K_3}{K_1}$, $C_2 = \frac{K_4}{K_1}$, $C_3 = \frac{K_2}{K_1}$

⑲ then $P = p \times R \times \frac{A + C_1}{A + C_3}$

⑳ and $M = p \times R \times r \times \frac{C_2}{A + C_3}$

The values of C_1, C_2 & C_3 are as follows:

$$C_1 = \frac{K_3}{K_1} = \frac{1.94\,\phi - 0.47\sin 2\,\phi - \sin\phi\cos\alpha}{6\,\phi + 3\sin 2\,\phi - \frac{12\sin^2\phi}{\phi}}$$

$$C_2 = \frac{K_4}{K_1} = \frac{\frac{\sin^2\phi}{\phi} - \sin\phi\cos\alpha}{6\,\phi\,\tfrac{1}{2}\,3\sin 2\,\phi - \frac{12\sin^2\phi}{\phi}}$$

$$C_3 = \frac{K_2}{K_1} = \frac{1.94\,\phi - 0.47\sin 2\,\phi}{6\,\phi + 3\sin 2\,\phi - \frac{12\sin^2\phi}{\phi}}$$

Reference—Paper No. 1483 Trans. A. S. C. E. 1922. "The Circular Arch under normal Loads" by Prof. Wm. Cain.

It is seen from Fig. 11A that the stresses have been kept moderate. It will also be noted from Fig. 11A and the accompanying table that a short cut method compared with Fig. 9 has been used in the calculations. This was devised by A. C. Hoff. The derivation of the constants in Fig. 11A is shown on Fig. 11. The stress sheet (Fig. 11) was calculated with the intention of constructing the dam to elevation 2025, but construction was temporarily stopped at elevation 2015. In the lower zone where apparent tension exists, in case the full water-load is figured as borne by the arch, this same full water load can also be borne by the shear action along the rock contact, creating only moderate shear stresses. The load therefore, divides between the two actions and actual tension in the faces can not exist to any extent. The action of Poisson's ratio also tends to eliminate tension in the faces towards lower levels.

The fact that concrete expands when wet is a well known phenomena. Professors Campbell and White at the University of Michigan, who have carried out a series of careful experiments extending over several years, give the expansion of concrete as between 0.02 and 0.04 per cent of its length when dry.

For concrete having a modulus of elasticity of 2,000,000 and a coefficient of expansion due to being wetted of 0.0002, such expansion would equalize a stretch due to a tension of 400 lb. per sq. in.

Along the upstream face where the heaviest tension (apparent or real) exists, the concrete is water-soaked and will, therefore, have its complete expansion with reservoir full.

Along the down stream face the concrete is less water soaked and it will not have expanded as much as 0.02 per cent, but the effect of this expansion in neutralizing the tension is not so much needed along the downstream face as along the upstream face.

The maximum foundation pressure exists at the bottom, being about 430 lb. per sq. in. along the inclined downstream face, in the middle. With Poisson's ratio between 1/5 and 1/6 the resulting axial or horizontal compression will be about 75 lb. per sq. in., at elevation 1650 on the downstream side at least in the middle, thus being able to compensate for a considerable arch tension at the downstream face. At elevation 1800 where the arch

tension is the greatest (on the downstream side 63), it is found that the action of Poisson's ratio, due to the weight of the dam above just about compensates for this tension. The action of Poisson's ratio is as positive as the action of the elasticity of the material and can be taken into full consideration when looking for means of relieving the tension. The lateral expansion begins as soon as the vertical compression begins. It is not like the action of the time factor, dependent upon a certain high value of

unit stress being first reached in the material.

Due to the narrowness of the canyon, shear action predominates toward the bottom and pure arch action exists only towards the top. In the lower zone shear and arch action will divide the load between them and inasmuch as each action is sufficient to carry the whole load, the dam should be very safe for this portion. The shear cannot be transmitted from the middle to the abutments through the thick arch (horizontal

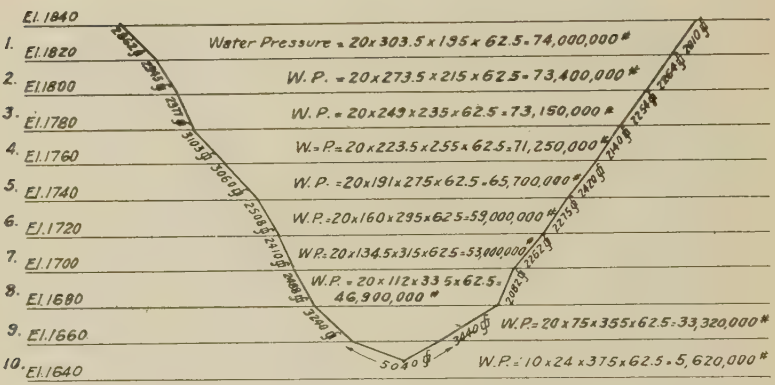

FIG. 11A—CALCULATION OF FINAL DESIGN, PACOIMA DAM

1. If all of the load *below El.* 1840 is assumed taken up by *Shear Action* the *Average Shear* in the martial along the area of rock contact will be

$$S = \frac{481,340,000 + 74,000,000}{144 \times (45708 + 2862 + 2010)} = \frac{555,340,000}{144 \times 50,580} = 76.2 \text{ lbs./in.}^2$$

2. Under the same assumption as for 1. the average shear below El. 1820 will be

$$S = \frac{407,940,000 + 73,400,000}{144 \times (41099 + 2345 + 2264)} = \frac{481,340,000}{144 \times 45,708} = 73.1 \text{ lbs./in.}^2$$

3. Under the same assumption as for 1. the average shear below El. 1800 will be

$$S = \frac{334,790,000 + 73,150,000}{144 \times (36468 + 2377 + 2254)} = \frac{407,940,000}{144 \times 41,099} = 68.9 \text{ lbs./in.}^2$$

4. Under the same assumption as for 1. the average shear below El. 1780 will be

$$S = \frac{26,3540,000 + 71,250,000}{144 \times (3103 + 31225 + 2140)} = \frac{334,790,000}{144 \times 36,468} = 63.7 \text{ lbs./in.}^2$$

5. Under the same assumption as for 1. the average shear below El. 1760 will be

$$S = \frac{197,840,000 + 65,700,000}{144 \times (3060 + 25745 + 2420)} = \frac{263,540,000}{144 \times 31,225} = 58.6 \text{ lbs./in.}^2$$

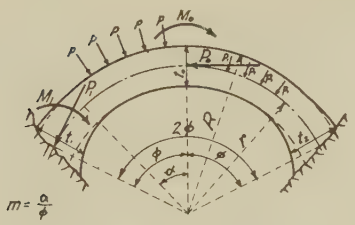
6. Under the same assumption as for 1. the average shear below El. 1740 will be

$$S = \frac{138,840,000 + 59,000,000}{144 \times (2508 + 20962 + 2275)} = \frac{197,840,000}{144 \times 25,745} = 53.6 \text{ lbs./in.}^2$$

7. Under the same assumption as for 1. the average shear below El. 1720 will be

$$S = \frac{85,840,000 + 53,000,000}{144 \times (2410 + 16290 + 2262)} = \frac{138,840,000}{144 \times 20,962} = 45.9 \text{ lbs./in.}^2$$

8. Under the same assumption as for 1. the average shear below El. 1700 will be



$$S = \frac{38,940,000 + 46,900,000}{144 \times (2488 + 11720 + 2082)} = \frac{85,840,000}{144 \times 16,290} = 36.6 \text{ lbs./in.}^2$$

9. Under the same assumption as for 1. the average shear below El. 1680 will be

$$S = \frac{33,320,000 + 5,620,000}{144 \times (5040 + 3240 + 3440)} = \frac{38,940,000}{144 \times 11,720} = 23.1 \text{ lbs./in.}^2$$

10. Under the same assumptions as for 1. the average shear below El. 1660 will be

$$S = \frac{5,620,000}{144 \times 5,040} = 7.7 \text{ lbs./in.}^2$$

NOMENCLATURE.

The values of C_1, C_2 & C_3 are

$$C_1 = \frac{1.94\phi - 0.47 \sin 2\phi - \sin\phi \cos\alpha}{6\phi + 3\sin 2\phi - \frac{12\sin^2\phi}{\phi}}$$

$$C_2 = \frac{\frac{3\sin^2\phi}{\phi} - \sin\phi\cos\alpha}{6\phi + 3\sin 2\phi - \frac{12\sin^2\phi}{\phi}}$$

$$C_3 = \frac{1.94\phi - 0.47\sin 2\phi}{6\phi + 3\sin 2\phi - \frac{12\sin^2\phi}{\phi}}$$

NOTE—

The calculations are made on the assumption of an arch with fixed ends carrying the total water load with no help from cantilever.

Under the assumptions governing shear calculations we have the approximate increase in shear from the base upwards rather than the exact stress at any single point. In narrow canyons, the halves of the arch partially become horizontal cantilevers through whose vertical sections the load is transmitted by shear to the abutments. This transmission of the stress occurs only with deformation of the cantilever, which deformation is the result of the joint action of arch and horizontal cantilevers.

Reference—"The Circular Arch Under Normal Loads," by Prof. Wm. Cain, Paper No. 1483, Trans. A. S. C. E. 1922.

FIG. 11A

cantilever) without deformation, but the two actions, arch and punching shear, go together and the actual deformation is the result of the joint action. How the load actually divides between the various possible actions towards the bottom is a problem not yet solved by any one, but the principal action presumably is punching shear in connection with some sort of cantilever action both vertical and horizontal. The ultimate crushing strength of the concrete was well above 4000 lb. per sq. in. and the factor of safety should, therefore, be at least five.

The contraction joints, some details of which are shown, were closed somewhat too early. Observation on finished structures has shown that these joints do not open fully for quite a long time after construction is finished. They may show openings on

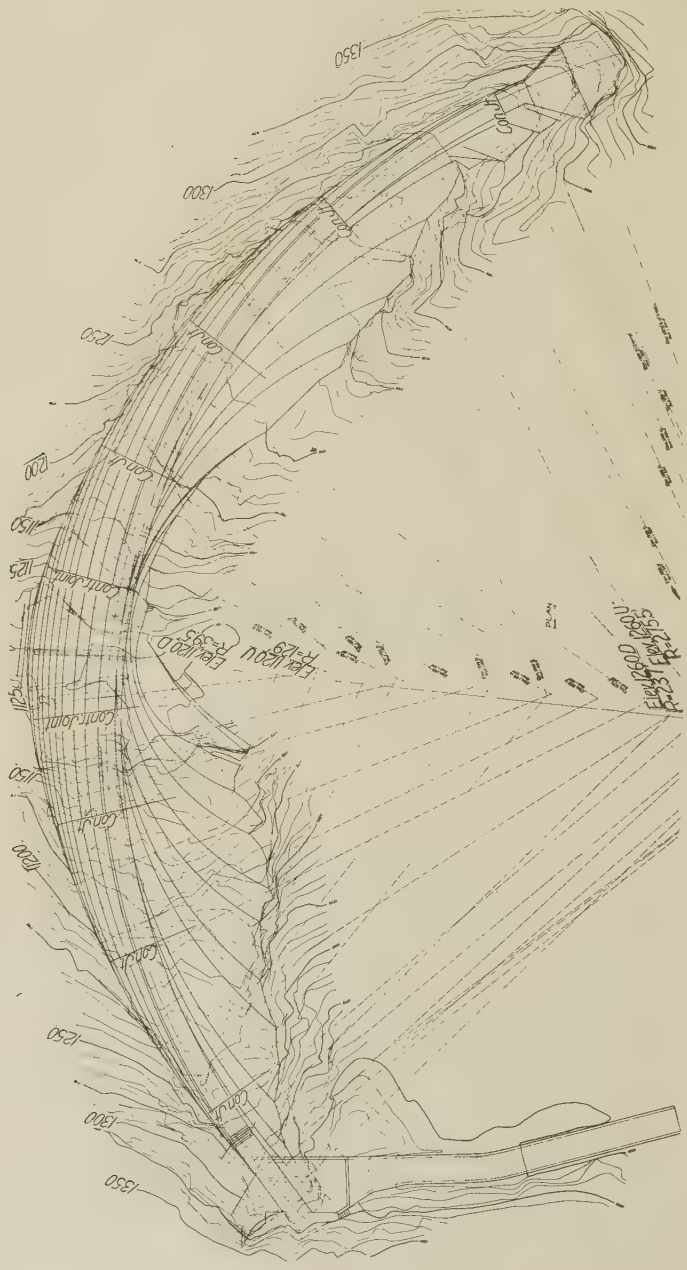


FIG. 12—PLAN—BIG SANTA ANITA DAM

the up and down-stream faces, but farther inside the body where the temperature is highest, due to the presence of the chemical heat and the fact that the structure has not been subject to compressive stresses, the voussoirs still have contact with one another.

If the joints had been grouted during the coldest season after the dam had withstood full water pressure once, the condition of the dam when loaded should correspond to that assumed when making the calculations shown in Fig. 11A. Any increase in temperature will relieve the bending stresses as the arch deflection becomes less with increase in temperature. The condition may actually arise where the expansion of the arch due to increase in temperature is equal to the contraction due to the arch compression in which case there are no bending moments to take care of.

As will be seen from the details, the contraction joints are provided with grout pipes, also with Smith asphaltum waterstops along the upstream face with a copper or galvanized iron stop (grout stop) along the faces. It is between these two stops that the grout is injected. The top of the contraction joint is generally not corked. The grout is injected to just fill the joint to the top. It is not desirable to have the crest of the dam grouted to the extent of exerting a pressure in an upstream direction with a cold dam body inasmuch as the load near the crest is always small compared with the cross section available to support it. At lower elevations there will be grout pressure due to the corresponding static head of the grout.

BIG SANTA ANITA DAM

Figures 12 and 12A show the plan and cross section of the Big Santa Anita dam also built by the Los Angeles County Flood Control District and finished a year ago. Figures 13 and 13A and accompanying table show the calculations. While the tension in the faces is apparently above 100 lb. per sq. in. at elevation 1160, this tension is not paired with a very high compression and this arch slice (and all others below) is located so close to the bottom that it obtains considerable support from punching shear.

Compared with the stresses in the Lake Spaulding Dam, the Santa Anita stresses are not high. Lake Spaulding dam as

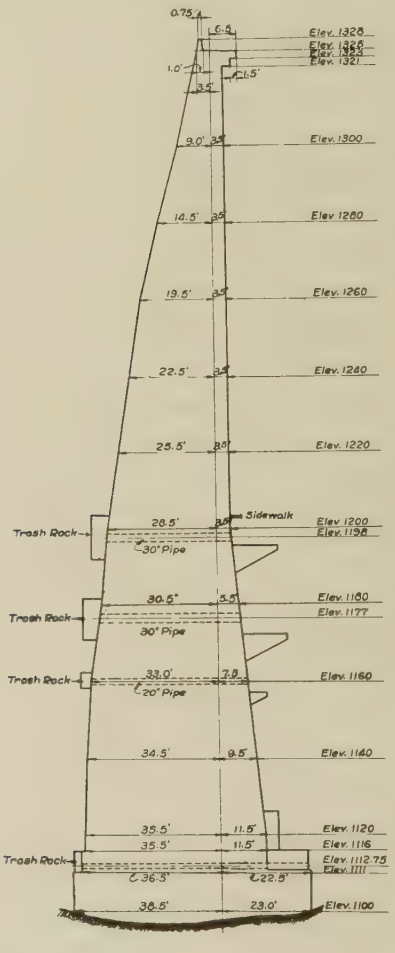

FIG. 12A—MAXIMUM SECTION BIG SANTA ANITA DAM

described in the Transaction of the American Society of Civil Engineers—Volume 78—1915—page 716 was designed at a time, when the simple arch formula was used practically exclusively.

Take for instance—at elevation 4725 the average stress found from the simple arch formula is 308 lb. per sq. in compression. Using the Cain formula, the abutment stresses are found to be

723 lb. compression and 289 lb. tension per sq. in. No particular indication of harm due to this high apparent tension is visible. Very likely the watersoaking effect of the concrete more than compensates for the expansion due to the tension.

FIG. 12B—BIG SANTA ANITA DAM. HEIGHT 225 FT.; SPAN 515 FT.; THICKNESS AT CREST, 7 FT.; AT BOTTOM, 48 FT.

The Big Santa Anita dam is 225 ft. high above stream bed. The length of the upstream radius at the crest is 306 ft. and at the bottom it is 129 ft. long. The span is 515 ft. About 76,000 cu. yd. of concrete went into the dam.

The Pacoima Dam and this dam are thickened gradually from the middle towards the abutments except near the crest. Most

100 lin. ft. placing steel discharge pipes	@	1.00
1,000 ft. 3 in. grout holes	@	2.00
28,000 cu. yd. excavation for roadway to damsite	@	1.12

Further details can be obtained from B. F. Jakobsen's paper,* also from articles in Western Construction News, Aug. 25, 1926, by J. W. Reagan and by E. Court Eaton in the Nov. 25, 1927, issue.

B. F. Jakobsen was engineer in charge of the Pacoima Dam and the Big Santa Anita Dam until three years ago. R. B. Metcalf was resident engineer on the Big Santa Anita Dam and Kenneth Harrison was resident engineer on the Pacoima Dam.

DIABLO CANYON DAM

A large constant angle arch dam now nearing completion is shown in Figures 14 and 14A, 14B and 14C. This is the Diablo Canyon dam owned by the City of Seattle, Washington. This represents typical construction of a high arch dam spanning a large gap. Two abutments of gravity section are run out to meet the arch in order to cut down the length of the upstream radius. The arch span proper is 540 ft. and the total gap closed has a maximum width of 950 ft. The maximum height above river bed is 363 ft. and the thickness at the bottom 116.5 ft. Length of upstream radius at the crest is 390 ft. and at the bottom 148.6 ft.

The gravity abutments are built to take care of the overflow during high water in the river and the spillway capacity thus obtained is in excess of 100,000 sec. ft. Normally the spillway bays are closed by means of radial gates. A pressure tunnel connects the reservoir with a powerhouse to be constructed about 2000 ft. below the dam.

*"Stresses in thick Arches of Dams," Trans. of Am. Soc. C. E., 1927, V. 90, p. 583.

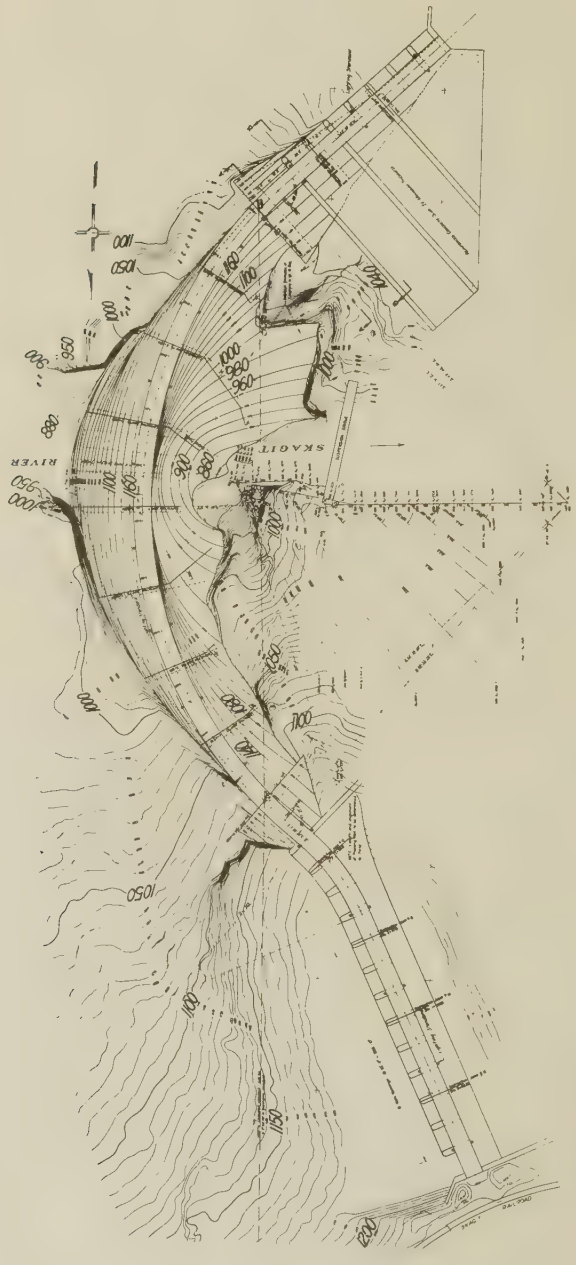

FIG. 14—PLAN OF DIABLO CANYON DAM

Referring to Fig. 14, it will be noted that the gravity abutment has a base thickness of 85 per cent of its height and also that the axis of the abutment is not tangent to the arch crest but inclined from the tangent by an angle of 5 degrees. The abutments are subjected to two sets of external forces: first, the normal water pressure on the upstream face, and second, the resultants of all the arch forces.

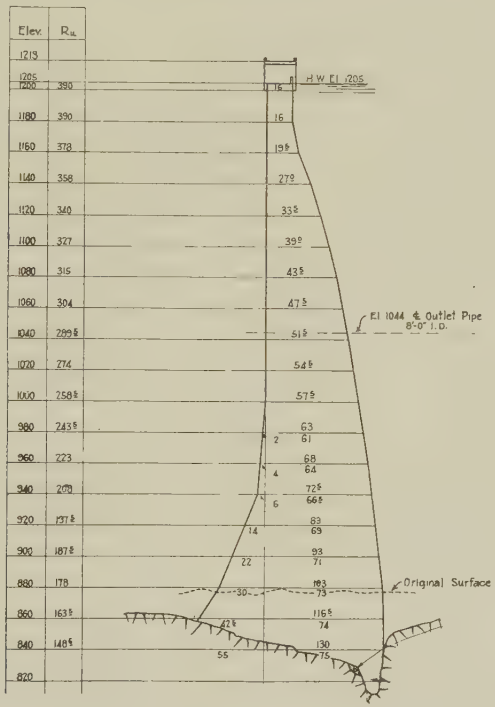

FIG. 14A—MAXIMUM SECTION, DIABLO DAM

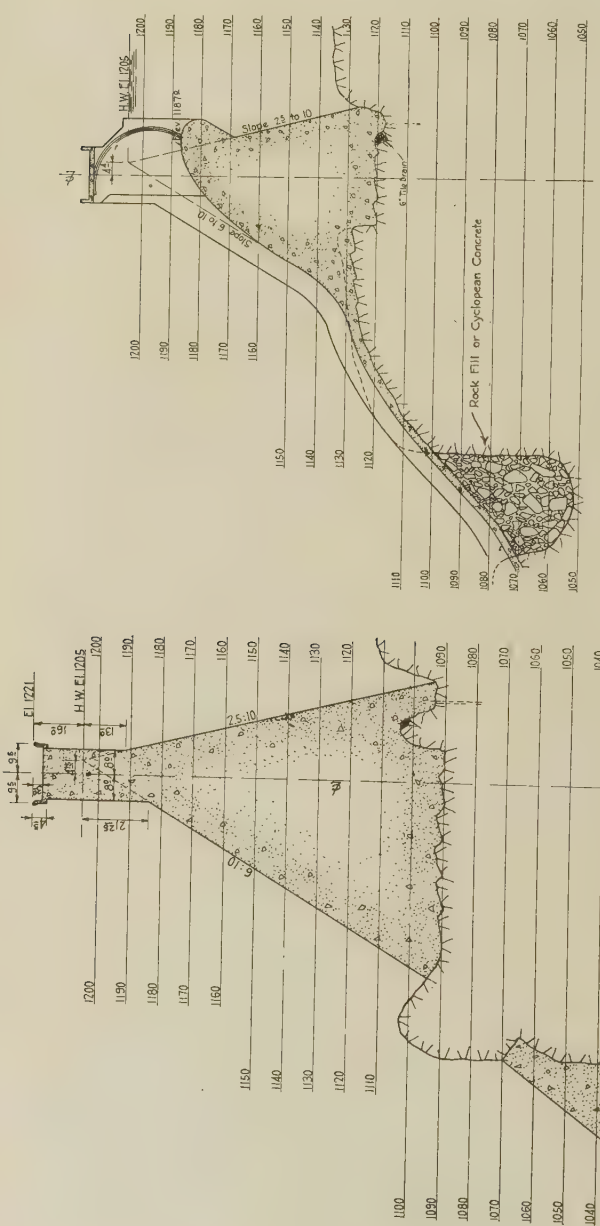
The arch resultants may be in turn resolved into their two components, thrust and shear. The arch thrusts are themselves eccentric with respect to the neutral axis of the arch.

In designing the gravity abutments for the Diablo dam it was necessary to find the magnitude and direction of the resultant of all the arch thrusts and radial shears and place the axis of the abutment parallel to this resultant. As a further means of increasing the safety factor of the abutment against overturning,



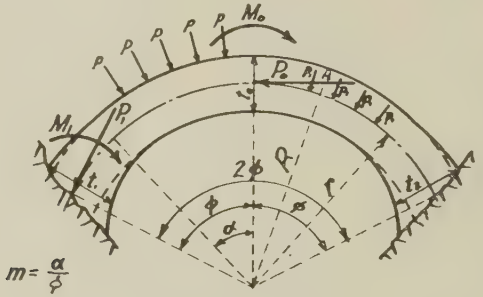


FIG. 14B—SECTIONS, DIABLO DAM

FIG. 14D—DIABLO DAM, 370 FT. HIGH ABOVE FOUNDATION. WIDTH OF GAP CLOSED, 950 FT.; LENGTH OF UPSTREAM RADIUS AT CREST, 390 FT., AT BOTTOM 148.6 FT. 316,000 CU. YDS. OF CONCRETE IN DAM PROPER

in order that it should be comparable to that of the arch itself, the base width of the abutment was made 85 per cent of its height.

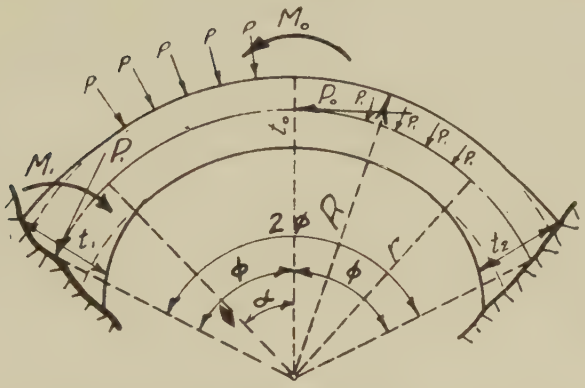
As will be observed from Fig. 14, most of the contraction joints are not radial. On account of the fairly large thickness of the arch and the short radius used, this could not be done so well. The grout pipes used in this dam are of an improved type, patented by Arthur Troiel, San Francisco, California, consisting of sheet iron half cylinders and fittings inserted in each face of the contraction joints. When contraction takes place, they offer

NOMENCLATURE.

The values of C_1, C_2 & C_3 are

$$C_1 = \frac{1.94\phi - 0.47\sin 2\phi - \sin\phi\cos\alpha}{6\phi + 3\sin 2\phi - \frac{12\sin^2\phi}{\phi}}$$

$$C_2 = \frac{\frac{\sin^2\phi}{\phi} - \sin\phi\cos\alpha}{6\phi + 3\sin 2\phi - \frac{12\sin^2\phi}{\phi}}$$



$$C_3 = \frac{1.94\phi - 0.47\sin 2\phi}{6\phi + 3\sin 2\phi - \frac{12\sin^2\phi}{\phi}}$$

NOTE:

The calculations are made on the assumption of an arch with fixed ends carrying the total water load with no help from cantilever.

These calculations are based on actual lines of excavation as of Oct. 15, 1928.

FIG. 15—FINAL DESIGN, DIAGRAM FOR COMPUTATION DIABLO DAM

NOMENCLATURE

Computations of Stresses are made in accordance with Prof. Wm. Cain's Paper No. 1603, Trans. A. S. C. E. 1927, "Stresses in Thick Arches of Dams."

NOTE: These computations are made under the assumption that the arches shall take the *full water pressure* and that arches are fixed at the abutments.

FIG. 15A—FINAL DESIGN. DIAGRAM FOR COMPUTATIONS FOR DIABLO DAM

100 per cent exit opening for the grout as against perhaps 50 per cent in a slotted pipe and they are cheaper to install.

Figures 15 and 15A and accompanying table give the method and result of the stress calculation for the arch down to elevation 920. From and including elevation 960 to the bottom, that is the thick portion of the arch dam, a graphical solution (see also Fig. 15A) for obtaining the arch stresses has been used, as shown on Figures 16, 17, 18, 19 and 20. This method (drawings by G. Goodall) has the advantage that the location of the center line of pressure is visible and if its direction should be unfavorable at the abutments the downstream face of the dam can easily be changed here to improve general conditions at the abutments.

The arch is short and thick below elevation 900 and punching shear stresses are very low even assuming all the load taken up by punching shear. This dam is therefore, exceptionally safe below elevation 900, notwithstanding the fact that apparent arch stresses show up high in the calculations.

Fig. 21, shows the installation of the grout pipes and waterstops on the face of the contraction joint and Figures 22, 22A and 22B give some details of the bridge across the dam. The bridge was designed by Fred Vogt.

The reservoir will store 90,000 acre ft. of water and will regulate the Skagit River to a certain extent for the benefit of an existing power-plant located approximately eight miles below.

In the near future a large power plant will be finished below the Diablo Dam utilizing about 335 ft. head.

This dam is being constructed by Winston Bros., Minneapolis, who were low bidders at the following unit prices. Cement furnished by the City of Seattle at $2.50 per bbl. is included in the bid:

River diversion and control—lump sum	@	$190,000.00
63,000 cu. yd. solid rock excavation above elv. 900	@	3.50
3,000 cu. yd. solid rock excavation below elv. 900	@	6.75
7,000 cu. yd. solid rock excavation in tunnel and shaft	@	6.75
12,000 cu. yd. of earth and loose rock excavation	@	3.50
210,000 cu. yd. of class "A" concrete	@	6.97
20,000 cu. yd. of class "B" concrete	@	7.40
12,000 cu. yd. of class "C" concrete	@	9.25
20,000 lb. of copper waterstops	@	.53
1,600 ft. asphaltum in contraction joints	@	1.73
2,000 barrels of cement for grout	@	7.20
Total cost of dam—approximately		$3,000,000.00

There is a bonus and penalty clause in connection with this estimate. It is desired to have the dam constructed to elevation 1050 as soon as possible in order to make some storage available for the lower power plant. The contractor receives a bonus of $1,000.00 per day for each day he completes the dam to this elevation sooner than 366 days from the day he was told to go ahead. He pays a penalty of $1,000.00 a day for each day he runs over this period.

It is desired to have the dam completed in 731 days and there is a clause in the contract providing for a bonus or penalty of $200.00 per day in this connection.

Gravel of a good grade is available within about 1000 ft. of the dam. At this place is also the terminus of a standard gauge railway built by the City of Seattle for hauling cement and other material to the dam site.

The major portion of the concrete in the dam contains 5 sacks cement per cubic yard but the upstream face of the dam to a depth of 4 ft. contains 6 sacks per cu. yd. The City of Seattle maintains a laboratory adjoining the construction camp and conducts sieve analyses of all aggregates. The exact proportion of the mix is determined as a result of these tests and careful

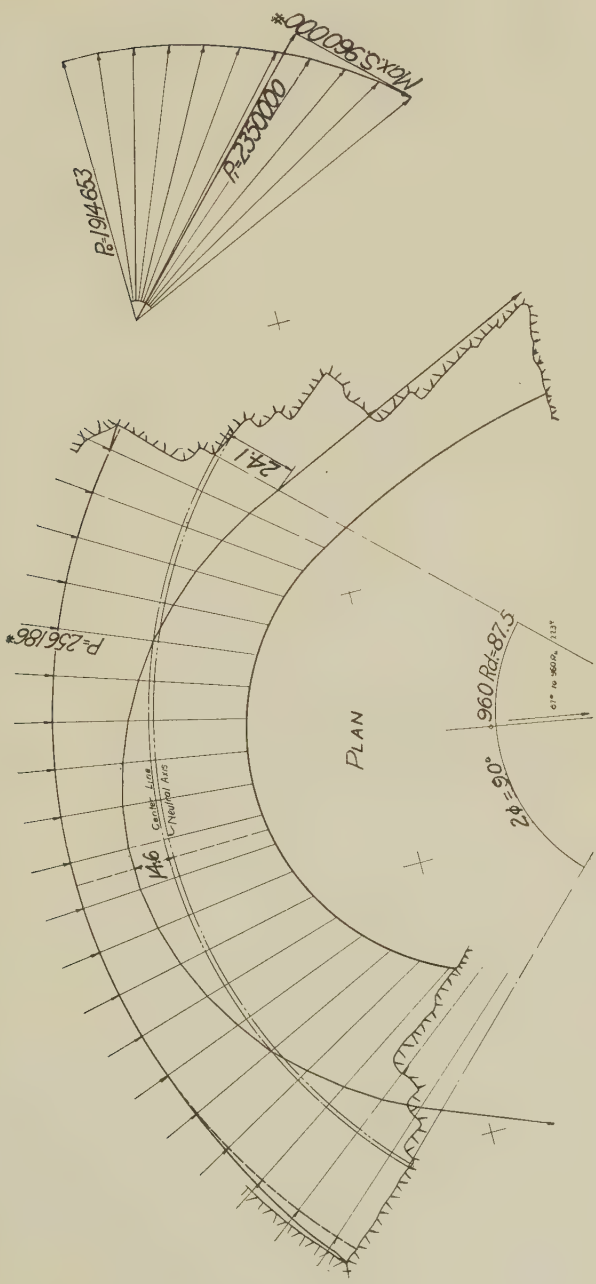

FIG. 20—DIABLO CANYON DAM. PRESSURE DIAGRAM FOR ELEVATION 960

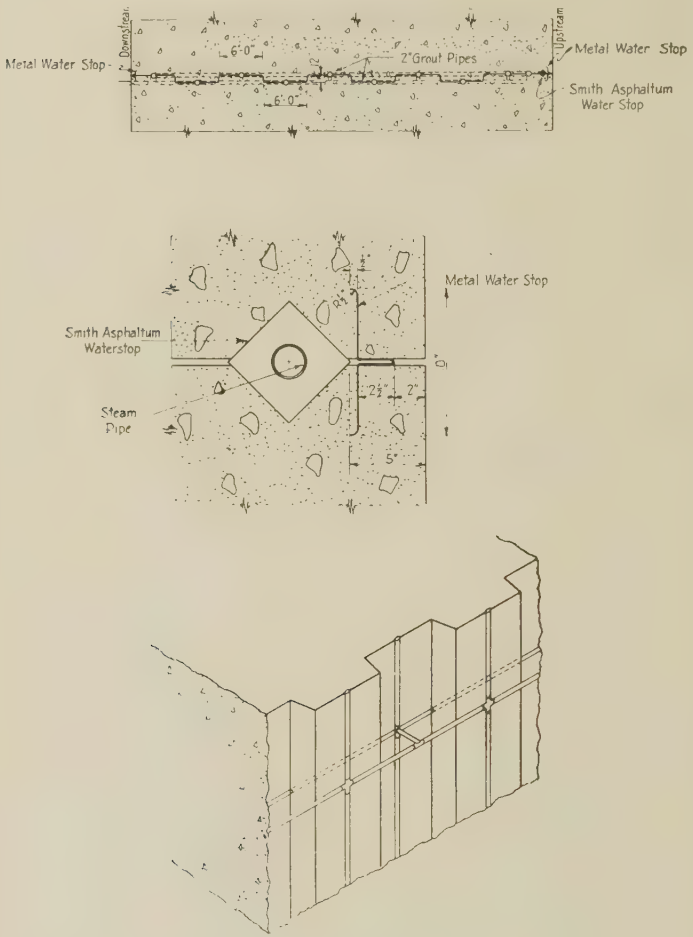

FIG. 21—DETAILS OF WATER STOP, DIABLO CANYON DAM, AND SKETCH SHOWING ARRANGEMENT OF PIPES

control is maintained over the water-cement ratio. As a result of the care in proportioning the mix and the exceptionally fine quality of the aggregates, the concrete develops high crushing strength in 28 days. The general average compressive strength in 28 days is about 4200 lb. per sq. in. The maximum compressive stress in any portion of the dam as computed by Cain's analysis is 599 lb. per sq. in.

The effect of swelling due to water soaking was investigated in connection with the design of this dam. The calculation of these stresses was made by use of the formulas derived by B. F. Jakobsen in his paper on "Stresses in Thick Arches of Dams" and published in Vol. 90 Trans. Am. Soc. C. E.

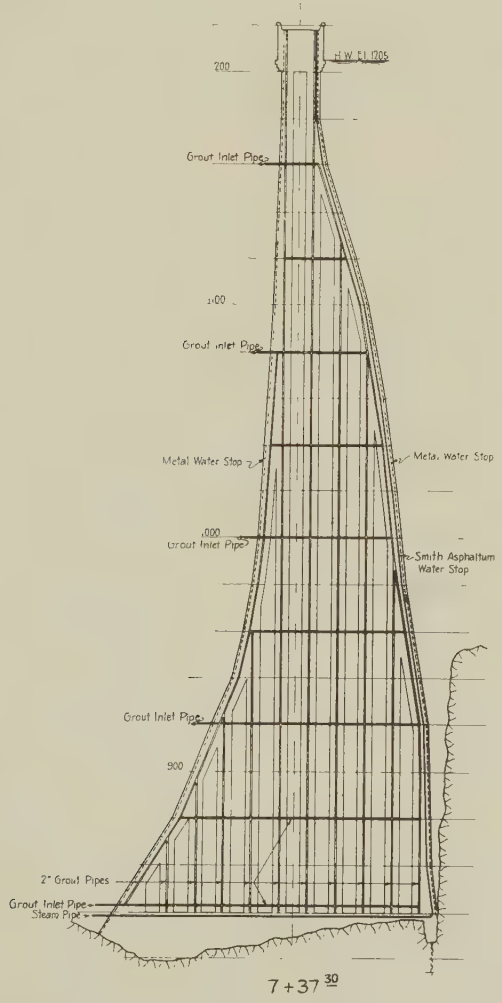

FIG. 21A—INSTALLATION OF GROUT PIPES AND WATER STOPS, DIABLO CANYON DAM

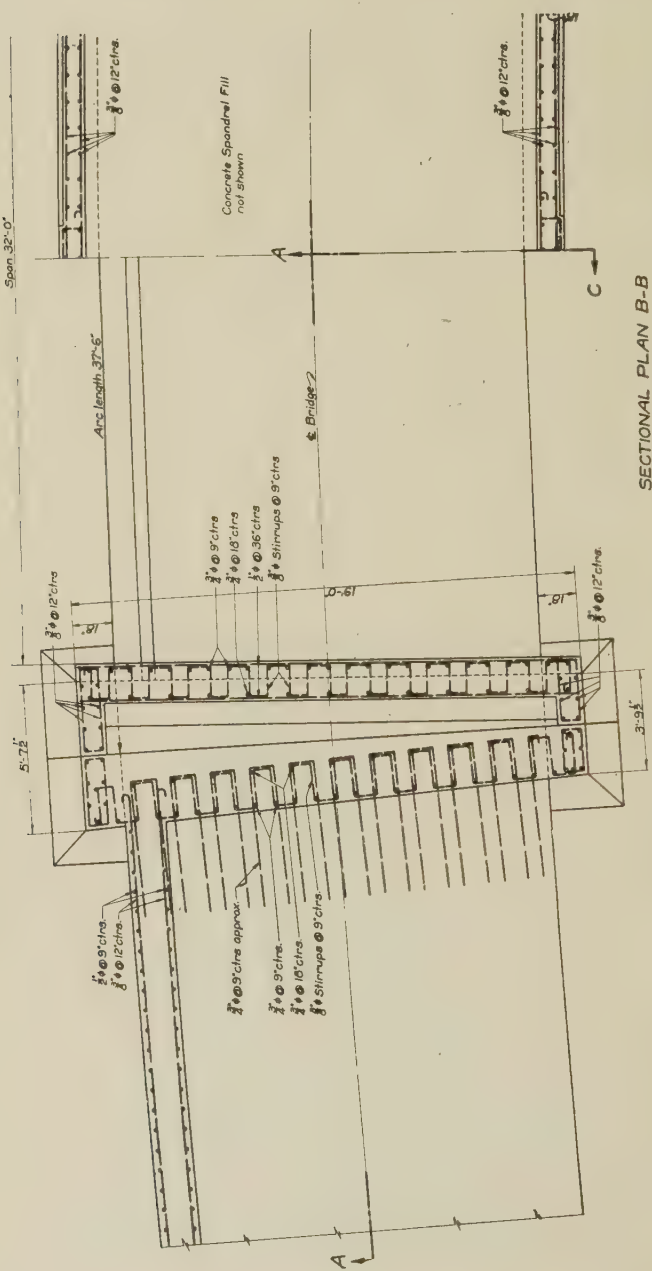

FIG. 22—DIABLO CANYON DAM. SECTIONAL PLAN OF ARCH BRIDGE

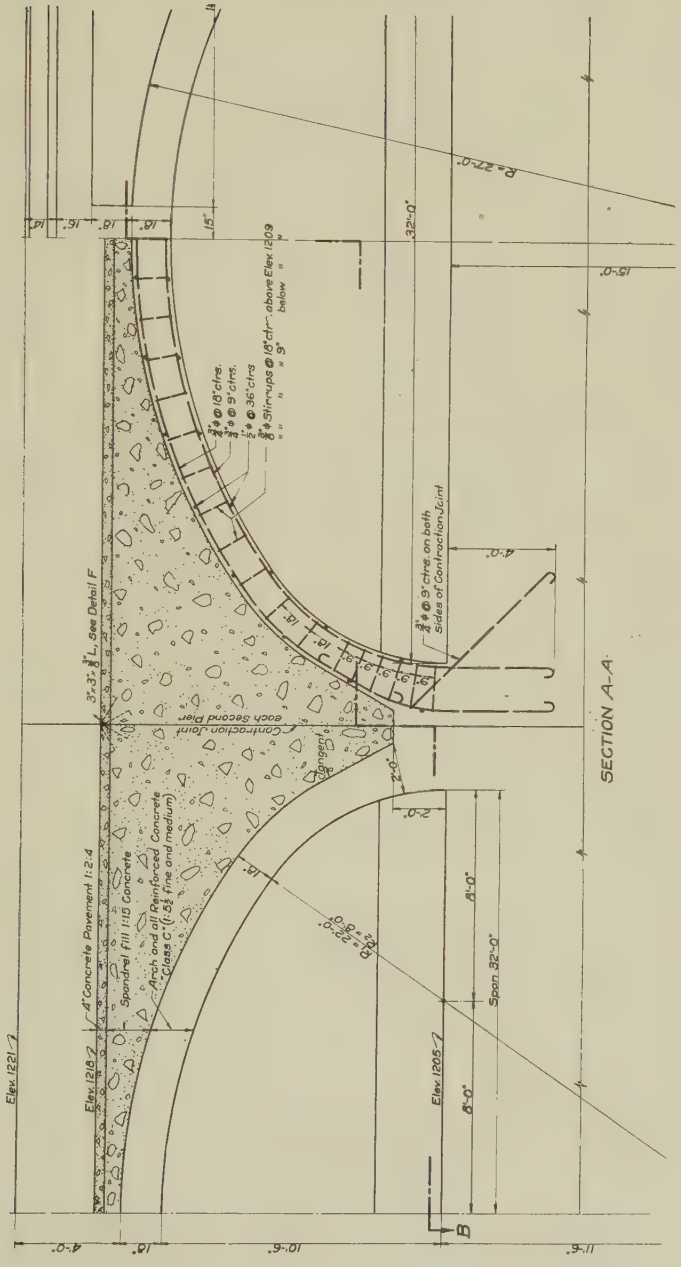

FIG. 22A—DIABLO CANYON DAM. DETAILS OF ARCH BRIDGE

For the Diablo Dam, the calculation of stresses due to swelling showed small increases in the compressive stresses at the crown section values of thickness divided by mean radius less than 0.25 and for ratios greater than 0.25, greater increase of compressive stresses at the extrados accompanied by a lowering of the compressive stress at the intrados, or if Cain's analysis indicated tension at the intrados, then an increase in the tension.

At the abutments the effect of swelling was much greater, the bending moments being large and of opposite sign to the moments due to water load on the arch. The general effect was to cause a very material decrease in compression at the intrados and an increase in compression at the extrados so that if Cain's analysis indicated tension at the extrados, the stresses due to swelling being of opposite sign, the resulting stress became compression.

For numerical values of all stresses in Diablo Dam and a detailed description of the dam and appurtenances refer to "Diablo Dam" by G. E. Goodall in Western Construction News, May 25, 1929.

The Constant Angle Arch Dam Co. furnished the design and acts as consulting engineers. City Engineer W. C. Morse, had charge of the development at the start. Later, W. D. Barkhuff was appointed city engineer and took over Mr. Morse's duties. T. H. Cover was his original assistant in charge of the work.

It is expected to finish this dam in the fall of 1930.

When looking back over the various structures described in the foregoing, it will be noticed that no regularity about the spacing of the contraction joints exists.

The writer has not yet found any spacing which he thinks is the best in general.

To be sure that no vertical cracks would appear between the artificial contraction joints, it would be necessary to have a joint every 40 ft. (or perhaps 50 ft. would still be safe). Since each joint costs a comparatively large amount of money the desire for increasing this distance is apparent and it will be noted that the spacing of the contraction joints on the dams illustrated in the foregoing is nearer twice 40 ft. than 40 ft.

On a "round" slender arch dam this spacing will generally still be safe, without any other cracks developing later, but on some of the heavier arches some chance of a vertical crack appearing

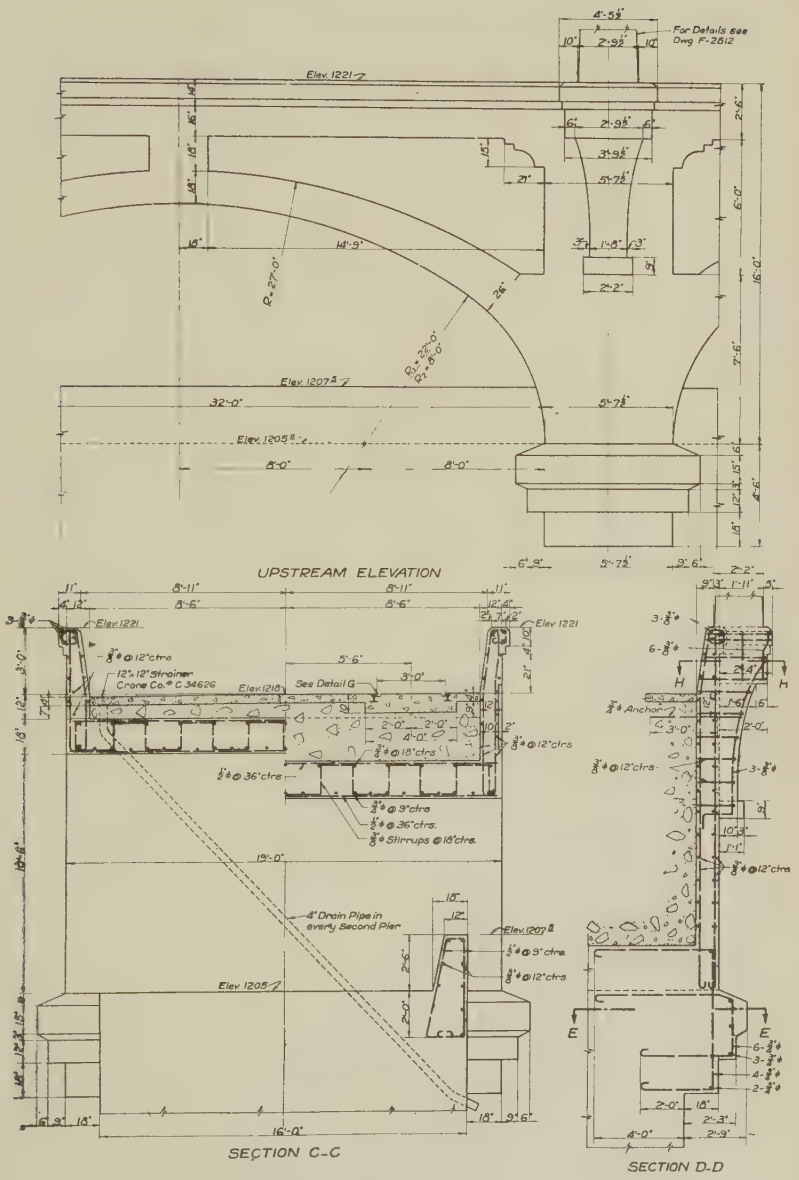

FIG. 22B—DIABLO CANYON DAM. DETAILS OF ARCH BRIDGE

between two contraction joints has been taken in order to lessen the joint cost. It is felt that such a crack will in each instance close water tight when the regular contraction joints are grouted.

On the Lake Spaulding dam previously mentioned such vertical cracks did appear very definitely, but the writer recalls but few other instances of pronounced cracks between artificial joints spaced over 50 ft. apart.

When a reservoir is filled for the first time, the dam or the foundation or mostly both will be found to leak some. Some of these leaks will close up by themselves but most of them will need grouting. It is not difficult to make a concrete dam and especially an arch dam commercially water tight by grouting. Theoretical water tightness can not be obtained, at least the writer has not observed this condition as yet, but it is important to carry on the grouting work to a considerable extent, when a dam is first put into use. The tighter the concrete dam the longer it can be expected to exist. Some owners or their engineers are rather reluctant in carrying out this process of water tightening after the structure is finished. They will go and look at some other dam, which leaks worse than theirs and then be satisfied with their own in a state not close enough to perfection.

It will perhaps be noted that temperature stresses have not been included in the calculations of the dams described. More importance is attached to the grouting of the contraction joints at a time when the dam body has its minimum temperature or at least as near the minimum as practicable. After this is done there can be no additional temperature stresses with water in the reservoir. With rising temperature the stresses will be less than calculated since the expansion due to the higher temperature will compensate in a measure for the rib-shortening whereby the bending stresses become smaller or may be entirely eliminated. If a reservoir is being filled gradually during the spring and early summer, it is not uncommon to observe the dam (arch dam) deflecting only about one third of what it would have deflected had the temperature remained constant and a minimum during the time of filling.

Readers are referred to the JOURNAL *for January, 1931, for discussion which may develop. Such discussion should reach the Secretary by December 1, 1930.*

Construction Specifications For Concrete Work on the Small Job

Proposed American Concrete Institute Specification No. 506

ARTHUR R. LORD,* AUTHOR-CHAIRMAN
Committee 506—Concrete Specifications for the Small Job.†

This proposed specification is unusual in conception and treatment. It may be read straight through on right-hand pages only, but is supplemented by "Specification Notes" appearing on left-hand pages and keyed to the specification proper by note numbers.—Editor

TO THE USER

This specification is intended for the use of Architects and Engineers, to be incorporated as a whole in the specifications for particular structures by reference in the proper place in the typewritten pages, and to become a part of the contract in the usual manner. It is intended for use on the *small job* on which full time inspection is not maintained, and it is based on the assumption that such work will be awarded by the Architect or Engineer *to honest contractors only* who can be depended upon to do high grade work without close inspection. This specification attempts to explain to the less experienced contractor, by means of numerous notes, why the work must be done in the specified manner. It assumes that poor concrete work on small jobs is due to lack of technical knowledge rather than to dishonesty and that the contractor, in preparing an estimate under such a specification as this is, will understand what is required of him to do good concrete work and will submit his bid on the basis

*President, Lord and Holinger, Inc., civil and architectural engineers, Chicago.

Specification Notes. *(See Specification Text Opposite)*

GENERAL NOTE ON CONCRETE MAKING

The major factor in determining the degree to which any concrete will develop strength, watertightness, and many other desirable properties, is the *ratio of the water to the cement* in the concrete as finally deposited in the forms. This basic relation was first reported by Duff A. Abrams in 1915, and has been exhaustively verified by many other experimenters. It has been shown to apply to concretes having strengths ranging all the way from 200 lb. per sq. in. to over 50,000 lb. per sq. in. Specification of concrete quality in terms of water-cement ratio (generally expressed as number of *gallons of water per sack of cement*) is now almost universal on larger work and is the only safe and intelligent basis of specification for small jobs also.

The time honored specification by loose volumes, e. g. one part cement to two parts sand to four parts gravel (or stone), is definitely obsolete; 1:2:4 concrete may develop a strength of 5000 lb. per sq. in. when used with a low water-cement ratio such as is employed in tamped paving bases, or it may develop less than 10 per cent of that strength when used with excess mixing water. The use of a *water-cement ratio* type of specification releases the contractor from fixed arbitrary proportions of sand and gravel (or stone). Under this type of specification the proportions of fine and coarse aggregate may be varied at will by the Contractor, during the time used to determine upon the mix to be used on any job, so as to produce the maximum economy obtainable without sacrificing the necessary ease in placing the concrete. This best proportion, as thus determined from trial batches (see Article 10), will vary widely with different fine and coarse aggregates and is rarely found to be in the old ratio of two to four.

A "philosophy" of concrete making—and what is more important, a practical comprehensive discussion of the entire subject—may be found in a small book by Franklin R. McMillan, "Basic Principles of Concrete making."*

Concrete is a mass of inert aggregates held together by hardened paste of portland cement and water. The properties of the paste—strength, water-

*McGraw Hill Book Co., $2.00. The following extracts from an abstract of this book (*News Letter*, JOURNAL OF THE AMERICAN CONCRETE INSTITUTE, Dec. 1929) indicate basic considerations developed fully in the book.

(*Notes Continued Page 68*)

of following these instructions, even though not forced by supervision to do so. While this is an unusual specification, as regards these explanatory and educative notes, it is obvious that the only assurance of quality on a job subject only to casual and occasional inspection lies in the character of the contractor himself. When the Architect or Engineer has discovered his honest contractor, it is believed that this type of specification will materially help in securing fine concrete work. If the contractor is dishonest, no form of specification will prevent poor work in the absence of effective and continual supervision.

The following wording is suggested to be used in the Architect's and Engineer's typewritten specification for individual buildings:

Specification for Concrete Work
Name and Location of Building
Name and Address of Owner
Name and Address of Architect or Engineer

All plain and reinforced concrete work on this structure shall be done in strict accordance with Specification No. 506 of the American Concrete Institute, which is hereby made a part of these specifications and which will be made a part of the contract for this work. All the provisions of Specifications No. 506 shall be in full force and effect, except as expressly modified or supplemented in the following special instructions for this structure.

(Here incorporate any clauses required or suggested by unusual conditions surrounding the work to be done.)

Wherever the words "Architect or Engineer" are used the same shall be construed to mean the Architect Engineer (strike out one) only.

This specification has been submitted to the following critic members of Committee 506, who have greatly assisted the author by their thorough cooperation and experienced criticism:

Theodore Crane, Professor of Architectural Engineering, Yale University, New Haven, Conn.

P. J. Freeman, Dept. of Public Works, Allegheny Co., Pittsburgh, Penna.

S. C. Hollister, Consulting Engineer, Swarthmore, Penna.

W. F. Way, Henry and McFee Contracting Co., Contractors and Engineers, Seattle, Washington

(*Specification Notes—Continued from Page 66*)

tightness, durability, etc.—determine the properties of the concrete. The quality of paste depends upon characteristics of cement; upon water-cement ratio; and upon time, favorable temperature and continued presence of water to complete hydration of the cement.

A plastic, homogeneous mixture is vital to good concrete making, meaning a mixture in which the constituent materials are evenly distributed in all parts of the mass as finally placed and hardened and one which, when freshly mixed, flows sluggishly but without segregation of water or fine materials from the coarse.

Plasticity depends upon relative quantities of paste and aggregate, upon plasticity of the paste itself, upon grading of aggregates and upon shape and surface characteristics of aggregate particles. The amount of paste must be sufficient completely to fill the voids in the aggregates and to float the aggregate particles. The paste must not be so diluted with water as to be unable to hold the particles in a cohesive mass nor so stiff as to make whole mass difficult to handle and place. Grading of aggregates determines quantity of paste required to float particles and also resistance to ready motion or flow of the aggregate itself. Shape of aggregate particles likewise affects the resistance to flow of the aggregate and of concrete made from it. Surface characteristics affect readiness with which paste surrounds and firmness with which it holds the particles and amount of paste required for plastic concrete.

A portion only of the water used in mixing concrete combines chemically with the cement—if only enough water were used to hydrate cement, concrete would be entirely unplaceable. Remainder of water—commonly the greater part of water used—makes it possible to handle the concrete but is also responsible for most of later difficulties. The greater the amount of uncombined water the less the water-tightness of the concrete. Additional curing causes more water to combine with cement.

Very great increases in strength are secured by continued curing. Curing is a major factor in concrete strength and its importance is not sufficiently realized on job. Age, with continued curing, shows consistent gain in strength following a W/C ratio law at all ages. The superiority of concrete with low W/C ratio over that with high W/C ratio increases with age.

A thorough study of this book will assist a Contractor to produce better concrete at no increase in cost.

Contractors who, for business reasons, deal entirely with one material dealer and who can obtain the same cement and aggregates on much or all of their concrete work, will do well to have experiments made to determine the water-cement-ratio-strength law for that particular combination of materials. For it must be recognized that the materials used affect the strength of concrete. In the absence of such advance tests the approximate strength of *well-cured plastic homogeneous concrete*, made from

(*Notes Continued Page 70*)

1. General conditions of the contract

This Contractor shall acquaint himself fully with the General Conditions of the Contract for this work. He shall be bound by all requirements of these general conditions insofar as they are applicable to his part of the work in the opinion of the Architect or Engineer. These General Conditions shall be made a part of the contract for the concrete work covered by this specification.

The Contractor shall read this Specification with the greatest care, taking into consideration all specification notes appearing herein, and shall carry on the work in accordance with the letter and spirit of this specification at all times without regard to the presence or absence of the inspector.

2. Scope of the concrete work

This Contractor shall provide all necessary labor and material and install complete, ready for convenient use, all portions of the structure specifically mentioned in these specifications and/or shown on the architectural or engineering plans or details of the structure, and also all usual necessary and essential portions of a structure of this type, that would commonly be made of plain or reinforced concrete, whether or not the same are definitely shown on the plans or listed in the specifications. In general the work of this Contractor shall include: concrete foundations; concrete floors on the ground, including fine grading and filling therefor; concrete retaining walls at building lines and area ways; concrete columns, roofs and floors; concrete walls; concrete or terrazzo floor or stair finish; any cutting, shoring, sheeting, hand excavation, backfilling or underpinning necessary to install concrete work properly; concrete sidewalks, paving and parking strips; installation of masonry ties or other inserts; concrete steps and stairways; concrete penthouses or tank supports; formwork for all concrete work requiring same; and so forth. This contractor shall also furnish and place all necessary reinforcing material, properly bent and marked, together with complete accessories to securely hold all reinforcement in its designed position during construction.

(*Specification Notes—Continued from Page 68*)

ordinary materials, may be taken as stated in article 10. Certain brands of cement develop strength much more rapidly than others, (*see Note 3*) and concrete made of them will have higher early strength. Crushed stone has been found to give higher strengths than gravel, with the same water-cement ratio. This apparent gain is almost exactly neutralized in the average case, however, by the fact that more paste is required to make crushed stone concrete workable than is required for gravel concrete. In much the same way finer aggregate seems to give higher strengths than coarser aggregate at the same water-cement ratio, but here again more paste is required to make the concrete thoroughly workable as the aggregate becomes finer.

For practical purposes the water-cement-ratio-strength law is limited, in its application to actual construction work,

(1) to plastic (readily placeable, not over-dry nor over-wet) mixes (see abstract reprinted above)

(2) to favorable conditions on the job that provide ample moisture in the concrete for the continued hydration of the cement (*see Note 11*)

(3) to favorable temperatures on the job. The rate of gain in strength of concrete is very much less at low temperatures than at high temperatures, becoming almost nil at temperatures below 40° F. (*see Note 19*).

Each subsequent note applies to that portion of the specification after which the same reference number appears.

Note 1

It is rarely possible to use sand from the excavation, on account of the high probability that dirt will become mixed with or may be already contained in it, in injurious quantities. This is a very frequent source of trouble, and aggregates from the site must not be used, except with the Architect's or Engineer's permission and only after exceptionally thorough tests.

Stone that deteriorates on exposure to the weather, or from pits or quarries where there is evidence of such deterioration, is unsafe to use.

Note 2

For sand for mortar topping (floors, sidewalks, etc.) not over 10 per cent shall pass the No. 100 sieve.

3. Conditions at site of work

This Contractor shall visit the site of the work and make himself thoroughly familiar with all conditions affecting the conduct of his work, the location and arrangement of his plant, the storage of materials, and so forth. He shall make any necessary observations as to soil conditions, ground water level, sewers or public utilities, traffic requirements and so forth. No additional allowance of time or money shall be asked or granted because of this Contractor's lack of knowledge of conditions prevailing at the site at the time of estimating, or which may be readily foreseen to exist at the time that the work is undertaken.

4. Concrete materials

Portland cement shall be used for all concrete work. This cement shall be certified by the dealer to comply with all requirements of the standard specifications of the American Society for Testing Materials. (Serial designation: C9-26, or latest standard of this Society.)

Aggregate for this work shall be certified by the dealer (*See Note 1 opposite*) to comply with the following specifications:

Fine aggregate for this work shall consist of well graded natural or artificial sand, or other approved inert materials with similar characteristics, taken from sources that have furnished satisfactory materials for previous concrete work for several years, or if from a new source shall be thoroughly tested for soundness and permanence. It shall comply with the provisions of the Tentative Purchase Specifications for Concrete Aggregates, E5-A-26T, (or latest standard of the Institute) of the American Concrete Institute. In applying these provisions the sieve analysis of dried aggregate shall show as follows:

Passing No. 4 sieve—not less than 85 per cent.

Passing No. 50 sieve—between 5 and 30 per cent. (*Note 2 opposite*)

Passing No. 100 sieve—not more than 5 per cent.

Fineness Modulus—not less than 2.50

and the weight of clay and silt removed by decantation shall not exceed 3 per cent.

Coarse aggregate for this work shall consist of crushed stone, gravel, air-cooled blast-furnace slag, or other approved inert materials of similar characteristics, taken from sources that have

Note 3

This provision is essential for uniform concrete quality. Various portland cements and even the same brand of cement from different mills may vary in color, strength, rapidity of set, and workability. Changes in the character of grading of the sand, gravel or stone will cause variations (often large) in the workability of the concrete and in the amount of water required to produce a workable concrete on any particular job. Since both the strength and water-tightness of concrete depend on the ratio of water to cement, any changes in materials, resulting as they do in changes in water content, affect the quality and uniformity of the concrete to an important degree. Variation in kind of sand or gravel or stone may also affect the color and texture of the concrete and give a blotchy appearance. The Contractor's orders for materials for this work must include this requirement of a constant source and unchanging characteristics for the entire job.

Note 4

Cement will absorb water rapidly from the ground or even from the air on humid days. Water absorbed in this way hydrates the cement in the sack and destroys or greatly impairs its ability to make concrete. Cement must not be permitted to hydrate until the proper time—when it is placed in the mixer with the water, sand and gravel (or stone).

Note 5

Uniform concrete of specified quality can only be made by accurate measurement of each ingredient and by the continued repetition of this measurement in each successive batch. If the sand and gravel piles are permitted to overlap it is not longer possible to accurately measure either material. With too much sand the concrete becomes too stiff, while if water is added to restore its workability, the strength is reduced. With too much gravel or stone the concrete becomes too wet and tends to separate, the mortar running away from the stone. This results in concrete of uneven quality and also frequently in sand streaks or stone pockets and the extra cost of patching.

Gravel or stone piled up carelessly tends to separate, the coarser particles running down outside to the bottom of the pile.

(*Note 5 Continued Page 74*)

furnished satisfactory materials for previous concrete work for several years or if from a new source shall be thoroughly tested for soundness and permanence. It shall comply with the provisions of the Tentative Purchase Specifications for Concrete Aggregates, E5-A-26T (or latest standard of the Institute) of the American Concrete Institute. In applying these provisions the sieve analysis of dried aggregate shall show as follows:

Passing 1-inch sieve—not less than 95 per cent.

Passing No. 4 sieve—not more than 10 per cent.

Passing No. 8 sieve—not more than 5 per cent.

Fineness Modulus—between 6.30 and 7.50.

The weight of slag shall not be less than 65 lb. per cu. ft. The weight of soft, friable, thin, elongated or laminated pieces shall not exceed 3 per cent.

Aggregates shall be so stored and handled at all times as to remain separate from each other and free of all foreign material until placed in the mixer. (*See Note 5*) Drainage shall be provided where necessary to avoid accumulation of water in aggregates.

Water shall be taken from the usual drinking supply and shall be paid for by this Contractor.

The same materials shall be used throughout the work, including the same brand of Portland Cement from the same mill, the same sand and gravel or crushed rock from the same source and from the same bin at the screening plant. (*See Note 3*) This Contractor shall be fully responsible for the correct certification of all materials by the material dealer, as provided above. In case of doubt this contractor shall pay for the necessary tests to be made under the direction of the Architect or Engineer.

5. Storage and handling of materials on the job

Cement shall be stored in a weather tight shed or building if kept on hand more than three days. If used promptly, it may be stored on a platform raised above the ground or so stored or handled as not to permit it to take up moisture before being placed in the mixer. All the cement in any container, in which part of the cement has become caked or has otherwise deteriorated, shall be entirely removed from the work. (*Note 4*)

Sand and gravel (or stone) shall be kept entirely separate from each other, until placed in the mixer. (*Note 5*) They shall be

(*Note 5 Continued from Page 72*)

When this has occurred the effect is similar to that of mixing the sand and gravel. When all coarse particles are used for gravel, the concrete becomes too wet. When all fine particles are used the concrete becomes too stiff. In either case the uniformity of the concrete is lost, the cost and labor of placing the concrete is increased, and the value of the finished work is impaired. The stock piles should be placed and removed in horizontal layers and all sliding or rolling particles in the piles avoided as far as possible.

Note 6

On the Pacific Coast and in one or two cities elsewhere, structural grade new billet steel may be used, provided the Engineer's approval is secured. Higher stress is permitted on intermediate grade new billet steel or on rail steel than on structural grade new billet steel and this substitution can only be made when the stresses used in the Engineer's design are suitable for structural grade steel. In other parts of the United States, the dealers in reinforcing materials have standardized on the two grades of steel mentioned in article 6 and no other grade is available except on special mill order.

Note 7

No dependence can be placed on the long discredited practice of lifting the bottom steel off the forms, as the concrete is placed, and depending upon the concrete or on pebbles or stones taken from the concrete and placed under the bars, to keep the bars up. Properly designed, rigid supports must be provided and completely placed before concreting is started.

The strength of a reinforced concrete structure, and frequently its fire safety also, depends on the placing of the steel at its designed location as shown on the plans. The load on a chair is frequently very heavy, as when a heavy man carrying one end of a runway steps upon it. Chairs and spacing devices made of soft steel or of too light section, are readily flattened down or bent out of shape. Such devices must not be used, as they only give a false sense of security and the money spent for them is largely wasted.

Note 8

This Contractor should allow in his estimate for a small supply of $\frac{3}{8}$-in. round bars which will be available for filling in

(*Note 8 Continued Page 76*)

stored in bins or dumped only on clean platforms or pavements, and no dirt, rubbish or other foreign material shall be permitted to mix with them. In dumping gravel or stone the various sizes of particles shall not be permitted to separate, but the mass must be kept well graded at all times. (*Note 5*)

6. Reinforcing steel and inserts

All reinforcing steel for this work shall be furnished and placed by this Contractor. All bars shall be of intermediate grade new billet stock or of rail steel, meeting the standard specifications of the American Society for Testing Materials (Serial Designation: A 15-14 or A 16-14). (*Note 6*) All bars shall be supported at the proper height and at the proper spacing as shown by the drawings, using precast concrete or metal chairs, spacers and supports to hold them securely in place. (*Note 7*) Metal chairs, spacers and supports shall be made of stiff springy steel of such strength as not to be flattened out or be displaced by workmen. (*Note 7*) All reinforcement as used shall be thoroughly cleaned of mill or rust scale and of coatings of any kind that will destroy or impair the bond between concrete and steel. All reinforcement shall be carefully formed to the shapes and dimensions shown on plans. Tie wire shall be soft annealed iron wire not smaller than No. 18 gauge.

All bent bars, ties and stirrups shall be tagged with metal or other persistent identification marks to insure their location in the proper part of the structure as shown by the drawings. Heating of reinforcement or rebending of bars will be permitted only when the entire operation is approved by the Architect or Engineer.

All portions of the concrete work shall be provided with reinforcement (unless resting directly on firm, undisturbed ground.) Any gaps in the reinforcement as shown on the plans shall be suitably filled, using not less than $\frac{3}{8}$ in. round bars at 6 in. on centers in one direction in any case. (*Note 8*)

7. Formwork

Forms for this work may be made of wood, steel or other material which has been satisfactorily used on similar work for this purpose. Where panel forms are re-used they shall be thor-

(Note 8 Continued from Page 74)

gaps as specified. By the term "gap" is meant a *small* unreinforced area such as sometimes occurs between pipe sleeves, or where the regular groups of parallel bars leave a small triangle between them. Any unreinforced space above 5 sq. ft. in area, or extending for any considerable distance should be promptly called to the attention of the Architect or Engineer and a request made for instructions.

Note 9

Wooden formwork tends to dry out and to open up cracks between the boards. Dirt gathers in these cracks and when the forms are wetted, either by rain or in preparation for concreting, the dirt prevents the cracks from closing and as a result, the surface of the finished concrete shows a succession of unsightly ridges where the mortar has filled these open cracks. The swelling of the forms also causes movements at the sides of the building, at elevator and stair openings, etc., and requires expensive cutting to plumb up the walls and shafts. This cutting may reduce the fireproofing or even expose the steel to rusting. All this can be easily and inexpensively prevented by the simple expedient of keeping the formwork always damp, as specified.

Note 10

It is much better to cut a hole of the size of the end of a 4x4 or a 6x6 and build in a shore in advance so as to bear directly on the concrete, than it is to remove the forms and then "re-shore" (put in new posts), wedging the same against the new slab. Re-shoring operations permit the slab to sag and then force it back again to an undetermined amount. Slabs have frequently been weakened or even cracked by re-shoring and this practice should be entirely discontinued. Built-in shores must be selected so as to have sufficient stiffness to support their load after the bracing has been removed with the regular formwork.

oughly cleaned and repaired to produce a true, even surface. All forms shall be mortar-tight and sufficiently rigid to prevent sagging between supports. Surfaces of metal forms shall be free of marked irregularities, dents or sags. Knotholes or broken places in wood forms shall be covered with metal patches. All formwork shall be so designed (cleanout openings at base of columns, at bottoms of deep girders, etc.) as to permit of ready cleaning and inspection after the reinforcement has been placed. For spans in the structure in excess of twenty feet, the bottoms of beams, or girders, shall be cambered, allowing one-twenty-fourth of an inch rise per foot of span. Joints in formwork shall be either horizontal or vertical. All interior angles not occurring on an exposed face of the structure shall be formed with a one-inch bevelled fillet, unless otherwise called for on plans.

Wooden formwork shall preferably be kept continually moist after being erected, so as to prevent the opening up of cracks in which dirt may lodge. (*Note 9*) Paraffin or other suitable formwork oil shall be applied to forms immediately before the reinforcement is placed. In no case shall the oil be permitted to coat the reinforcement. No oil shall be used where the concrete surface in contact with the formwork is later to receive plaster. Concrete shall be placed as soon as possible after the reinforcement has been placed and inspected, so as to prevent the collection of dust and dirt on the oiled formwork.

The design of the formwork shall include all necessary shores built in place in advance of concreting in cases where portions of the forms require to be removed before the concrete on them is ready to support itself. These shores shall not be disturbed in the removal of the adjacent formwork. No re-shoring will be permitted. (*Note 10*) Formwork supports shall be trussed as necessary for stability and to prevent settlement when foundation conditions for shores are bad. Where internal ties are necessary bolts or rods shall be used; they shall be so arranged that no metal shall be left within one inch of the surface of the concrete. All holes left by the withdrawal of these bolts or rods shall be neatly patched. Tie wires will be permitted only for concrete members entirely protected from the weather (or other corrosive exposures) and only by especial permission of the Architect or Engineer.

Note 11

The rapidity with which concrete gains in strength depends on several factors, which must be considered in connection with removing form work. Certain portland cements give a higher strength at early ages than others. Concrete gains strength much more rapidly at high temperatures than at low temperatures. Stiff concrete gains strength more rapidly than sloppy concrete. Concrete must have moisture in order to maintain its increase in strength, and concrete from which moisture has been rapidly evaporated within a few days after placing may be expected to be weak and leaky. On any particular job the temperature since the concrete was placed is most important, while the other items mentioned are important in case any doubt exists as to the wisdom of removing form work.

Note 12

Accurate measurement, providing the same amount of each material in every batch, will result in concrete of the same workability and will make all the operations of mixing, transporting, and placing concrete, as simple as possible. Inaccuracy of measurement will cause variation in the consistency of the concrete with corresponding uncertainties in the mixing, transporting, and placing and will result in concrete of unequal strength, water-tightness and quality. Stoppages in the chutes, with their attendant mess and expense, are commonly due to variations in measurements (or in grading) that result in a too-stiff batch that sticks, or a too-wet batch that races. All such troubles may be readily avoided by careful control of the materials (see note 5, page 72) and consistent accuracy of measurement.

An experienced workman shall be employed at all times during the placing of concrete to watch the formwork and its supports and to strengthen any portions that may show signs of sagging, displacement or failure.

8. Removing formwork

This Contractor shall be solely responsible for the safety of the construction during and after form removal, and no act of the Architect or Engineer or of his representatives on the work shall relieve this Contractor of such responsibility. Subject to this limitation, and measured in days of good curing temperatures (not less than 60° F., twenty-four hour average), forms for columns shall not be removed in less than one day; forms for slabs or other members whose span does not exceed five feet nor eight times their depth and which carry only their own weight (or in which all super-imposed loads are adequately supported by built-in shores [*Note 10*]), shall not be removed in less than three days. Other forms shall not be removed in less than seven days. At average temperatures, lower than 60° F., a longer period shall elapse sufficient to produce the same strength of concrete. (*Note 11*)

9. Patch formwork

Forms for patches (where temporary openings have been left for any reason) shall be rigidly supported, being posted from the floor below or suspended by rods or bolts and not hung by twisted wires or other means that will permit displacement of the patch formwork, and unsightly surfaces.

10. Measurement of the batch

Job measurements shall be so made as to insure that each successive batch of concrete is made up of identical volumes (or weights) of cement, water, sand and gravel (or stone). (*Note 12*) Each batch shall be proportioned to use only whole sacks of cement, unless a suitable container is provided to measure accurately the required amount of cement from broken sacks, or unless the required amount of cement is determining by weighing on the job. Sand and gravel or stone may be measured in measuring boxes containing the required volume for one batch, such boxes being struck off level full at each use, or any equivalent accurate method may be used. At least one wooden box

Note 12A

In this specification the *water-cement ratio* is the fixed requirement. The strengths given are based on the usual experience with average materials. The Architect or Engineer, under this specification, does not require this strength, but he does reserve the right to require the use of other common and readily available materials, in place of those selected by the Contractor, should the latter prove to be exceptional and to result in lower strength than that intended. The approximate mixes are likewise not binding upon the Contractor, who is free to use as much aggregate as he can while maintaining the specified water-cement ratio and a workable consistency.

of one cubic foot capacity, with handles, shall be provided for checking volume measurements. Unless weighed or measured in an accurate measuring tank, water shall be measured in a pail with a line painted on it to give the proper water level at each filling.

The proportions of cement, water and aggregate (sand and gravel) shall be taken as follows:

Class A concrete, requiring a strength of approximately 2000 lb. per sq. in. at 28 days, shall be made with 7.5 gallons of water per sack of cement. The approximate ratio of the volume of the cement to the sum of the combined volumes (measured separately) of the sand and gravel (or stone) will be 1 to 5.75 (*Note 12A*) Unless otherwise noted on the plans, all concrete will be Class A concrete.

Class B concrete, requiring a strength of approximately 2500 lb. per sq. in. at 28 days, shall be made with 6.75 gallons of water per sack of cement. The approximate ratio of the volume of the cement to the sum of the volumes of the sand and gravel (or stone) will be 1 to 5. (*Note 12A*)

Class C concrete, requiring a strength of approximately 3000 lb. per sq. in. at 28 days, shall be made with 6 gallons of water per sack of cement. The approximate ratio of the volume of the cement to the sum of the volumes of the sand and gravel (or stone) will be 1 to 4.25. (*Note 12A*)

Equivalent weights may be used in place of volume measurements for all classes.

In determining the amount of water, allowance shall be made for the free (surface) water on the aggregate. In the absence of job tests, sand shall be considered to carry 0.25 gallons of surface water per cu. ft. if damp, and 0.8 gallons per cu. ft. if wet. Gravel or stone shall be considered to carry 0.15 gallons per cu. ft. if damp, and 0.5 gallons per cu. ft. if wet.

Trial batches shall be made on the job to determine the final volume (or weight) of sand and gravel (or stone) to be used. The water-cement ratio shall not be changed but the amount of aggregate shall be increased or decreased to give the proper workability of the concrete as specified in article 11. The division of the aggregate between sand and gravel (or stone) shall be

Note 13

Sand and gravel (or stone) may be considered as fillers in the concrete, the quality of the concrete depending primarily on the water-cement ratio, which determines the quality of the "paste." Variation in this proportion of sand to gravel (or stone) affects the workability of the concrete greatly and the trial batches should cover a considerable range so that the best proportion for the economical transporting and placing of the concrete may be selected. The limiting proportions given here are determined from experience with a very wide range of materials.

determined by trial so as to give the most workable and non-separating concrete, but the volume of sand shall not be less than one-third nor more than one-half of the total volume of the sand and gravel (or stone) measured separately. (*Note 13*)

11. Mixing concrete

Concrete shall preferably be mixed in a power driven rotary batch mixer. In no case shall the capacity of the mixer be less than a one sack batch and a large mixer with a capacity of two or three sacks of cement (with the corresponding quantities of water, sand and gravel (or stone) shall be provided except on very small jobs. Other devices, mixing concrete equally well, may be used with the consent of the Architect or Engineer. The capacity of the mixing equipment shall be such as to produce all the concrete required at any one level above the foundations in a single working day. In case of very large areas to be built at a single level this requirement may be waived by the Architect or Engineer.

Mixing equipment shall be cleaned at frequent intervals so as to keep all parts operating efficiently. Batch mixers shall be fully discharged before the next batch is admitted to the drum. Concrete which has partially hardened shall not be remixed with added water. Such concrete shall be wasted.

The requirements of Article 10 apply equally to hand mixing when this is resorted to for small quantities of concrete. Hand mixing shall be done in a clean, watertight, mortar box or on a level, watertight, clean wood, metal of concrete floor or platform which has been thoroughly wetted to prevent absorption of water from the concrete. The sand shall first be spread in a layer of uniform thickness on the mixing platform. The gravel or stone shall then be placed on top of the sand in a second layer of uniform thickness and covering the entire first layer. The two layers shall then be turned and mixed with shovels for at least three complete turns and until the mixture is uniform in color and appearance. The mixture shall then be levelled off and the cement spread in another layer of uniform thickness over the entire mass. This shall then be turned with shovels for at least three additional complete turns and until the mixture is uniform in color. The material shall then be levelled off, depressions

Note 14

Hand mixing of concrete is generally prohibited, not because a satisfactory concrete cannot be made by this method, but because the work is often done in a careless and lazy manner. This Contractor and his superintendent on the job must give personal attention to hand mixing operations, training a crew of men to do the work systematically and thoroughly and affording them time to carry out these specifications properly. Each "turn" must handle *all* of the material and there must be a clear gap in the pile (up to the time that water is added) between the portion turned and that not yet turned on each operation. Thus the pile moves bodily to the left at one turn and back to its original position at the right on the next turn, etc. The platform or mixing box must be of sufficient size to permit of this movement for a full batch. Much skill is shown by some workmen in securing a thorough mixing of the materials, by the proper twist of the shovel, and also much skill in working the water into the mixed cement, sand and gravel (or stone) evenly, and without permitting any to escape. Workmen showing such skill must be employed at this work in preference to those without it.

Note 15

The greatest economy, resulting from the use of more sand and gravel (or stone) with the same amount of cement and water, will be found with the stiffer consistencies. Too stiff a consistency will increase the difficulties of placing, however, unless the concrete can be tamped in placing. In the case of footings or of floors laid on the ground, very stiff concrete, consolidated by tamping, is permissible and economical. The sloping portions of footings may be built without forms in this way. Since the water-cement ratio is definitely fixed, and the consistency limited by these specifications, the greater amounts of aggregate necessarily involve stiffer concrete.

The consistency of concrete, made from any fixed set of materials, may be judged by the slump test, using a truncated cone-shaped mold as described in the A. S. T. M. specification D 138-2-T. This device is especially useful in case the moisture in the aggregate varies rapidly (as after rainy weather), to de-

(*Note 15 Continued Page 86*)

shall be made in the surface uniformly distributed and of sufficient size to hold all the mixing water for the entire batch and this water shall be poured into the depressions to give as near uniform distribution as possible. With the shovel, work the ridges of mixed cement and aggregate so as to take up all the water without letting any escape, and then turn the mass with shovels for at least two additional complete turns and until it is uniform in consistency. (*Note 14*) Only enough water shall be used to give a quaking, jelly-like mass, from which the water will not separate and run out on the platform, after mixing is completed.

The consistency of the concrete when mixing is completed, shall be such that the concrete flows slowly with a rounded edge, and without any visible separation of the water or of the mortar from the gravel or stone. For concrete to be placed in thin walls or about congested reinforcement or in other difficult places, the rounded edge may be permitted to be quite thin, while for concrete placed on a level deck with very little steel the concrete should be as stiff as possible while still showing a decided tendency to flow. (*Note 15*)

12. Time of mixing

One full minute shall elapse between the time when all the material for any given batch is placed in the mixer and the time when the first concrete of that batch is discharged from the mixer, except that a portion of the mixing water may be introduced during the first ten seconds of the mixing time.

13. Conveying concrete

The consistency of the concrete at the completion of mixing, as specified above, shall be maintained during the transportation of the concrete from the mixer to the forms. The methods used by this Contractor on this work shall be such as to comply fully with this requirement. (*Note 16*) Separation of the mortar from the coarse aggregate shall not be permitted at any stage.

14. Placing concrete

Before commencing the placing of concrete all formwork shall have been thoroughly washed (*Note 17*) and shall be clean and free from construction dirt and debris, all reinforcement shall be properly placed and supported and all inserts and openings shall be completely installed for a distance of at least thirty feet ahead

(*Note 15 Continued from Page 84*)

termine quickly and accurately the change in mixing water required to keep the specified consistency.

Note 16

Chutes may be used in transporting concrete provided the results on this work at all times meet the requirements of article 13. It is possible to use chutes so that this is done, but it is all too common that failure results in the attempt. Chutes must be sloped at just the right angle to cause the concrete to flow without separation. A hopper must be provided at the end of the chute and the concrete wheeled or shovelled from this hopper into the forms; the only permissible exception (permitting concreting direct from the chute) being where concrete is placed in a large mass, as in a footing, where there is no chance for it to flow out to a thin edge and to separate. Carts or wheelbarrows will be used more commonly on jobs of the small size covered by this specification.

Note 17

Even in freezing weather the formwork should be cleaned with water or steam, as this is the only practical means of removing the loose dirt. If the temperature is sufficiently high for the proper placing of concrete under this specification, the water will not freeze.

Note 18

On small jobs it is even easier than on large ones to change frequently from concrete to "grout" and so keep the mortar always fresh and soft when the concrete is placed. In hot, dry weather, especially, good judgment must be used in the timing of mortar batches, as in such weather the thin edges of the mortar dry quickly and there is a tendency for such dried edges to scale off later. For this reason the consistency of the mortar should always be such that it flows with a slightly rounded edge. The amount of water to be used to give this consistency is readily determined by trial.

Where the steel is very congested, as in thin walls, so that the concrete is separated by hitting rods repeatedly as it falls, this difficulty may be readily overcome by using a portable metal

(*Note 18 Continued Page 88*)

of the concreting operation on all sides. Runways shall have been placed and the resulting dirt cleaned up and any steel disturbed shall be properly replaced. Column capital forms or other depressions at which the washing water may gather shall be drained and the concrete shall not be deposited in standing water. In weather requiring heating of the fresh concrete in place, the salamanders or other heating devices shall be in operation before concreting starts. No snow or ice shall be left in any part of the forms.

In columns, or similar slender vertical or slightly inclined members, the bottom shall be filled with mortar (concrete from which the coarse aggregate and much of the usual water has been omitted) which shall be sufficient in quantity and proper in consistency to work up with the concrete and to fill all spaces between closely spaced bars or between the steel and the formwork. In girders or other similar members, in which the congestion of steel makes placing difficult, the lower part of the forms shall be filled with mortar in the same manner. This mortar, in either case, shall be placed immediately in advance of placing the concrete and shall not be permitted to dry out or set so as to lose its mobility before the concrete is placed on top of it.

Concrete shall not be dropped through reinforcing steel (as in walls or beams with top reinforcement) so as to cause separation of the coarse aggregate from the mortar on account of repeatedly hitting rods as it falls. In such cases hoppers, and, if necessary, vertical ducts shall be used in the wall forms or on the outer face of the wall forms, (*Note 18*) or other means employed so that the concrete may reach the place of final deposit without separation. Concrete shall be deposited in small amounts at many points and shall not be required or permitted to flow along the forms for more than a very short distance, or from beam forms into column or wall forms.

Concrete shall be worked around the reinforcing rods, inserts, etc., and against vertical forms as it is being placed, so as to produce smooth, dense, surfaces and complete filling of all spaces within the forms but care shall be taken not to over-spade the concrete so as to cause segregation locally. Concrete being placed with a very stiff consistency (as in paving base or in sloped foot-

(*Note 18 Continued from Page 86*)

duct with a hopper top that may be inserted inside the form so as to conduct the concrete past the bars, or when the space between bars is very small, wooden ducts may be built by housing in the space between adjacent studs and cutting openings through the side form to admit the concrete below the steel. A duct 3 in. to 4 in. wide by 16 in. to 20 in. long in cross section is adequate for this purpose. In the case of the outside wooden duct a baffle fastened to a long handle should be lowered inside the forms and placed directly opposite the opening in the form and close up to the form to prevent the concrete from segregating as it flows through the hole.

ings concreted without forms) shall be consolidated by tamping or vibration of the concrete or by vibration of the forms (never by vibration applied directly to the reinforcement).

15. Construction joints

All the concrete in vertical members (such as columns or walls) shall have been placed at least two hours before any concrete is placed in the beams or slabs directly over such columns or walls. This interval may be increased if desired (over night, for example) but necessary precautions shall be taken to insure that the new concrete bonds to the older concrete, if the interval exceed thirty hours, or if the weather is hot and drying. In any case, any excess water or fines that may rise to the top at a horizontal construction joint, shall be removed and the concrete cut away as necessary to insure strong, dense concrete at the joint.

Construction joints in beams and slabs shall be vertical and shall be located close to the center of the span, unless a beam intersects a girder at this point, in which case the joint in the girder shall be offset a distance equal to twice the width of the beam and inclined reinforcement provided to take the shear across the offset construction joint. Construction joints shall be made with a key at the center of depth and with reinforcement near each face of the member, additional bars, at least 60 bar diameters in length, being provided where steel is lacking in either face of the member cut by the construction joint. The added bars shall have a cross sectional area not less than .0025 of the area of the member cut by the construction joint. The member of construction joints in beams and slabs shall be kept to a minimum. (See article 11—capacity of mixer required.)

16. Placing against hardened concrete

Before depositing new concrete on or against concrete which has set, the forms shall be retightened, the surface of the set concrete shall be roughened as required by the Architect or Engineer, thoroughly cleaned of foreign matter and laitance, and saturated with water. The new concrete placed in contact with hardened or partially hardened concrete, shall contain an excess of mortar to insure bond, and shall not be placed until the saturated surface has become dull (but not lightened in color) through absorption or removal of all excess water.

Note 19

Watertight concrete can readily be obtained without the use of any admixture or compound. The concrete must be so proportioned as to have sufficient mortar to fill all the voids in the gravel (or stone), which is also a requirement for good workability and easy placing. If, then, the concrete is held to the consistency specified above and placed with care to prevent segregation (stone pockets or sand streaks indicate bad segregation and careless work) the concrete will be watertight when the cement is properly hydrated. It is the experience of investigators that almost all usual concrete mixes produce waterproof concrete under laboratory conditions. The difficulty in the field probably arises largely from segregation during transporting and placing of the concrete and from joints where the concrete is not made to bond properly. (See article 16.) The process of hydration requires favorable conditions—warmth and moisture always present—and a reasonable length of time. The strength as well as the water-tightness is greatly improved by long, warm, moist curing. Warmth without moisture simply dries out the concrete and all gain in strength or water-tightness ceases in dry concrete. Moisture without warmth is equally useless or may be harmful if freezing occurs. Below 40°F concrete is practically dormant. It is important also that concrete is provided with both warmth and moisture when it is young, as the chemical activity decreases with age.

Note 20

Concrete deposited in a trench or on the ground can be "effectively enclosed" by a covering of hay on all exposed surfaces or by laying a tarpaulin over the trench and covering it with hay. Concrete in large masses develops ample chemical heat for its own curing, provided this heat is prevented from escaping. In elevated work, the problem of effective enclosure is more difficult, and care must be taken with the usual enclosure of tarpaulins (heated with salamanders) to properly support the tarpaulins with timber to prevent openings in windy weather and to keep the tarpaulins away from the surface of the concrete at edges of a floor. The arrangement must be such as to provide warm air surrounding

(*Note 20 Continued Page 92*)

17. Defective concrete

Any defective work discovered after the forms have been removed, which in the opinion of the Architect or Engineer cannot be repaired satisfactorily, shall be removed at once and replaced. No compensation will be allowed for patches or replacements because of defects. Defects shall include honeycombing, or other surface blemishes; or portions which through lack of uniformity in the concrete render them, in the opinion of the Architect or Engineer, inadequate in strength; or improper alignment of outside or exposed faces.

Patching where permitted shall be done only under the supervision of the Architect or Engineer. The cavity to receive the patch shall be wetted thoroughly and allowed to stand sufficient time for the surface of the cavity to become dull but not lightened in color. The patching material shall be of the same material and in the same proportions as the concrete receiving the patch. It shall be worked into place in a dry consistency and shall be thoroughly rammed. The patch shall be built up and supported in such a manner as will prevent sagging. Especial care shall be taken to prevent patch concrete from drying out and to cure it thoroughly, as required in article 18 below.

18. Curing of concrete

Concrete, after taking its initial set, shall be protected from drying out at all times during the first seven days after it is deposited. If the concrete is so located as to require especial water tightness this curing period shall be increased to twenty-one days. (*Note 19*) Protection may be afforded by replenishing the supply of moisture to offset losses by evaporation or by sealing in the water carried by the concrete so that it cannot later evaporate. All portions of the structure shall be kept moist and warm simultaneously for the full curing period of seven or twenty-one days and any portion of the time during which either moisture or warmth is lacking shall not be counted as effective for curing.

19. Cold weather protection

Artificial heat shall be provided and effective enclosure maintained, whenever necessary, to insure that the air in contact with concrete, for a period of seven days after placing, shall not fall below 50° F. for any considerable time. The temperature within

(*Note 20 Continued from Page 90*)

all the concrete. Where, in moderate weather, only the story below the freshly placed concrete floor is enclosed, the upper surface of the concrete must be protected with sawdust, hay or similar insulating material. Temperatures in excess of 100°F in the enclosure, tend to dry out the concrete. If salamanders with water-evaporating pans over them are used, or if live steam is used for curing, there is no danger (and in fact much gain) from using moderately high temperatures in the enclosure.

Note 21

In heating sand or gravel (or stone) on a small job by the usual method—maintaining a fire in a metal tunnel through the storage pile—considerable moisture will be driven off and the mixing water may be increased to maintain the usual warm weather consistency (best measured as slump—see note 13, page 82) for the water-cement ratio specified. Where live steam is permitted to escape in the piles, on the other hand, much water is introduced into the sand and gravel (or stone) and the measured water must be *reduced* to maintain the consistency. Heating the water alone is the cheapest way to heat concrete and introduces the fewest complications, and there is no limit to the temperature of the water, provided it is introduced into the mixer with the sand and gravel (or stone) and so cooled to 150°F or less before it meets the cement. Very hot water may cause a flash set of the cement and should not be used with hand mixing. A properly operated kerosene torch in the mixer is effective, provided sufficient time is allowed to heat the entire mass of the concrete.

Note 22

Since the strength, water-tightness and other desirable properties of concrete are dependent on a low water-cement ratio, any increase in the water content by rain or snow or ground water has the same effect as increasing the mixing water. Where concreting must be continued in bad weather, the consistency should be made as stiff as can be handled properly (with extra spading) and the extra cement added as specified. As soon as possible the fresh concrete should be covered. In many cases, it is possible to

(*Note 22 Continued Page 94*)

the enclosures shall not exceed 100° F. (*Note 20*) Moisture shall be provided within the enclosure as required by article 15.

When necessary to insure that the fresh concrete shall reach the forms at a temeprature of not less than 50° F., the materials (water only in moderately cold weather and aggregates also in very severe weather) shall be heated. The concrete may be heated in the mixer by any means that will not impair its quality, (*Note 21*) and subject to the approval of the Architect or Engineer. Dependence shall not be placed on salt or other chemicals to prevent concrete from freezing. No frozen materials or material containing lumps of snow or ice shall be used. Manure when used for protection, or moisture from manure, shall not be applied directly to, nor be permitted to come in contact with concrete.

20. Water supply

An adequate supply of water for cleaning formwork and for curing concrete shall be installed so as to be available (at all levels) before concreting starts and for at least the period of curing as required by article 15.

21. Protection of concrete work

Concrete shall be protected from washing and from the addition of excess water in the concrete during stormy weather, until such time as it has sufficiently hardened to resist washing or penetration. One extra sack of cement, per cu. yd. of concrete mixed during stormy weather, shall be added to maintain the required water-cement ratio and surface water shall be drained away from the fresh concrete during heavy rains. (*Note 22*) Additional measures shall be taken to safeguard the quality of the concrete, if necessary.

Concrete work shall be protected from injury during the removal of formwork and from injury due to the storage or movement of materials in or over the structure during construction.

22. Cement floor finish and under-finish

Cement floor finish or under-finish (cement finish shown on plans to be covered by linoleum or other surfacing material), if less than one and one-half inches thick, shall be placed as soon as the structural concrete has hardened sufficiently for workmen

(*Note 22 Continued from Page 92*)

leave the finished surface slightly low and to bring it up to grade by scattering on a mixture of dry sand and cement (in the same proportions as the sand and cement in the regular mix) to absorb the extra water. In footings it is permissable to use a dry batch of concrete for the same purpose. All methods used for this purpose must be approved by the Architect or Engineer.

Note 23

A steel trowel is a dangerous tool and may easily be (generally is) overworked. Dusting of concrete floors is commonly due to overworking with a steel trowel and to the use of fine sand. For work exposed to the weather, such as sidewalk finish, it is much better not to use the steel trowel at all. A wood float will give a sufficiently smooth and far more permanent finish. Where a trowelled finish is required the finishers must be restrained from starting until a single trowelling will leave the surface completed. Each additional trowelling damages the surface by bringing additional fine material to the top. Water should never be sprinkled on a finish to permit of easier trowelling—it is certain to result in dusting and impermanence. Floor finish should have especially good curing, as they are subject to severe wear.

Note 24

A mortar (or concrete) topping for concrete slabs, far superior to the usual product, may be secured at a very reasonable cost in spite of its novelty to the average cement finisher, by the following method. Instead of the usual mortar, use for topping a *concrete* composed of one part cement, one part coarse grained sand (not over 10 per cent passing the No. 50 sieve) and one and one-half to two parts of gravel or crushed stone retained on the No. 4 sieve and passing the $\frac{3}{8}$-in. screen. Mix this with 4.5 to 5 gal. of water per sack of cement for a period of two minutes (to give a fat, easily worked concrete). Place, screed and wood float this topping, then allow to stand for from 30 to 48 minutes, so that it becomes sufficiently stiff to prevent the fine material from being drawn to the surface by the steel trowel. Finally go over with the steel trowel, to give a dense, hard surface. With this kind of

(*Note 24 Continued Page 96*)

to walk on it, or a dry mixture of *coarse* sand (*Note 2*) and cement, in the same proportions as the mortar in the concrete, may be distributed uniformly over the surface of the concrete before initial set has occurred. In either case the method used must result in the formation of a mortar surface layer of uniform consistency (about four-inch slump) without excess water which shall be darbied to a true surface and trowelled later to a dense, smooth finish. The surface shall not be gone over more than twice with a steel trowel. For surface exposed to the weather, a wood float shall be used, entirely replacing the steel trowel. (*Note 23*)

Stair finish shall be laid in the same manner as floor finish.

Mortar for floor finish or under-finish shall be made with the same proportions of cement and sand as is used in the concrete to which the finish is to be applied. In no case shall the volume of cement exceed 40 per cent of the volume of the fine aggregate. (*Note 24*)

23. Concrete floors on ground

Concrete floors shall not be placed directly on the ground, other than sand or similar material, except for the lower course of two-course floors having a water-proofing layer between the courses. One-course concrete floors on ground, sidewalks and parking strips, shall be laid on top of a plain cinder, stone or sand filling at least five inches thick, tamped and finished accurately to the required grade of the underside of the concrete. They shall be of Class A concrete of the thickness shown on plans (but not less than five inches thick.) They shall be finished as specified in general for floors or as called for on plans.

Open joints ($\frac{7}{8}$ inch wide) shall be left between such a floor slab and the enclosing walls and columns and this joint shall later be caulked with asphalt mastic. In case the floor slab is exposed to more than 40° F. variation in temperature, or is subject to changes in moisture content, or is more than 100 feet long in any direction, similar joints shall be made at intervals of not to exceed one hundred feet and caulked in the same manner.

(Readers are referred to the Journal *for January, 1931, for discussion which may develop. Such discussion should reach the Secretary by December 1, 1930.)*

(Note 24 Continued from Page 94)

topping (with very little fine material in it), after it has been allowed to stiffen, the damage from steel trowelling is avoided and fine, dust-free, weather-resistant surfaces are produced.

A topping of concrete instead of the usual mortar is not required by this specification. It is *permitted* as an alternate, unless the Architect or Engineer definitely calls for it, in his typewritten specification.

Discussion of Report of Committee 502

Construction Specifications for Concrete Work on Ordinary Buildings (502-30T)

The discussion of this specification is continued from the Journal *for March* (A. C. I. Proc., *Vol. 26, p. 580*). *Written by Mr. Lord, as Author-chairman of Committee 502, with the cooperation of the critic members, it was published in the* Journal *for November, 1929* (*Vol. 26, p. 1*) *and presented to the 26th annual convention. As there amended* (*See Vol. 26, p. 580*) *it was given tentative adoption. If unamended in substance it will be in order at the 1931 convention to move its submission to letter ballot as a Standard of the Institute.*— Editor

BY GEORGE A. SMITH*

I am most heartily in accord with the Institute's present plan of standardizing practices involving the use of portland cement, and feel that what is done will be for the best interest of all. With present practice in the manufacture of concrete so variable, I am impressed with the value of such a Specification as that presented by Committee 502. It surely will help greatly in unifying practice.

My attention was directed particularly to Article 10. "Admixtures and Special Cements." If paragraph one were included in a specification and then interpreted literally, such materials could have no part in the program until such a time as it would be possible to obtain all the information stipulated. Any specification should be reasonable and just.

Any material used in concrete should be studied as carefully and thoroughly as time and conditions permit. However, to

*Johns-Manville Corp., Manville, N. J.

require that materials shall be "thoroughly tested by reputable independent investigators, so as to demonstrate their effect on the strength, elastic properties, permeability and permanence of concrete produced from materials such as are being used on this work," before it may be used appears to be unnecessary in view of the Architect's and Engineer's present knowledge of admixtures and their functioning.

How many tests are made to determine the elastic properties, and permeability or the permanence of concrete made with the particular brand of cement proposed for a particular job? Because portland cement is to be used is no reason why all the properties of the concrete will be the same regardless of the brand used. Different brands of portland cement may have different properties due to different methods of manufacture, to small variations in the chemical composition or to inherent properties of the raw materials. All portland cements are acceptable for concrete work when they pass the minimum requirements of the A. S. T. M. because experience has shown that such cements have usually given satisfactory results when properly used. When this is taken into consideration why should such a question be raised about admixtures which are manufactured under definite specifications and which have given successful service in the past? Elaborate studies for determining the various properties are generally not required because of the time and expense involved in securing the data. In exceptional cases, however, most complete information may be desirable and highly important but such is not the rule especially on "Ordinary Buildings."

Progress in the art of concrete or in any other art is not attained by sitting back and waiting until some independent investigator sees fit to take up the study of some particular product. To insure progress and the introduction of new process and new products, manufacturers are continually studying and establishing definite knowledge regarding the uses of their materials. This information is of unquestioned value to industry and is generally accepted by engineers.

Among the admixtures now on the market many have unknown and unproven characteristics, and the data available are not so extensive as might be desired. There are, however, other admix-

tures which have proven their worth and which have been used successfully for a number of years.

Many prominent engineers and architects have found from their own experience and from that of others that some admixtures are effective in producing certain desirable results and go so far as to incorporate their use in their specifications. What better data are to be desired than the experience of engineers and architects? Is not such information reliable? The proposed specification at present excludes such materials and prevents their being used until such a time as elaborate and comprehensive tests are made under a multitude of conditions.

In order, therefore, that the proposed specification may be consistent in this regard with present practice I would suggest that paragraph one Article 10 be struck out and that the following paragraph be substituted:

Materials to be added other than the usual ingredients of concrete (portland cement, fine and coarse aggregate and water) shall be proven suitable to the satisfaction of the Architect or Engineer. Approval for the use of such additional materials shall be in writing.

Aside from the question of approval or disapproval of admixtures, I am impressed by the incompatability of the proposed specification with the ability, and the rights and prerogatives of the Architect or Engineer. In Article 9 "Constant Source of Supply," we find "having determined upon the source and kind of cement and aggregate to the satisfaction of the Architect or Engineer, etc." Here, from data available, be it from experience or from test, he is allowed to exercise his ability and his judgment in selecting what materials shall be used. Yet, when considering other possible ingredients, we find that the specification is dictating to the responsible head what he shall do and how he shall do it. Is the specification written to govern the Architect and the Engineer or is it to govern the job and the Contractor? If it is the intent, to regulate and control the acts and decisions of the Engineer or Architect, there can be little exception to the specification. However, I do feel that such is not the meaning.

Responsible architects and engineers are capable of judging what materials shall be used and would, in all probability, incorporate as a part of their specification the above proposed amendment. To add the last part of paragraph 1 Article 10 stipulating

what the Engineer or Architect may consider would be a reflection on his ability. As now proposed we have the approval in writing and then some one comes along and dictates "and then only such materials shall be added, etc." Why not let the matter rest upon "to the satisfaction of the Architect or Engineer"?

BY G. W. HUTCHINSON*

Among other details of the material specifications, the manner of presentation of paragraph 10 "Admixtures and Special Cements" is open to question, especially when the first impression is reinforced by the tone of the author's criticism.

In a specification, drawn for national use, the amount of consideration accorded it depends not only upon its practicability, but also upon its interpretation as regards prejudice and commercialism.

It occurs to me that this paragraph should either be eliminated or relieved of the impression it will convey as now worded.

There are admixtures and special cements of several classes. Without doubt, some are not suited for all purposes, and possibly some are unsuited for any purpose. On the other hand, a prejudice is set up against those that have been used with beneficial effect.

It is felt that it is a matter of competition among producers to show the superiority of their product, etc., rather than to give them all a technical "black eye."

Due to the activity of both the proponents and opponents of admixtures, the subject has become prominent during the past few years. Upon analysis, the majority of discussion has been confined to the producers of admixtures and producers of portland cements. The controversy has reached a ridiculous stage in some instances, and reflected no credit to either side. Further, technical magazines and societies have published the "pros and cons" without censorship.

Engineers and architects, who are the judges of admixtures on their individual projects, will be handicapped by the adoption of a specification of this nature. It is assumed that the general

*Consulting Engineer, Riverton Lime Co., Inc., Riverton, Va.

specification will be promoted, in one way or another, into the building codes of the various cities. Under these circumstances, the architect or engineer for private work, regardless of his desires, finds himself unable to specify an admixture, as his specifications must conform to local building code requirements. Paragraph 10, in question, requires more information about admixtures than we know about the cement and aggregates which appear to be accepted without question.

Without going further than to discuss this paragraph generally, it would appear to the writer that an amendment should be made to remove the present reference and substitute one along the following lines.

> Admixtures and Special Cements, unless specified, shall be used only upon approval of the Architect or Engineer in writing. The producer of any admixture or special cement shall have available, not only complete information regarding his product, but shall also have sufficient test data, from various acceptable sources, to indicate a consistent agreement between them with regard to the effect of the product upon the desired qualities of concrete.

It is well recognized that many of the tests regarding certain admixtures cannot be duplicated at will, and are the result of either poor testing routine, or are "freak" results so often encountered. For this reason, a reasonable agreement between laboratories would be desirable to give the user protection against the exploitation of favorable tests and the discarding of those of unfavorable nature. It would relieve the "salesman" objection, a point well taken by the author in his own criticism.

As stated before, it is desired to relieve this point rather than to attempt to discuss details in connection with the whole specification at this time. It is to the best interests of the Institute to further the use of a specification agreeable to all and at the same time protect the user and secure the most economical concrete.

The paragraph regarding admixtures and special cements is undoubtedly objectionable to a large number, and, on account of the relations between the architect or engineer and the local building inspection departments, is a serious handicap.

Unless the whole specification is considered seriously; accepted in a national sense, and not subjected to criticism during its promotion, it will reflect against rather than to the credit of the Institute.

BY C. E. ELLSWORTH*

Due to the public's confident acceptance of the Institute's work, the Institute has a most serious responsibility to the public.

If Article 10 of the "Construction Specification for Concrete Work on Ordinary Buildings" is permitted to stand, it will virtually exclude all admixtures from concrete made under this Specification.

Will it best serve the public interest to exclude *all* admixtures from concrete manufactured under this Specification?

Of late years engineers have appreciated more and more the fact that impermeability is of even more importance than strength and rigidity, in its effect on the permanence of concrete structures. In fact, never in the history of concrete construction has there been a time when the subject of water-tightness received as much thought and attention as it does at present. And the problem is not confined to such structures as dams, reservoirs, aqueducts, water-treating tanks and basins, where loss of water through percolation is involved, but includes roads, culverts, bridges, piers and abutments, retaining walls and revetments, tunnels, sewers, footings and foundations, basement and building walls, etc., as well.

Concrete surfaces exposed to the weather have a tendency to check and craze; this weathering action being due to alternate and unequal expansion and contraction of the surface concrete, under the influence of varying temperature and moisture content. Water enters the fine cracks thus formed; and in cold weather freezes, enlarges the cracks and causes incipient disintegration of the surface concrete. This cracking and disintegration progresses deeper and deeper into the concrete, permitting corrosion of the steel reinforcement, and reducing the effective sectional area of both steel and concrete.

Underground concrete surfaces are often exposed to acid and alkaline ground waters which are highly corrosive in their action. These waters are absorbed by the surface pores and are thus brought into close contact with a tremendous area of concrete surface; and, due to the large area affected, dissolution of chemical

*Chief Engineer, Construction Division, National Lime Association.

constituents of the cementing material takes place at a proportionate rate, resulting in a porous or cellular concrete structure. The reinforcing steel is also attacked and corroded; and, in the course of time, the underground, concrete structure becomes unfit for service, and expensive repairs or replacement becomes necessary.

It is evident that if concrete structures are to prove permanent and safe, they must be water-tight; and *the condition of many concrete structures today is conclusive evidence that plain concrete alone is not in itself sufficiently water-tight.* Thus the importance of an effective means for waterproofing concrete becomes obvious.

The writer's statements so far as fully confirmed by F. R. McMillan and Inge Lyse of the Portland Cement Association in the Introduction to their paper "Some Permeability Studies of Concrete:"[1] The paper referred to possesses unusual merit; and the co-authors deserve much commendation and respect for the accuracy and frankness which marks their work. The most significant conclusion reached by these two investigators is expressed by them as follows: "The tests have demonstrated what has been observed in concrete structures that defects in placing are a much more important factor in the leakage than ordinary differences in mixtures, materials, or water content." This statement is really an unqualified endorsement of a proper admixture; for it cannot be disputed that such an admixture improves the workability of concrete, and that improved workability operates to prevent defects in placing.

Granting that concrete must be quite workable when placed, if it is to prove sufficiently waterproof for permanence and safety, is then a proper admixture to be preferred to added cement as a means to obtain the required degree of workability? There are several good and sufficient reasons why such an admixture—hydrated lime for instance, is to be preferred:

(1) Lime putty is much more viscous, sticky and slippery than cement paste; hence not only is a lesser volume of the former required for a definite degree of workability, but also volume for volume lime costs only one-half as much as cement. The viscous, sticky lime putty is also more efficient in preventing the separation

[1] JOURNAL, A. C. I., December, 1929 (*A. C. I. Proc.*, Vol. 26, p. 101).

(unmixing) and segregation of the component materials of the concrete; thus guarding against the defects in placing which is the most important factor influencing leakage in the finished concrete. The slippery lime putty acts also as a lubricant coating the particles of the cement and aggregates, and makes them smooth and mobile and easy to chute and otherwise handle into the forms and around and between the reinforcing steel; thus the cost of handling and placing the concrete is reduced and, furthermore, exposed concrete surfaces require no patching or finishing.

(2) The extremely minute lime particles, as compared with cement particles, is another reason for increased impermeability where lime is used; for these minute particles of lime act to fill the void spaces between the cement particles as well as the sand particles, leaving only the most infinitesimal void spaces between the lime particles themselves for the possible passage of water. In addition, these extremely minute lime particles when saturated with water become colloidal or gelatinous (glue-like) in nature, and not only make the lime putty viscous and sticky but also act to seal the infinitesimal void spaces left between the lime particles themselves. The presence of these minute lime particles in the void spaces between the sand and cement particles also makes a stiffer and denser matrix which holds the coarse aggregate in suspension during transportation of the concrete from mixer to forms.

(3) Added cement means a richer concrete mix; and the richer the mix the greater the volume changes in the concrete due to variations in temperature and in moisture content. It has already been pointed out in this discussion, that volume change is responsible for cracking and disintegration of surface concrete; hence lime is to be preferred to added cement, much less lime being required and, also, a mixture of lime and cement being less sensible to temperature and moisture changes than straight cement.

(4) An admixture of lime increases both the strength and the toughness of all but the richest concrete mixes, while added cement increases the strength only.

Hydrated lime is probably the most efficient integral water-tightening medium available today for concrete. Test data accumulated over a period of more than 30 years support this con-

clusion. Portland cement was invented in 1825, but, prior to 1900, very little was used in the United States; hence it can be said that lime has been successfully used as an admixture in concrete from the time portland cement concrete was first recognized in this country. Results of authoritative and unbiased tests made during the 30 year period referred to above, and representing competent evidence of the value of lime as an admixture in concrete, follow:

It seems obvious that the exclusion of reputable and time-tested admixtures from any concrete specification will not serve best the interest of the American public and, that being the case, Paragraph 10 of the "Construction Specification for Concrete Work on Ordinary Buildings" should be amended at once to not only permit but even recommend the use of a reputable and time-tested admixture.

DATA

Tests by Sanford E. Thompson

The textbook "Concrete, Plain and Reinforced," by Taylor and Thompson, is well known to concrete engineers. Sanford E. Thompson, co-author of this book, was one of the earliest advocates of lime in concrete, and used it extensively in his own work. As early as 1903, he made a few permeability tests with hydrated lime as an admixture, and found it a valuable material for water-proofing. In 1906, he made another test which he reports as follows:

TEST FOR: Permeability.
CONCRETE MIX: 1:2:4.
CONCRETE THICKNESS: 4 inches.
WATER PRESSURE: 80 pounds per square inch.

*Hydrated Lime Per Cent	Flow of Water, Grams per Minute		
	14 Days	21 Days	28 Days
0	5.52	2.92	1.91
2	9.20	2.55	1.63
4	2.82	1.49	0.76

*In terms of weight of cement.

From these test data, Mr. Thompson decided that 5 per cent hydrated lime was the proper amount to use; such figures being outside the range of the test, but the minimum possible figure indicated thereby.

Later tests by Mr. Thompson lead him to the following conclusions, presented in a paper before the A. S. T. M. in June, 1908:

(1) Hydrated lime increases the water-tightness of concrete.
(2) Effective proportions of hydrated lime for water-tight concrete are as follows:
For one part Portland cement, two parts sand, four parts stone, add 8 per cent hydrated lime.
For one part Portland cement, 2½ parts sand, 4½ parts stone, add 12 per cent hydrated lime.
For one part portland cement, 3 parts sand, 5 parts stone, add 16 per cent hydrated lime.
These percentages are based on the weight of the dry hydrated lime to the weight of the dry portland cement.
(3) The cost of large waterproof concrete structures frequently may be reduced by employing leaner proportions of concrete with hydrated lime admixture, and small structures such as tanks, may be made water-tight.

These conclusions are based in part at least on the following:

TEST FOR: Permeability.
CONCRETE MIX: See Table.
WATER PRESSURE: 60 pounds per square inch.

*Lime Per Cent	Concrete Age Days	Test Period Hours	Flow of Water Grams per Hour
1:2:4 Concrete:			
1	40	4¼	74.8
4	41	5	28.4
7	42	6¼	5.2
10	46	18	1.6
1:2½:4½ Concrete:			
0	45	6	32.5
10	49	11	0
14	50	27	0
1:3:5 Concrete:			
0	50	14	70.6
8	51	17	3.6
14	50	13	0.7
20	53	15	0.7

*In terms of weignt of cement.

Tests by Prof. M. O. Withey

Permeability and strength test, with lime as an admixture, were conducted at the University of Wisconsin in 1920 under the direction of Prof. M. O. Withey. Two different concrete mixes were tested and the following conclusions were drawn from the results of the tests:

(1) Hydrated lime, when added to the cement increased the compressive strength of the concrete which had a slump of 4 inches, about 4 per cent for each per cent of lime added. For the concrete which had a slump of 9 inches, the strength was increased about 6½ per cent for each per cent of lime added.

(2) The 1:2.8:6.5 mix by volume was very pervious. The addition of 4 per cent of hydrated lime increased the imperviousness of the mix very materially. The addition of 8 per cent of hydrated lime produced practically the same effect as the addition of 4 per cent.

The test data for the richer mix show conclusively that the addition of a proper amount of hydrated lime improves both the strength and the water-tightness of even the richer concrete mixes; hence such test data are included herewith.

TEST FOR: Permeability and Strength.
CONCRETE MIX: 1:2.1:4.9.
WATER PRESSURES: 40 pounds per square inch.

*Lime Per Cent	†Water Per Cent	Unit Strength	Flow of Water, Gallons per Hour 0-50 Hrs.	20-50 Hrs.	40-50 Hrs.
0	6.66	2,030	.00023	.00015	.00011
2	6.83	2,235	.00017	.00009	.00006
4	6.80	2,678	.00019	.00012	.00011
6	6.73	2,855	.00017	.00011	.00010
8	6.86	2,470	.00015	.00007	.00007
10	6.87	3,035	.00017	.00012	.00012
0	7.40	1,266	.00030	.00021	.00018
2	7.37	1,884	.00036	.00023	.00023
4	7.30	1,585	.00026	.00016	.00017
6	7.40	1,664	.00022	.00013	.00012
8	7.40	1,893	.00022	.00012	.00010
10	7.43	2,225	.00025	.00016	.00013

*In terms of weight of cement.
†In terms of total weight of dry materials.

Further tests under the direction of Professor M. O. Withey at the University of Wisconsin were conducted in 1921; and the following conclusions were drawn from the results of this check series:

(1) The rate of flow of water into specimens was, in general, decreased by the addition of hydrated lime to the mix. The decrease was also generally greater for 10 per cent of lime than for 5 per cent.

(2) For the gravel concrete series of 4-inch slump the results do not indicate a great advantage in the use of hydrated lime. The set with 5 per cent of lime was somewhat more impervious than the plain concrete, and the set with 10 per cent of lime showed about the same flow as the concrete with no lime.

(3) The series of gravel concretes with a 9-inch slump shows that the addition of 5 per cent of lime slightly decreased the flow of water, and that 10 per cent of lime decreased it to less than half of the flow for plain concrete. As before, the results are variable for the plain concrete slightly more uniform for 5 per cent of lime, and quite uniform for 10 per cent lime. . . . Again the uniform results and decreased rate of flow indicate that hydrated lime increased the water-tightness of the concrete.

(4) The limestone series of specimens gives average results which indicate that the addition of 5 per cent of lime decreased the rate of flow to about one-tenth of the rate for plain concrete, and 10 per cent of lime causes some additional reduction:

(5) These results again show that hydrated lime decreased the permeability of concrete, but do not give any indication of the relative effect of the addition of 5 per cent and 10 per cent of lime. The great gain in water-tightness when 5 per cent of lime is added can be attributed mainly to gain in workability, and partly to the effect of the lime in filling the voids in the mix. . . . The first 5 per cent of lime made the mix workable, and dense cores were obtained. The addition of the next 5 per cent of lime could not be expected, in the case of this aggregate, to cause a corresponding gain in water-tightness.

The test data on the limestone concrete for the intervals 0-100 hours, 20-100 hours and 40-100 hours follow. The rapid leakage in the case of the plain concrete is due to separation and segregation of the component materials.

TEST FOR: Permeability and Strength.
CONCRETE MIX: 1:2.45:6.2.
WATER PRESSURE: 40 pounds per square inch.

*Lime Per Cent	†Water Per Cent	Unit Strength	Rate of Flow, Gallons per Hour 0-100 Hrs.	20-100 Hrs.	40-100 Hrs.
0	6.47	1,580	All specimens leaked rapidly		
5	6.58	1,828	.00201	.00176	.00179
10	6.65	1,912	.00153	.00134	.00234

*In terms of weight of cement.
†In terms of total weight of dry materials.

Tests by Prof. H. C. Berry.

Strength tests with hydrated lime as an admixture were conducted at the University of Pennsylvania in 1921 under the direction of Prof. H. C. Berry. Two different concrete mixes were included in the tests, and each mix tested at a wet and at a dry consistency corresponding to a flow of 190 and 165 respectively on the U. S. Bureau of Standards Flow Table. The data follow:

TEST FOR: Strength.
CONCRETE MIX: 1:2:4

*Lime Per Cent	†Per Cent Water Dry Mix	Wet Mix	Compressive Strength Dry Mix	Wet Mix
¾-inch Crushed Stone Aggregate:				
0	8.7	9.4	2,842	2,049
5	8.9	10.0	2,889	2,842
10	9.5	10.0	3,021	2,540
¾-inch Gravel Aggregate:				
0	7.8	8.9	2,673	2,016
5	8.5	8.9	2,338	2,338
10	8.9	9.3	2,340	2,340

*In terms of weight of cement.
†In terms of total weight of dry material exclusive of lime.

TEST FOR: Strength.
CONCRETE MIX: 1:2½:5.

*Lime Per Cent	†Per Cent Water Dry Mix	Wet Mix	Compressive Strength Dry Mix	Wet Mix
¾-inch Crushed Stone Aggregate:				
0	7.6	8.1	1,842	1,505
5	8.25	8.6	2,116	2,248
10	8.6	9.1	2,022	2,384
¾-inch Gravel Aggregate:				
0	7.5	8.3	1,957	1.631
5	8.3	8.35	1,865	1,716
10	8.2	8.3	1,822	1,914

*In terms of weight of cement.
†In terms of total weight of dry material exclusive of lime.

It should be noted that the "Dry Mix" concrete is much too dry for practical use in the field, and that the addition of lime increased the strength in every case for the "Wet Mix" i. e., a practical field mix. Thus, these results are in entire accord with the findings of Prof. M. O. Withey and Sanford E. Thompson. Many other tests can be cited, the results of which are in substantial agreement with those quoted; however, this discussion of lime as an admixture in concrete will close with the following report on Wacker Drive, a two-level street in the new Chicago Boulevard system.

Concrete in Wacker Drive is designed to withstand the severe exposure to the elements imposed by its location. Hence the specifications required an admixture of 8 pounds of hydrated lime per sack of cement in all exposed concrete. T. A. Evans, Engineer of Design, Bureau of Design, Chicago Board of Local Improvements, is the authority for the following tabulated figures and pertinent comments under date of September 25, 1925.

EFFECT OF HYDRATED LIME ON †WORKABILITY OF CONCRETE MIXTURES

*Lime Per Cent	Concrete Mix 1:1½:3	1:2:4	1:2½:5	1:3:6
0	44	108	169	242
5	33	103	167	202
10	31	81	125	185
15			129	171

*In terms of weight of cement.
†The lower the workability figure the more workable the concrete.

We have poured a portion of the viaduct structure without the use of hydrated lime and have found that the work of handling and tamping around the heavily reinforced portion of the concrete structure was greatly facilitated on the sections on which we have added lime to the mixture, so we are now using lime on the balance of the work.

A more comprehensive report by R. W. Priest, Field Testing Engineer, follows:

Hydrated Lime in Wacker Drive Concrete—(Synopsis)

A certain degree of skepticism is often expressed by engineers and contractors as to the real advantage to be gained by the use of an admixture in concrete. Questions as to the relative strength-deterioration, absorption, permeability, density and workability of concrete with and without an admixture often arise. As Field Testing Engineer for the City of Chicago on the Wacker Drive, the writer has had exceptional opportunity to study this question. The facts obtained by test on this job are believed to be conclusive.

Hydrated lime was used as an admixture in approximately 60 per cent of the 120,000 cubic yards of concrete in this project, the exception being that lime was not used in the concrete placed below ground, such as caissons, sub-girders and pavement foundations.

The concrete on this work was a nominal 1:2.33:3.67 mixture (1:6 specifications). The fineness modulus of the coarse aggregate and the sand were respectively 6.84 and 2.86. The total water allowance was 7 gallons per sack of cement and each batch of concrete was mixed 1½ minutes in a rotary batch mixer. From all concrete poured, 6-inch by 12-inch field cylinders were made at regular intervals and cured under three conditions so that the results express actual conditions in the concrete as placed.

These field specimens were tested for compressive strength at various ages up to one year and additional specimens were tested for absorption and permeability. The results of these tests are now available and it is possible to make a conclusive comparison between the concrete without admixture and concrete containing 8 pounds of hydrated lime per sack of cement.

A careful study has been made of the compressive strength of about 1,000 representative cylinders taken over a period of two years. These thousand cylinders are only about one-sixth of those taken on the job, but they represent identical mixtures and identical conditions, of curing and testing, which are necessary for a fair and conclusive comparison.

Number of Cylinders	Age at Test	Compressive Strength Average per Square Inch
Concrete without lime (1:6 Mix):		
250	7 days	1,632 lbs.
250	28 days	3,176 lbs.
10	1 year	4,362 lbs.
Concrete with 8 per cent lime (1:6 Mix):		
250	7 days	1,720 lbs.
250	28 days	3,214 lbs.
10	1 year	4,630 lbs.

Considering the large number of the tests made under identical conditions, it is conclusive that the addition of lime does not lessen the strength of concrete and, without reducing the water content as is possible with lime, the strength was slightly increased at all ages tested.

In a test to determine the effect of the addition of lime on the absorption of concrete, it was found that these cylinders containing the admixture absorbed an average of 3.23 per cent of water by weight during an immersion of 96 hours. The specimens without the lime gave an average absorption of 4.126 per cent with the same time of immersion.

The investigation also included penetration tests which were on disc specimens 8 inches in diameter and 2 inches thick, 28 days old at the time of test. Ten square inches of the face of these discs were subjected to a water pressure of 22 pounds per square inch for a period of 72 hours. The discs containing no admixture permitted the passage of 15 per cent more water than those containing hydrated lime.

In order to settle, to our own satisfaction, the question of the yield of concrete when an admixture is used, a series of tests were conducted which demonstrated that the use of 8 per cent of lime did not give an increase, but rather resulted in a slightly less volume of concrete than when it was omitted. The writer believes that this work proves that concrete containing lime is more dense than without it.

In conclusion it was observed on the work at Wacker Drive that concrete containing lime was more plastic and workable, and was more easily handled with less chance of segregation of aggregates. To a contractor these features are money savers.

From the Engineers' standpoint it was observed that with lime, less water was needed to make a workable mixture. The tests showed increased strength, decreased absorption and decreased penetration; all of which follow logically the demonstrated greater density of lime concrete.—R. W. PRIEST, Field Testing Engineer, Wacker Drive; Board of Local Improvments; Bureau of Design, Chicago.

AUTHOR'S CLOSURE*

MR. BROWN'S discussion† was not received by me prior to the convention and was not discussed there. I am aware of the apparent hardship that disheartens him. But I still think that the Contractor, as the most experienced person connected with the detailed operations of construction work, should continue to provide "all usual necessary and essential portions" of the work even though not shown or specified completely. If he is in doubt in making up his estimate—the only complete list of every item required—as to whether lintels are stone, terra cotta or concrete, he should find out. On the ordinary building that is not a difficult thing to do and the Contractor is in far better

*By ARTHUR R. LORD, Lord & Holinger, Chicago.
†H. M. Brown, JOURNAL, March 1930. (*A. C. I. Proc.* Vol. 26, p. 580),

position than any one else to do this necessary safeguarding work.

The second paragraph in Article 11 deals with "gaps" in the reinforcement—small unreinforced areas such as may occur on any job either by oversight of the detailer or by careless steel placing. It has nothing to do with the spacing of bars in the regular bands or systems, but is concerned only with "gaps" where the regular systematic groupings of bars leave an unreinforced opening. If this opening were large, or if there were many of them, I assume that the Contractor would call in the Engineer to complete his design and that he would be paid for any considerable amount of additional steel required. But for the small unreinforced triangle or space indicated by the word "gap," no such elaborate or time consuming action is desirable—simply put in $\frac{3}{8}$ in. at 6 in. o. c. and pass on. This is the simplest and easiest way to cover such minor openings and the amount of steel consumed is negligible in my experience. This provision was added by a highly experienced critic.

Placing concrete under water is quite common in buildings involving cylindrical piers or "caissons" of concrete, which is a common type of foundation in our larger cities today. I have never seen bottom dump buckets used in such work but this device was nevertheless inserted in the specification before its adoption as a tentative standard by the Institute. So anyone may use this method who wishes to when operating under this specification.

One function of a specification of this sort is to protect owners from "extras" in cases where a reasonable contact of the bidder with the Architect or Engineer would eliminate uncertainties. I assume, and the lack of any considerable amount of unfavorable criticism of this specification appears to support the assumption, that Contractors want to stay on good terms with their clients and wish to cover in their bids all required work in their line, rather than to catch the Owner unawares with extra charges for a lot of petty items. These specifications follow the time-honored method of accomplishing this end—it makes the contractor financially interested in eliminating uncertainties before entering into contract.

Whenever it has seemed possible and proper I have, with the consent of the critic members of the committee, made the appropriate changes in the wording of this specification, as suggested by the discussion received. Many changes were submitted to the convention in 1930 and incorporated in the specification as tentatively adopted by the Institute. The recent discussion, received since the convention, has centered around article 10. With no thought of malice, I submit that the authors of this discussion have not read this article. Doubtless they meant to read it, but their discussion reveals that they did not read it soberly and with the wish to understand. It does not seem to me to be obscure. Article 10 does not prohibit the use of admixtures. On the contrary, it specifically provides for the use of such admixtures as come with a satisfactory record of use, or even those that can win the approval of the architect or engineer—a none too difficult feat surely. It does, by its negative form of statement, act to restrain the contractor from rushing into the arms of the first plausible admixture salesperson that he chances to meet.

There are today upward of 250 materials, or rather packaged products, the producers of which would like to have incorporated in concrete. It is a natural wish. So much concrete is used that even a small amount in every yard of concrete would make a nice business total. Some of these "admixtures" have been extensively used, others hardly used at all. Some of them are doubtless desirable additions to concrete for certain uses, common uses, as workability agents or waterproofers. Some of them are pure gambles. Article 10 requires evidence that admixtures used on work done under Specification 502 have a history as well as a sales agent. It is designed to protect the manufacturer of a worth-while admixture from unworthy competition. Evidently lime, one of the longest-used of this general class of material, does not wish protection. But the owner is entitled to protection in his specification, even if the manufacturer scorns it. I believe that Article 10 should stand, both for admixtures (including waterproofing compounds) and for the new special cements.

Mr. Ellsworth's leading witness in favor of lime is a job on which I personally approved its use, for the conditions holding on

that job. I rejected in the neighborhood of fifty other admixtures that were pushed for use on the same job, most of them depending chiefly on political backing rather than on the kind of evidence required by Article 10. If Mr. Ellsworth and Mr. Hutchinson will cool off long enough to read Article 10 quietly, I believe that they will agree that it is a common sense provision in a field where there are so many products of so diverse merits. It seems to me also that they might agree that even lime isn't the best admixture to use for all concrete, and that some concrete does not require any help from admixtures. Lime isn't altogether indicated for the concrete of a dam intended to impound lime-thirsty mountain water. Article 10 puts the decision on the architect or engineer where it properly rests. If this article results in worth-while materials being advanced on their scientific merits and proven results, instead of on the fallacious theory that concrete is a fair dumping ground for any material that does not stop the mixer, it will be worth a few misunderstandings such as these, much as I regret them.

Discussion of the Report of Committee 802

"Good Practice in Concrete Floor Finish"*

BY ROBERT SETH LINDSTROM†

The writer wishes to submit further discussion, so that when and if a specification is formally prepared and submitted to the Institute for adoption, all of the kinks will have been ironed out and a floor finish specification presented that will be accepted by the architect-engineer and building construction industry for universal use.

Portland cement is the tie that binds the ingredients entering into portland cement concrete, solidifying the structural mass to a point where concrete has been generally accepted in reinforced concrete construction. In wearing surfaces of portland cement concrete subjected to traffic as in floors, ramps, and stairs, there must also be a compact, homogeneous finish.

To obtain the densest possible concrete for floor finish the mix, sizes, shape, and quality of the aggregates must be considered more carefully than aggregates for structural concrete due to the experience that if the aggregate is not properly and uniformly graded from coarse to fine, voids will occur and the density of the floor topping be impaired.

Nothing has done more harm in lessening the use of concrete floors than the method called "Dusted-on Finish."

In a dusted-on finish all the rules and regulations of good practice are violated and the water-cement ratio lost sight of.

We have all learned by our field experiences that the proper amounts of water, cement and graded aggregate must have such a period in a mixer as will thoroughly mix water, cement and sand so that when leaving the mixer the mass will not segregate in handling or placing. Additional cement, sand or other ingredients thrown or dusted on in a dry state cannot cover the

*Journal, A. C. I., March, 1930; *A. C. I. Proc.*, Vol. 26, p. 520.
†General Manager, Advance Waterproof Cement Co., Chicago, Ill.

surface uniformly nor will there be sufficient water properly to take up the cement for a uniform, plastic condition like the material that has passed through the mixer.

Since standard portland cement must pass a certain percentage through a 200 mesh sieve it is necessary to use a fine aggregate grading, beginning nearer the fineness of the cement and gradually increasing the size to an ideal sand grading, meeting with Fuller's formula for ideal sand grading. This formula produces a grading as follows:

4	Mesh to the inch passing	100%
8	" " " " "	75%
14	" " " " "	50%
28	" " " " "	25%
48	" " " " "	15%
100	" " " " "	0

Such fine-to-coarse aggregate with portland cement and water, machine mixed for fully two minutes, properly laid and troweled will give a 100% non-dusting portland cement floor topping and any excess of cement and sand dusted on will change the entire mix and create a dusty, non-uniform mixture that will add to the cost of the work.

Field practice and years of tests have shown conclusively that the old 1:2 mix, taking into consideration amount of water and portland cement, together with size and grading of aggregate, should be standardized and offered to the committee that will formally and finally draft floor finish specifications.

Construction of Main Canal Lining on Kittitas Division, Yakima Reclamation Project, Washington

BY ARTHUR RUETTGERS AND A. A. WHITMORE*

Construction work performed on the Kittitas Division of the Yakima Reclamation Project during the seasons of 1927 and 1928 included the placing, by contract, of about 55,000 cu. yds. of concrete in canal and tunnel lining, combination lining and flume sections, inverted siphons, culverts, turnouts, bridges, and miscellaneous canal structures. The greater portion of the concrete, about 52 per cent, was placed in 3-in. reinforced canal lining. A description of this work, which involved the successful development and use of some novel construction equipment and the application of the more modern methods for scientifically controlling the concreting operations, forms the main substance of this paper.

LOCATION, PURPOSE, AND GENERAL DESCRIPTION OF WORK

The Kittitas division of the Yakima project will, upon completion, provide facilities for the irrigation of about 72,000 acres of land in the higher reaches of the bowl-shaped Kittitas Valley, surrounding privately-irrigated bottom land centered at Ellensburg, Washington. The irrigation plan contemplates the diversion of 1,320 second feet of water from the Yakima River at the Easton dam, about 40 miles northwest of Ellensburg. The Main Canal, now completed, traverses the southern slope of the Yakima River Canyon for 26 miles to its entrance into the Kittitas Valley, where the canal divides—the north or larger branch (of 925 second feet capacity) crossing the river and skirting the

northern and eastern rims of the valley, and the south branch (of 250 second feet capacity) following along the southern rim.

Stretches of the Main Canal, aggregating about half its entire length, were lined with 3-in. reinforced concrete to prevent excessive seepage losses in sand and gravel formations, to reduce the construction cost through heavy cuts, or to serve as a safeguard against expensive washouts on steep side-hill locations. Construction of the lined canal was performed under five separate

contracts by four different contractors. A typical section of the canal is shown in Fig. 1.

WORK PRELIMINARY TO CONCRETING

Excavation. All rough excavation of the canal section was performed by draglines equipped with buckets of 1 to 2½ cu. yds. capacity. (Fig. 2). Smaller draglines, usually equipped with clam-shell buckets, were used to dispose of excess material removed in the trimming operations. (Fig. 3).

Trimming. The final trimming was generally done with the aid of a traveling template (Figs. 4 and 5), mounted on rollers, and consisting of two wooden trapezoidal-shaped frames so constructed and placed with respect to the canal center line and grade that a straight-edge moved along between the frames indicated the proper subgrade for the side slopes and canal bottom. The roller track was made of 3-in. by 6-in. plank

firmly embedded in the canal bottom, adjacent to the toe of each side slope. (Fig. 9). Removal of the high spots in the canal section and backfilling of the cavities were performed by hand methods. Cavities deeper than 6 in. were backfilled by placing moist material in thin horizontal layers and compacting with standard iron tampers, otherwise the compacting was done with flat steel shovels. Where the material was excessively sandy a thin layer was removed and replaced with clay to prevent ravelling of the surface. Further efforts to prevent ravelling of finished surface consisted in keeping the subgrade moist by sprinkling until the concrete was finally deposited. (Fig. 6).

The traveling template was also utilized in providing narrow berms at the tops of the side slopes. A ribbon of plank, placed on these berms, served as a second track for the operation of a movable scaffold from which the reinforcing steel on the side slopes was tied (Fig. 6) and subsequently to guide and support the concrete distributing platform and lining machines.

Drainage. Inasmuch as a 3-in. concrete lining in a canal section of the dimensions used offers little resistance to external pressure when the canal is empty, and as the region traversed is subject to a mean annual precipitation of some 20 ins., with the major portion occurring during the non-irrigation season, particular care was taken to provide adequate drainage for the lining. Longitudinal drains of 4-in. to 12-in. vitrified or concrete pipe, embedded in gravel, (Fig. 7) were laid beneath the floor of the lining in one or two lines, depending on the topography and ground water conditions encountered in excavating. Where the conditions appeared to require it, feeder or "finger" drains of gravel or tile, at right angles to and connecting with the longitudinal drains, were placed in the upper side slope of the lining. The importance of these finger drains, particularly at draws, was emphasized during the progress of the work by the failure of several panels on the upper slope through the action of hydrostatic pressure back of the lining. (Fig. 8). The early practice was to place the longitudinal drains along the center line of the canal but this was abandoned in favor of locating the drains near the toe of the upper slope, the latter location offering more

direct connection with finger drains and better prospects for effective drainage in general. (Fig. 9). The longitudinal drains sloped in both directions to lateral or outlet drains, spaced 300 to 1,000 ft. or more apart and consisting of 6-in. to 12-in. pipe, with cemented joints, placed through or under the lower canal bank. (Fig. 10).

CONCRETING OPERATIONS

Requirements. The matter of devising the most suitable means for handling the concreting operations was not a simple one, as the character of the work and related specifications

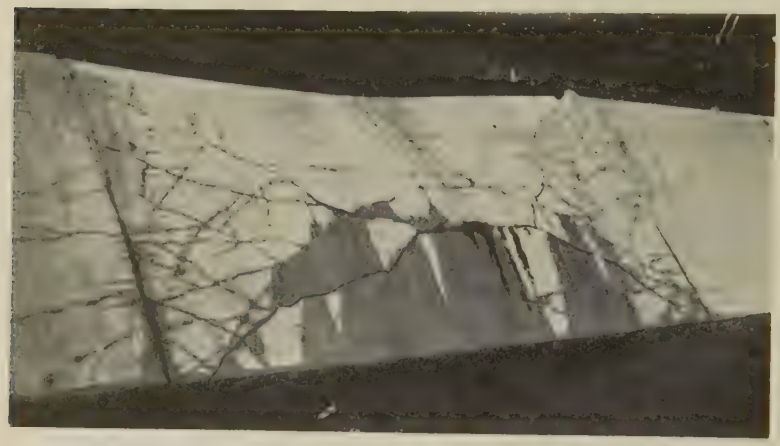

FIG. 8—BREAK IN CANAL LINING CAUSED BY DEVELOPMENT OF HYDROSTATIC HEAD BEHIND THE LINING. STATION 90, MAIN CANAL

FIG. 9—GRAVEL "FINGER" OR SIDE SLOPE FEEDER DRAINS. (NOTE THE LONGITUDINAL DRAIN PLACED NEAR UPPER SIDE OF CANAL BASE.) ALSO NOTE RIBBONS AT THE TOP OF SIDE SLOPES AND ON BOTTOM OF CANAL ON WHICH THE CONCRETE LINING PLATFORM RUNS. LOOKING UPSTREAM FROM STATION 1224—MAIN CANAL

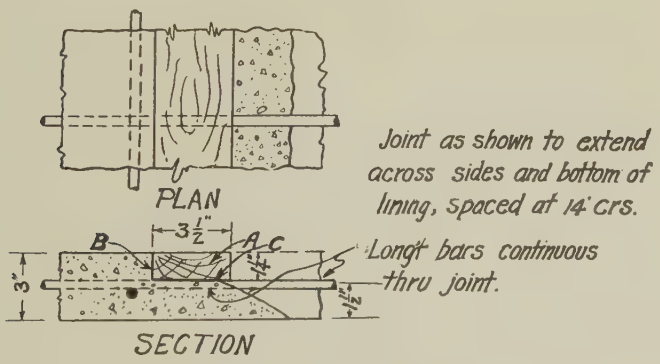

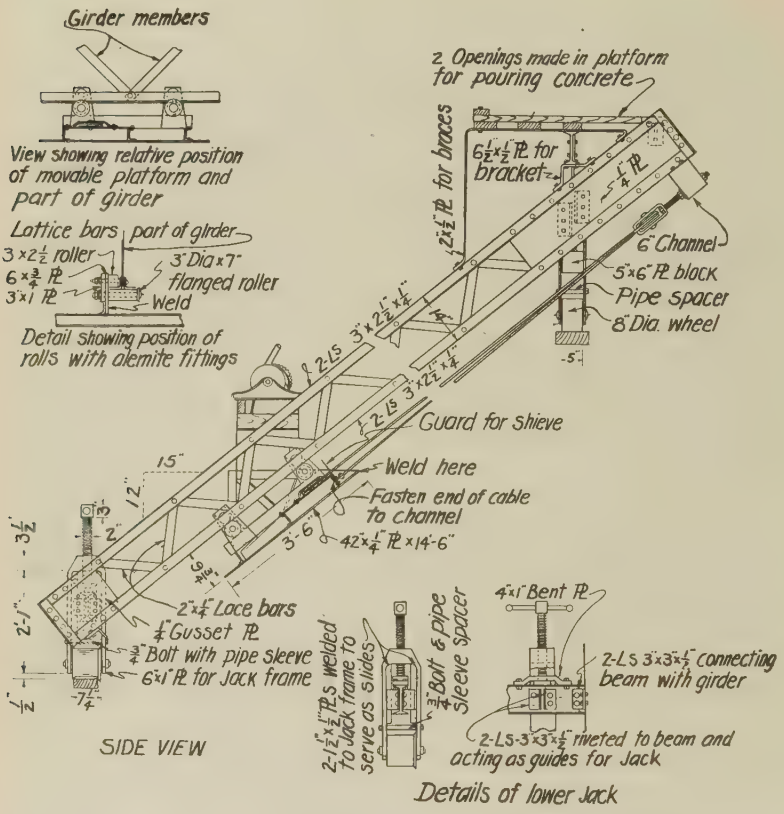

FIG. 11—DETAIL OF JOINT

required that account be taken of a variety of conditions, some of the principal ones being as follows:

(a) The size of the lined section, steepness of side slopes, small thickness of concrete, and difficulty of centering the reinforcing steel in the thin concrete slabs were not favorable for the adoption of the customary method of hand placement of the concrete.

(b) The top of the lower bank (of 14 ft. minimum width), which as a rule furnished the only means of direct access to the work, provided only a limited space for the storage of materials and the accommodation of operating equipment and crews.

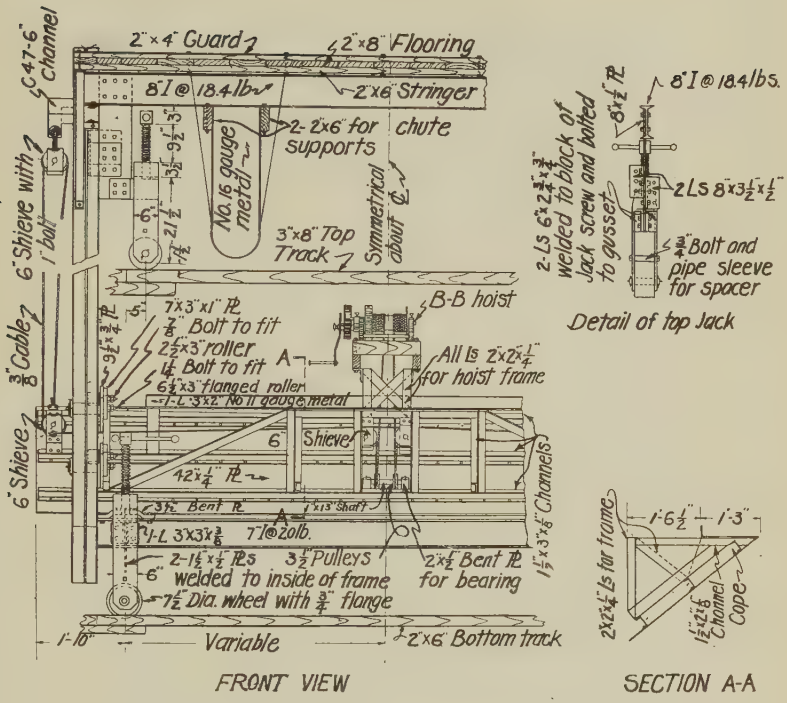

FIG. 12—MOVABLE FORM FOR PLACING CONCRETE LINING

(c) The distance over which the work was spread, and the necessity for completion within the allotted time, demanded mobility of all operating equipment. Simultaneous prosecution of concreting operations in several locations involved duplication of equipment and organization.

(d) The specifications required that the lining be placed monolithically in short panel sections and given a steel trowel finish. A special transverse joint (Fig. 11) later abandoned and replaced by a plain butt joint as hereinafter discussed was required at panel ends. Longitudinal joints (parallel to the axis of the canal) were not permitted.

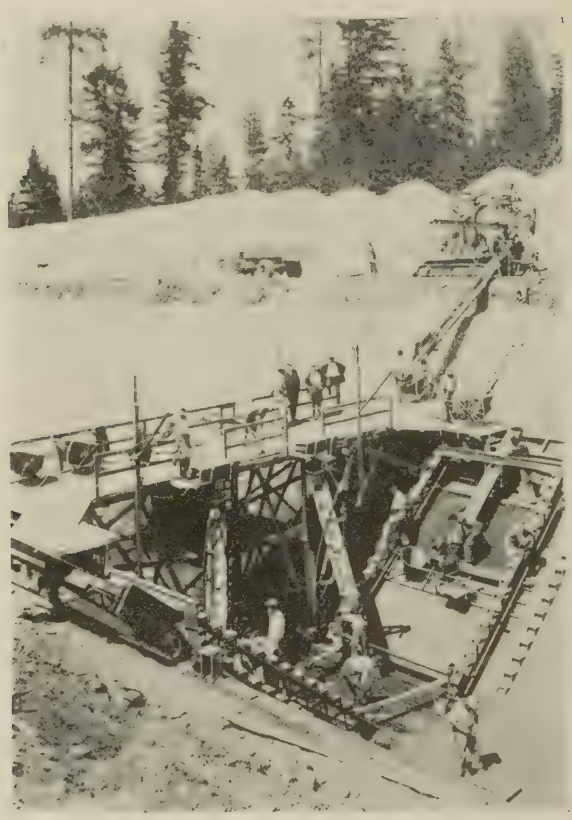

FIG. 13—ORIGINAL LINING MACHINE AND CONCRETE DISTRIBUTING PLATFORM DEVELOPED BY GENERAL CONSTRUCTION CO., CONTRACTOR FOR DIVISIONS 1 AND 2 MAIN CANAL. NOTE TRUCK ABOUT TO BACK UP AND DISCHARGE CEMENT AND AGGREGATES INTO HOPPER OF THE CATERPILLAR TRACTION PAVING MIXER. EACH TRUCK HANDLED 3 BATCHES OF DRY MATERIALS

(e) Neighboring creeks and the Yakima River furnished the only adequate and reliable sources of water.

(f) The bid prices were such that efficiency of operation and exercise of the strictest economy were essential for the realization of a profit.

The extent to which the first contractor succeeded in adapting his concreting operations to the particular requirements of the job, in lining approximately 2½ miles of Main Canal in 1927, is evidenced by the fact that all three of the other contractors who engaged in lining operations in 1928 employed methods and equipment embodying the same general principles, insofar as the handling and placing of concrete is concerned, as those which characterised the 1927 work.

Steel plate lining machine. Of particular interest is the novel machine designed and perfected by the forces of the General Construction Co. for lining the side slopes. (Fig. 12). It consists of a movable steel plate 14 ft. 6 in. long (the customary panel length being 14 ft.) and 3 ft. 6 in. wide, supported by and operating under two parallel fabricated steel girders with roller ends. (Figs. 13 and 14). An operating platform about 18 in. wide attached to the upper edge of the steel plate received the concrete and accommodated several workmen, in addition to carrying the winch by means of which the plate was made to travel upward along the canal slope and compact the concrete as it was spaded into the space back of the upper portion of the plate. A screw jack at each roller for raising or lowering the girders permitted adjustment of the plate to the required slope angle and thickness of concrete. The simultaneous use of two of these machines, one on each side slope, not only fulfilled the requirement for monolithic construction of panel units (the floor section being placed by hand immediately following completion of the slope sections) but also introduced an element of competition between the individual working crews which had a noticeable effect in speeding up the work.

Transporting and placing concrete. Wheel buggies were generally used to transport the concrete from the mixer, on the lower bank, to the canal section, where each batch was directed to its desired position on the side slope or bottom with the aid of a distributing platform mounted on rollers and equipped with a series of flexible chutes or spouts. The ribbons of plank track in the canal bottom and at the top of the lined slopes also served as screeds and, in the latter case, as outside forms for the 5-in. concrete berms.

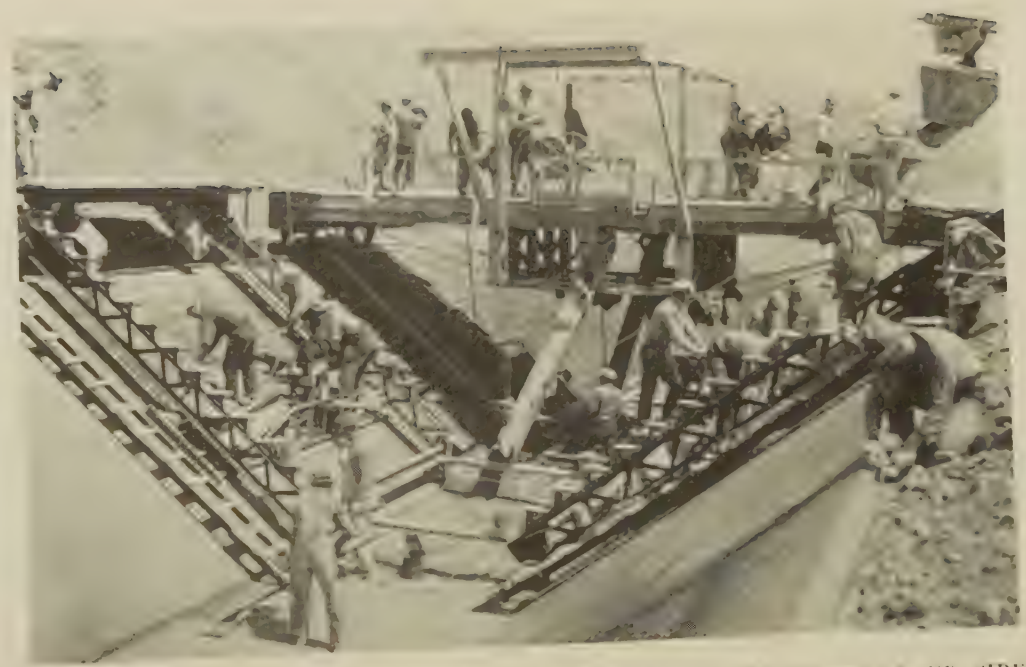

FIG. 14—LINING MACHINE SHOWING MOVABLE STEEL PLATE TRAVELING UP SIDE SLOPE. LINING IN PRECEDING PANEL BEING FINISHED AND CONCRETE BEING PLACED IN LOWER 31_2 FEET OF SIDE SLOPES FOR SUCCEEDING PANEL. NOTCHED SCREED BOARD ON SIDE SLOPE UNDER "JUMBO"

About 10 complete panel units (equivalent to 140 linear feet of lining) constituted the average pour for one working shift of 8 hours, the record for a shift being 14 panels or 196 ft. of lined canal. The reinforcing steel was kept above the subgrade by inserting small pre-cast cement mortar blocks underneath the bars at various points as conditions required. Experience proved that the most practicable procedure for pouring the lower 3½ feet of slope lining was to shovel the concrete directly on to the slope (Fig. 14) and, after striking it off roughly, to lower the steel plate to position and rap it with a bar in order to bring the fine material into contact with the plate. Upon completion of this operation, the plate was started on its upward course, its movement keeping pace with the addition of concrete from the platform by the spaders. The action of the moving steel plate, with proper spading, correct concrete consistency and other related factors under control, resulted in a true surface and a reasonably good finish. The finish was perfected by going over the entire surface lightly with a long-handled steel trowel. Any defects appearing on the surface, due to insufficient mortar or spading, were remedied by adding the amount of concrete or mortar needed and trowelling over. Mortar was also used to provide fillets at the intersections of the floor and side slopes. The floor, as previously indicated, was placed by the usual hand methods, one of the last operations being to remove the plank track or screeds and fill in the grooves with tamped concrete after thoroughly cleaning the grooves (Fig. 14).

Other types of lining machines. Photographs reproduced in Figs. 15 and 16 show types of lining apparatus in which the general principles of the movable plate lining machine and distributing platform were combined in a single unit. These forms of apparatus involved a smaller plant investment and were devised by two of the contractors whose lining operations were less extensive. As seen from the pictures, the movable steel plate in the original slope lining machine was replaced by a metal-lined plank strike-off board, with operating platform, which, instead of being rigidly held down at its ends, simply

FIG. 15—COMBINED DISTRIBUTING PLATFORM AND MOVABLE STRIKE-OFF BOARD TYPE OF APPARATUS EMPLOYED BY C. F. GRAFF, CONTRACTOR FOR CONSTRUCTION OF EASTON DAM AND UPPER HALF-MILE OF KITTITAS MAIN CANAL

rode on two plank screeds spaced a panel-length apart and under the distributing platform, or "jumbo," as it was called.

In comparison with the steel plate lining machine, the spading board was less effective in compacting the concrete and drawing mortar for finishing to the surface, consequently more hand-finishing and a greater use of mortar was required. This feature of the spading board type of apparatus, coupled with its lack of headroom, greater dependence on a definite consistency of concrete for satisfactory operation, and other characteristic features tended to reduce the speed of concrete placement below that obtained by the use of the more expensive type of equipment, although it is believed that the quality of the lining secured was considerably better, and the cost to the contractor less, than would have resulted under the ordinary methods of hand placement.

Concrete materials. The materials entering into the lining construction, including sand and gravel shipped from Puget

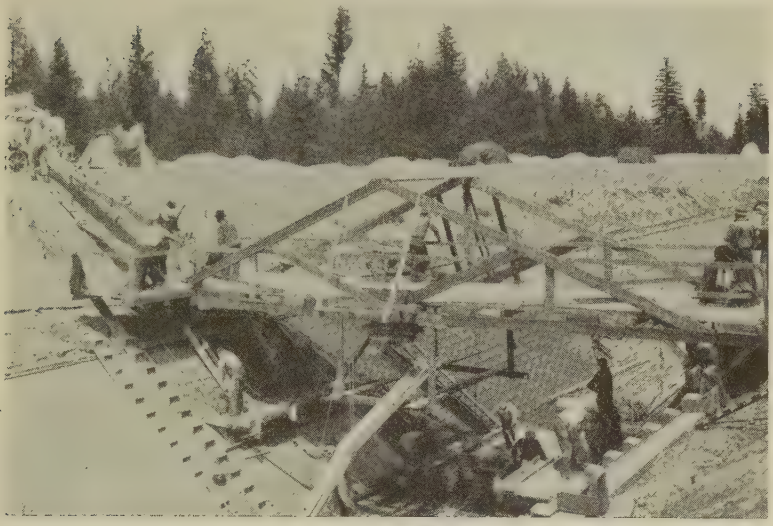

FIG. 16—COMBINED DISTRIBUTING PLATFORM AND MOVABLE STRIKE-OFF BOARD EMPLOYED BY S. H. NEWELL & CO., CONTRACTOR FOR CONSTRUCTION OF DIVISION 2 (SCHEDULE 2), MAIN CANAL. CONTRACTOR STOCK PILED THE CEMENT AND AGGREGATES ON THE CANAL OPERATING ROAD

Sound, cement, diatomaceous earth admixture, reinforcing steel, and drainpipe were received by the contractors at the most convenient railroad points and hauled by them in motor trucks to the work. As a rule, the aggregates were dumped into stock piles, from elevated spur tracks provided by the contractors at the railroad delivery points, and loaded into trucks by mechanical loaders, or elevated to storage bins of central proportioning or mixing plants.

Concrete mixing. Concrete for the first half-mile of lining on the Main Canal was mixed at a stationary mixing plant (constructed primarily for the production of concrete for the Easton diversion dam) and hauled to the scene of lining operations in narrow-gage cars drawn by dinkey locomotives. With this one exception, all concrete placed in Main Canal lining was mixed in portable mixers which traveled the canal bank along with the concrete placing equipment. Modern paving mixers with cater-

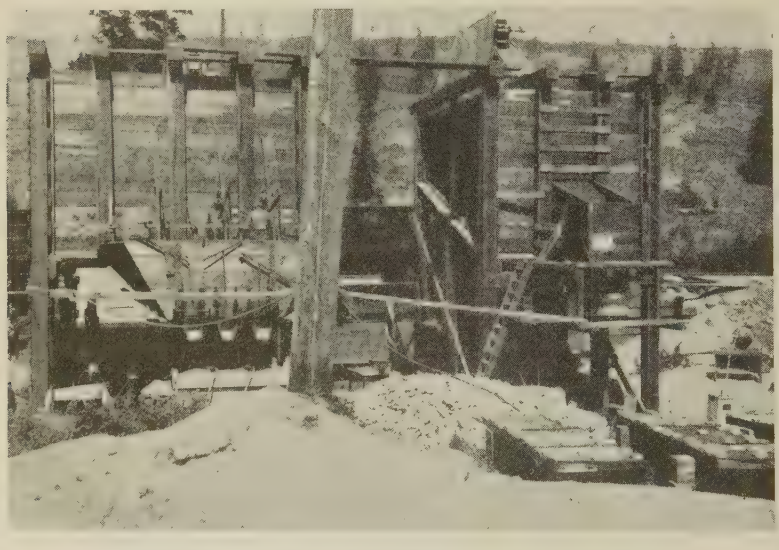

FIG. 17—DERBON CONSTRUCTION COMPANY'S SAND AND GRAVEL BUNKERS AT DERBON'S SPUR ON THE CHICAGO, MILWAUKEE, ST. PAUL & PACIFIC RAILROAD ABOUT 1½ MILES WEST OF HORLICK

pillar traction were employed on some of the more recent work. (Fig. 13).

On two of the contracts the mixer was fed from stock piles of materials on the top of the bank, supplemented, where necessary, by direct motor truck deliveries from the main sources of material supply. On the remaining two contracts, the contractors established central proportioning plants at the railroad delivery points (Fig. 17) where the requisite aggregates, cement and admixture for a mixer batch were measured out and loaded into trucks with bodies specially constructed to handle three batches of the dry materials and, upon arrival at the mixer, to unload the batches separately into the charging hopper.

Water problems. The necessity for almost constant sprinkling of the subgrade from the time of final trimming until the concrete was laid, the use of water for mixing concrete and supplying camp needs, and the specification requirement for keeping the freshly placed concrete continuously damp for a minimum period

of 14 days created a heavy and steady demand for water. This demand was met, on four of the contracts, by piping from neighboring creeks or the Yakima river, usually with the aid of pumps, and, on certain sections of the work, by diverting the creek flow into completed portions of the lined canal and impounding it behind a small earth dike in the canal section. On the fifth and largest contract, an adequate creek flow was not available, and water for all purposes except curing was obtained by pumping from the Yakima river, through approximately 600 linear feet of 3-in. pipe and against a head of about 350 ft. to an elevated storage tank adjacent to the canal, whence it was pumped through smaller pipe of varying lengths to the particular locations required.

FIG. 18—CURING CANAL LINING BY WATER METHOD, USING BABB SPRINKLERS. BURLAP COVERING THE GREEN CONCRETE IS SHOWN IN THE BACKGROUND. STATION 103, MAIN CANAL

Concrete curing. Curing of the concrete by the water method was effectively accomplished by the use of Babb sprinklers (Fig. 18) at short intervals along two lines of pipe paralleling the canal center line—one on each side slope. Operation of the sprinklers was continuous for 14 days after the date of pouring, except for short night periods in certain instances. The lining was completely covered with a layer of burlap during the first seven days of curing, which served principally to protect the green concrete

FIG. 19—COMPLETED CANAL LINING. CURED BY HUNT PROCESS PAINT METHOD. PAINT IS SPRAYED ON IMMEDIATELY FOLLOWING THE FINISHING OPERATIONS

from the direct rays of the sun and distribute the applied moisture more uniformly.

A substitute for the water sprinkling method was employed in curing the lining in the last 6 miles of the Main Canal. The method used (Hunt Process), which was based on the principle of conserving the original mixing water for cement hydration, consisted in coating the exposed surfaces of the fresh concrete with a special asphaltic compound. The material was applied with a spraying machine (Fig. 19), immediately following the finishing operation.

Panel joints. Considerable trouble was experienced, during the earlier lining operations, in obtaining a satisfactory transverse construction joint between adjacent panel units. Details of the type of joint originally contemplated, and employed on other projects for lining of 4-in. or greater thickness, are shown in Fig. 11. The theory of the joint is that when the plank form A is removed from the partially hardened concrete (shown in

section) and fresh concrete is added, a good bond should develop with the irregular shaped tongue C, but the formed vertical surface B should bond very imperfectly and act as a plane of weakness to induce a crack. This result was not realized in practice, the cracks frequently taking a zig-zag course within the limits of the tongue, or a fairly regular path along a plane other than the one intended. The small thickness of the lining, the difficulty of obtaining the vertical surface and holding it after removal of the plank, and the apparent impracticability of securing a substantial tongue of concrete, are some of the reasons attributed for failure to produce a satisfactory joint of the type described. Various attempts were made to improve the joint. One was to leave the plank in place until the second pouring was completed and then fill in the groove, but this resulted in the formation of cracks along both edges. The best results were in using end plank or screeds of the full lining thickness and notched to accommodate the interfering longitudinal reinforcing bars (Fig. 15), thus eliminating the troublesome tongue of concrete and producing a plain butt joint. With the introduction of the butt type of joint, the top surface of the concrete at the joint was penetrated to a depth of about ¾-in., with a special tool similar to a sidewalk jointer, while the concrete was plastic, and the operation repeated after the concrete had stiffened. Cutting the joint was early discontinued, upon discovering that it was not required to insure the development of the crack at the joint. Use of the cutting tool, however, produced an excellent joint in that rounded shoulders were formed each side of the joint which do not spall under slight movement of lining resulting from temperature changes.

Transverse cracks. The lined section and construction joint were designed with the view of controlling the inevitable development of transverse cracks by inducing their occurrence at short regular intervals and along straight sightly lines. That this control was not fully realized with the perfection of the construction joint was evidenced by the appearance of additional intermediate transverse cracks within several days to six weeks after the concrete was placed. A survey of side-slope cracks along selected stretches of completed lining showed that the number of

intermediate cracks averaged 0.8 per 14-ft. panel for the water-cured lining and 1.3 for that cured with the asphalt coating. In other words, taking account of the regular construction joint cracks, the transverse cracks occurred at average intervals of 8 ft. and 6 ft. for the water-cured and asphalt-treated lining respectively—indicating that the amount of longitudinal reinforcing steel used might have been in excess of that required to restrict the contraction cracks to the 14-ft. spacing, under the particular conditions prevailing. Three principal reasons advanced for the increased number of intermediate cracks in the asphalt-treated lining (which increase was more marked on the north or sunny slope) are (1) the apparent greater surface drying through evaporation, (2) the more rapid setting-up of the concrete, permitting less adjustment between the concrete and reinforcing steel during the setting period, and (3) the probable greater daily range of temperature variations in the concrete, due to the black color of the surface coating.

Another significant feature revealed by the survey was that the first panel placed each day exhibited a tendency to develop from 1½ to 3 times as many intermediate cracks as the panels placed subsequently. Evidence obtained from an investigation of the possible causes of this phenomenon indicated quite conclusively that the restrained condition of the longitudinal steel in the first panel, by virtue of its embedment in the hardened concrete of the previous day's pour, was chiefly responsible for the excessive cracking tendency—the theory being that the rigid steel immediately adjacent to the hardened concrete offered greater opposition to the contraction forces in the new concrete, and consequently forced cracks at closer intervals.

CONCRETE MIXES, TESTS, AND CONTROL METHODS

Need for control. The liberal appropriations available and in prospect at the time construction of the canal and distribution systems of the Kittitas division was inaugurated offered favorable prospects for the prosecution of work on a rather large scale. It was early recognized that the production of uniform concrete of the best quality for the money was dependent upon a wise choice of aggregates and the development of a carefully prepared plan of procedure for concrete design, inspection and control.

The vital importance of securing quality concrete, as well as the justification for a reasonable amount of investigational and directional work leading to this end, became manifest when it was realized that estimated expenditures for the production of concrete for canal lining and structures represented approximately 50 per cent of the total proposed construction investment of $9,000,000.

Investigation of aggregates and concrete mix. Attention was first directed to the selection of suitable aggregates. This involved the preliminary testing, by the Bureau of Standards, of numerous samples of materials taken from local deposits, followed by an exhaustive test of further samples from the one local deposit which promised to be satisfactory. The latter test was conducted at a laboratory which had been established at the project office at Ellensburg and equipped to make the customary physical analyses, mortar briquette tests, and the 6 x 12-in. standard cylinder compression tests. Additional apparatus was subsequently installed for making impermeability tests of concrete discs 12 in. in diameter and 4 in. thick under water pressure. Before completion of the tests the aggregates exhibited some questionable characteristics and decision was finally reached to use a high quality sand and gravel from the Puget Sound region.

The specific aggregates for use having been selected, an extensive series of laboratory tests was carried on to determine the gradings and maximum sizes of aggregates best suited to meeting the various concrete requirements, to develop water-cement ratio strength control curves for the range of mixes contemplated, to establish the water-pressure-resisting properties of the different mixes, and to acquire other information of value such as the relation between strength, density of concrete, and density of dry mixed aggregates for various gravel to sand ratios, the effects of varying periods and kinds of curing, the resistance of concrete to weathering, and last but not least, the economic relationships. Standard specifications were followed in all laboratory procedure, except where such specifications were not available, as in the case of the impermeability tests. In practically all cases the laboratory test specimens were made with 2-in. and 6-in. slump concrete, this being the range of consistencies permitted by the construc-

tion specifications. The gravel to sand ratios used in the mixes first designed were based on the recommendations of Duff A. Abrams. These were modified somewhat after thorough trial in the field, for it was found that an increase in the proportion of sand, especially in the richer mixes, resulted in marked improvement in workability and concrete placement, without any appreciable sacrifice of strength or other desirable properties.

Control methods. One of the factors instrumental in unifying field concreting practice was a pocket-size loose-leaf booklet of "Instructions for Concrete Inspection and Control" which was prepared and blueprinted locally to serve as an auxiliary guide in the application and interpretation of the contract specifications and was placed in the hands of each concrete inspector and other employee directly connected with the work. Chapters in the booklet were devoted to responsibilities and general duties of the inspector, inspection of materials, distribution of splices in longitudinal reinforcing bars, forms and their removal, methods and periods of curing, mixing and placing of concrete, making the slump test, measuring concrete materials, determination of moisture in sand or gravel, field calculations for converting designed mix to field mix, making and storing 6 x 12 in. test cylinders, sampling aggregates and making sieve analyses, and effects of proper and improper curing of concrete. Tables were also included giving bulking allowances for moist sand (for use in volumetric proportioning), designed mixes and their uses, batch weights (including moisture) per sack of cement for each approved mix, surface moisture in sand and gravel per sack of cement, relation between dry rodded and dry loose mixes, and other miscellaneous data for reducing field computations to the minimum. The latest revision of "Concrete Mixes—and Their Uses" is given in Table 1.

While the booklet of instructions served as a vehicle for arousing the inspector's interest, enlarging his knowledge of concrete, and supplying him with a set of working rules and tables, it could not be expected to maintain that spirit of alertness and constant attention to details so essential to the control of the numerous operations involved in the making of good concrete—especially when the work was progressing at top speed. In other

*Increasd by 5 per cent for field application.

words, a follow-up system was necessary and was provided by the following means:

(a) The various concreting jobs in progress were constantly visited by a so-called "Chief Inspector," a construction man of wide experience and mature judgment, who passed on the various features of the work and particularly those of a practical nature, such as the sufficiency of the forms, the proper placement and splicing of reinforcing bars, and the most suitable consistency of concrete for the particular conditions to be met. By consulting with the contractor, the inspector, and the division engineer, the Chief Inspector was able to check improper practices at their sources and iron out many differences or controversies.

(b) The Construction Engineer made a regular practice of going over all or part of the work at least once a week during the period of activity.

(c) Inspectors were required to make 6 x 12-in. test cylinders in accordance with a definite procedure and schedule, and to see that they were properly cared for until collected by a truck sent out from the project laboratory. After being collected, the cylinders were stored in moist-sand curing vats up to the date of breaking.

(d) Each concrete inspector was also required to prepare a daily "Inspector's Report" and "Cylinder Report," on mimeographed forms, principally to keep the project office informed and provide a permanent record for future reference. The "Inspector's Report" embraced all the essential features of the work, including location, work performed, delays, weather conditions, details of the mix and consistency, etc., and provided opportunity for the inspector to state his personal views or air his particular troubles. The reports were promptly checked by the division office engineer, then referred to the division engineer and mailed to the project office, where they were carefully reviewed. If any irregularities of consequence or requests for advice or assistance were noted, the matters were generally handled by correspondence, using short stereotyped-form of letters, or by a trip to the field on the part of the man directing the laboratory operations. The same agencies were utilized in the event any breaks of the field test cylinders proved to be abnormal and their abnormality was unaccounted for.

(e) Additional field trips were made by the laboratory representative, at rather frequent intervals and without warning, to check up on the more technical details incident to securing the specified concrete mixes (such as proper measurement of aggregates, water, etc.) or to investigate the conditions on particular jobs where there was reason to believe, based on information emanating from the Construction Engineer, Chief Inspector, or other source, that the control system was not functioning as well as it might.

Concrete mix used and basis for selection. The concrete mix used on the greater portion of the canal lining work was a 1:2.4:3.6 by volume, dry rodded, with 3 per cent diatomaceous silica admixture, and 2-in. average slump. A 1:2:4 mix was first attempted but proved deficient in sand for the best workability

and counteracting the harshening effect of field segregation of the coarse aggregate. Another change made in the early stage of construction was the reduction of the maximum size of the gravel from 1½ in. to 1¼ in.

Impermeability, rather than strength, was the governing factor in the selection of the canal lining mix. While strength reflects many of the desirable properties of concrete and serves as a convenient general measure of value, it is not necessarily a criterion of watertightness. In the case of the canal lining, the latter quality was regarded as of greater import in lengthening the life of the concrete by rendering it more resistant to the disintegrating forces to which the lining will be subjected, including contact with flowing water during the irrigation season and exposure to severe frost and variable moisture conditions during the balance of the year. What little test data on impermeability, for the particular aggregates chosen, was available at the time it became necessary to determine the canal lining mix, indicated that a mix leaner than a one to six by volume could not be relied upon to furnish the desired degree of watertightness, notwithstanding the relatively high compressive strength (about 4,500 pounds per square inch) corresponding to the one-six mix. This conclusion was substantiated by laboratory tests later conducted to investigate the water-pressure-resisting properties of 4 x 12 in. concrete discs of various mixes, as previously mentioned. Water pressures up to 500 pounds per square inch were employed in the tests, principally in connection with the determination of suitable mixes for siphons designed to operate under unusually high heads. Fig. 20 shows the latest form of impermeability apparatus developed. It is without the scope of this article to describe the details of the apparatus or give the results obtained from the tests, except to refer to one feature bearing directly on the canal lining mix; namely, that the addition of diatomaceous silica to the extent of 3 per cent by weight of the cement brought about a marked improvement in the watertightness of the concrete, although the original purpose in employing the admixture in the leaner mixes was mainly to improve the workability and lessen the tendency for segregation.

Measurement of concrete ingredients. A careful measurement of the ingredients in each batch of concrete for canal lining was

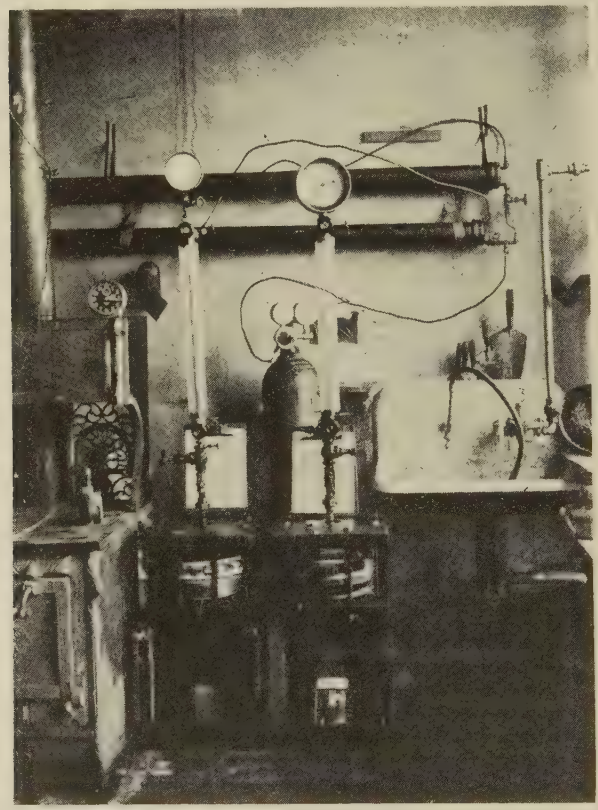

FIG. 20—IMPROVED TYPE OF APPARATUS FOR TESTING IMPERMEABILITY OF CONCRETE DISCS UNDER WATER PRESSURES OF 0-500 POUNDS PER SQUARE INCH

insisted upon. In all cases the sand was weighed and thus the problem of sand bulking was eliminated. The gravel was measured by weight or by volume, based on and occasionally checked by weight. Moisture in the aggregates, for determining the correct batch weights and accounting for the total water entering the concrete, was measured by means of apparatus embodying the water displacement principle, or by ordinary heating or alcohol-burning methods. The introduction of water at the mixer was gaged by the mixer man to bring the concrete to

the specified consistency or slump, the general practice being to regulate the mixer tank adjustment for the minimum water requirement and then add what little additional water was needed. This procedure was found to be the most practicable, and while on first thought it might seem to involve a material departure from rigid water control, a little reflection will reveal the fact that, with reasonably accurate measurement of the materials other than water, any variation in the water-cement ratio in bringing the concrete to the same consistency would be largely confined to the effect of variation in grading of the aggregates and would generally be insignificant. Considerable trouble was experienced by inspectors in determining the average amount of water added at the mixer, per batch of concrete, due principally to inefficient water regulating and measuring equipment on the mixers in use. In most cases the difficulties were wholly or partially overcome by calibrating the mixer tanks and supplementing the results with occasional check measurements of the mixer discharge by diverting it into a portable measuring tank.

Importance of controlling concrete consistency. Fortunately the contractors were as vitally interested as the Government in securing controlled concrete for the canal lining, inasmuch as consistency was a critical factor in the placement of the concrete on the side slopes. Even a variation of but 1 inch in slump made a marked difference in the results. If the slump was less than 2 in., the moving form left a honey-combed concrete; whereas a 3-in. slump produced a bulging and waving of the concrete. Best results were obtained with a slump of 2 to 2½ ins., a range which was quite consistently maintained by the mixer men after a little experience.

Field test data. The results of the 28-day breaks of field test cylinders on canal lining, for the 1928 construction season, are summarized in Table 2. Included in the table are average compressive strengths for the separate lining jobs and the work as a whole, a comparison between actual and predicted strengths, and data revealing the strength variations, including an improvised "Control Factor." Table 3 gives the compressive strengths of two series of 3 x 3 x 6 in. concrete test blocks which were cast

TABLE 2.—RESULTS OF 6 x 12-INCH TEST CYLINDERS—CANAL LINING—1928

Description	Contractor					Average of All Field Specimens (Moist Sand Cured)	Predicted Strength Based on Laboratory Control Curve
	C. F. Graff	General Construction Co.	S. H. Newell & Co.	Derbon Constr. Co.			
				Moist Sand Cured	Surface Treatment Cure		
Number of field test specimens	59	91	72	155	90	377	
Average reported W/C ratio	.77	.82	.83	.84	.84	.82	*.82
Average 28-day compr. strength	4359	4914	4572	4466	3755	4562	4400
Mean variation in strength was as follows:							
A. Per cent within 10 per cent of average strength	65%	62%	53%	51%	47%	56%	
B. Per cent within 15 per cent of average strength	87%	82%	68%	74%	74%	77%	
C. Per cent within 20 per cent of average strength	90%	98%	92%	85%	87%	90%	
Control factor = $\frac{A+B+C}{3}$	81%	81%	71%	70%	69%	74%	

*Water-cement ratio given represents average of field values reported and corresponds to laboratory water-cement ratio of about .87, the difference of .05 being due to aggregate absorption estimated at .5 per cent by weight.

TABLE 3.—COMPRESSIVE STRENGTH OF 3-IN. BY 3-IN. BY 6-IN. CONCRETE BLOCKS FROM CANAL LINING

Age at Test	From General Construction Company lining (Continuous sprinkling for 14 days)				From Derbon Construction Company lining (Cured by asphalt paint application—Hunt Process)			
	S. Slope	Floor	N. Slope	Average	S. Slope	Floor	N. Slope	Average
7 Days	3220	3610	3610	3480	4920	5305	4055	4760
14 Days	3780	4610	4000	4130	4330	5055	4330	4572
28 Days	4740	5000	4535	4758	5480	4000	4040	4507

NOTE: Lining containing blocks poured on July 20, 1928. Followed by 8 days of extremely hot weather, during which the temperature mounted to 110 degrees Fahrenheit and exceeded 100 degrees on 6 successive days.

and cured simultaneously as an integral part of the canal lining. One series is representative of water-cured lining, and the second of lining cured by the asphalt paint application (Hunt process). A striking feature of the test results in Table No. 3 is the gradual increase in strength of the water-cured specimens, as compared with the rapid hardening of the surface-treated blocks. As stated in the explanatory note, the block tests were carried on during a period of extreme summer temperatures. The slower-hardening of the water-cured blocks is accounted for mainly by the cooling effect of the continuous sprinkling.

Value of concrete control. Judging from the opinions expressed, there is little doubt in the minds of those connected with the concrete work, or of even the casual observers who witnessed the concreting operations or viewed the completed work, that the effect of the more systematic and precise concreting methods practiced was noticeably reflected in the finished product. (Figs. 21 and 22). The only question which remains, apparently, is whether the improvement realized will manifest itself in the form of decreased maintenance and increased life of the concrete to a sufficient extent to compensate for the additional effort expended, and while there is a general feeling of assurance that it will, the proof of the pudding is in the eating and time alone will tell. From the experience gained on the Kittitas division, this much at least may be said for control: (1) That it shows unmistakable evidence of improved concrete and may yield big financial returns; (2) That it brings forcefully to the attention of inspectors, and others engaged in directing the operations, the many influences affecting concrete in the making and the necessity for coordinating and controlling the various detail processes if concrete of uniformly high quality is to be produced; (3) That when control embodies properly made tests of laboratory and field specimens, it provides a definite and intelligent means for establishing the field mixtures and gauging the qualities of the final product, even though such specimens may not be truly representative of the concrete in the work; and (4) That it stimulates an interest in concrete and inspires further investigation, which in turn should eventually rid the manufacture of concrete of its major perplexities.

Personnel. The construction of the Kittitas division of the Yakima project was under the direction of Construction Engineer Walker R. Young. The development of technical control procedure for the concrete work and the prosecution of the laboratory work were under the general direction of Office Engineer Arthur Ruettgers. Division Engineer A. A. Whitmore was in direct charge of the reach of Main Canal which included the lining work contracted to C. F. Graff, S. H. Newell & Co., and the General Construction Co. The reach of canal comprising the lining constructed by the Derbon Construction Co. was in charge of Division Engineer V. W. Russell. The principal designing work for the Bureau of Reclamation is done in the Denver office under the general supervision of J. L. Savage, Chief Designing Engineer. All engineering and construction work is under the general supervision of R. F. Walter, Chief Engineer, with headquarters at Denver, and all activities of the bureau are under the general charge of Dr. Elwood Mead, Commissioner, with headquarters at Washington, D. C.

Readers are referred to the JOURNAL *for February, 1931, for discussion which may develop. Such discussion should reach the Secretary by January 1, 1931.*

Construction and Design Features of Haydite Concrete.

BY F. E. RICHART* AND V. P. JENSEN†

INTRODUCTION

General Statements: The development of the use of reinforced Haydite concrete has introduced various problems in design and construction with this material. While light weight is the property that makes desirable the use of Haydite concrete, the engineer and contractor require information on other properties, particularly those affecting strength, durability and ease of construction. There is a demand for information on proportions to produce a specified strength and workability, and on methods of quality control. The designer wants, in addition to data on unit weight and strength, information as to the elastic behavior of the material and its action in a structure. The effect of the relatively low modulus of elasticity of Haydite concrete is of importance, and may have a considerable influence upon the economy of design.

A recent paper by the authors, reporting an investigation of Haydite concrete in progress at the University of Illinois, gave test data on compressive strengths, bond and diagonal tension resistance, together with various other strength properties of Haydite concrete.‡ An attempt will be made in this paper to analyze certain of these test data and to apply the results to design and construction work.

The investigation mentioned above is being made at the Materials Testing Laboratory, University of Illinois, in cooperation with the Western Brick Co., Danville, Illinois, manufacturers of "Western" Haydite aggregates.

‡Proc. A. S. T. M., Vol. 30, Part II, 1930. "Tests of Plain and Reinforced Haydite Concrete."

The work is being conducted by the authors under the administrative direction of Dean M. S. Ketchum, Director of the Engineering Experiment Station, and Professor M. L. Enger, Head of the Department of Theoretical and Applied Mechanics, University of Illinois. I. N. Doughty, Manager of Research, and Frank Payne, Engineer, of the Western Brick Co., have represented their organization as an advisory committee on the work.

PROPERTIES OF MATERIALS

Aggregates: The Haydite aggregates to which this discussion applies are the "Western" fine or "A" size material, passing a $\frac{3}{16}$-in. round hole screen, and the coarse or "C" size, retained on the $\frac{7}{32}$-in. screen and passing the $\frac{3}{4}$-in. screen. The range in values of the properties of a number of lots used are given in Table 1. The apparent specific gravity of material passing the 200-mesh sieve was found to be 2.56, indicating that the absolute specific gravity of the material is as high or higher. The coarse particles, with an apparent specific gravity of 1.25 to 1.32, evidently have about 50 per cent porosity. The apparent specific gravity of the material increases as the size of particle decreases. There are usually a few particles in a sample that will float in water. The specific gravity of a graded sample is seen to be the average of individual values that vary considerably and is not so definite a property as that of a homogeneous material.

Types of Concrete Mixture: Reference will be made frequently to two types of mixture, one made with a natural sand and coarse "C" Haydite, which will be denoted as "C-Haydite" concrete; the other made with fine "A" Haydite and coarse "C" Haydite, denoted as "All-Haydite" concrete. The sand used in the first mixture was a torpedo sand from Covington, Indiana, having a fineness modulus of 3.08, unit weight, loose, dry, of 106 lb. per. cu. ft., absorption of 1.0 per cent, and specific gravity of 2.67.

Absorptive Properties of Aggregates: The absorption of mixing water, usually a minor factor in the production of concrete with sand, gravel and stone aggregates, becomes a matter of real importance when the aggregates are capable of absorbing a large amount of water. This presents a two-fold problem, of which one part concerns the drying of the concrete and consequent

change in workability due to rapid absorption of water by the Haydite during and immediately after mixing; the other involves the determination of the true water-cement ratio, or some related property, which varies as the absorption of the mixing water proceeds. The latter variation obviously adds some difficulty to the use of water-cement ratio as a strength control.

The tests of absorption made thus far have been of a preliminary sort; however, a more thorough study is now being started and should furnish needed data. The tests indicated one unexpected phenomenon; the fine Haydite absorbed a larger percentage of water by weight in a given length of time than did the coarse material. Considering that the material consists of a mass of closed cells of infinitesimal size, it is seen that in view of the greater surface area of the fine material, a certain depth of penetration by the water should produce the greater absorption in the fine material. It is probable that the total absorption over a long period would be greater for the coarse material; tests up to 7 days showed continuing absorption at the end of the period. It is also likely that the absorption by the very fine material, such as that passing the No. 100 sieve, would be small due to the lower porosity.

The absorption tests made were on dry material and on material with various initial moisture contents. The procedure used with the coarse aggregate was the usual immersion method, using a covered wire basket suspended from one arm of a balance. The material was surface dried by rolling it on a paper towel. The method finally used with the fine material was to place a sample of the soaked material in a centrifuge, which was used to remove surface water. The criterion for surface dryness was the ability of the material to run freely through the fingers. In both tests the amount of absorbed water was found by oven-drying.

Fig. 1 (a) shows the absorption determined for dry fine and coarse Haydite for various periods of immersion. Fig. 1 (b) shows similar data for both dry and initially moist materials for various immersion periods. It is clear that Haydite does not have a *fixed* amount of absorption in a given time, as usually assumed for ordinary aggregates, but the amount depends upon the initial moisture content. Moist aggregates show a larger total absorption than initially dry ones, especially in the case of

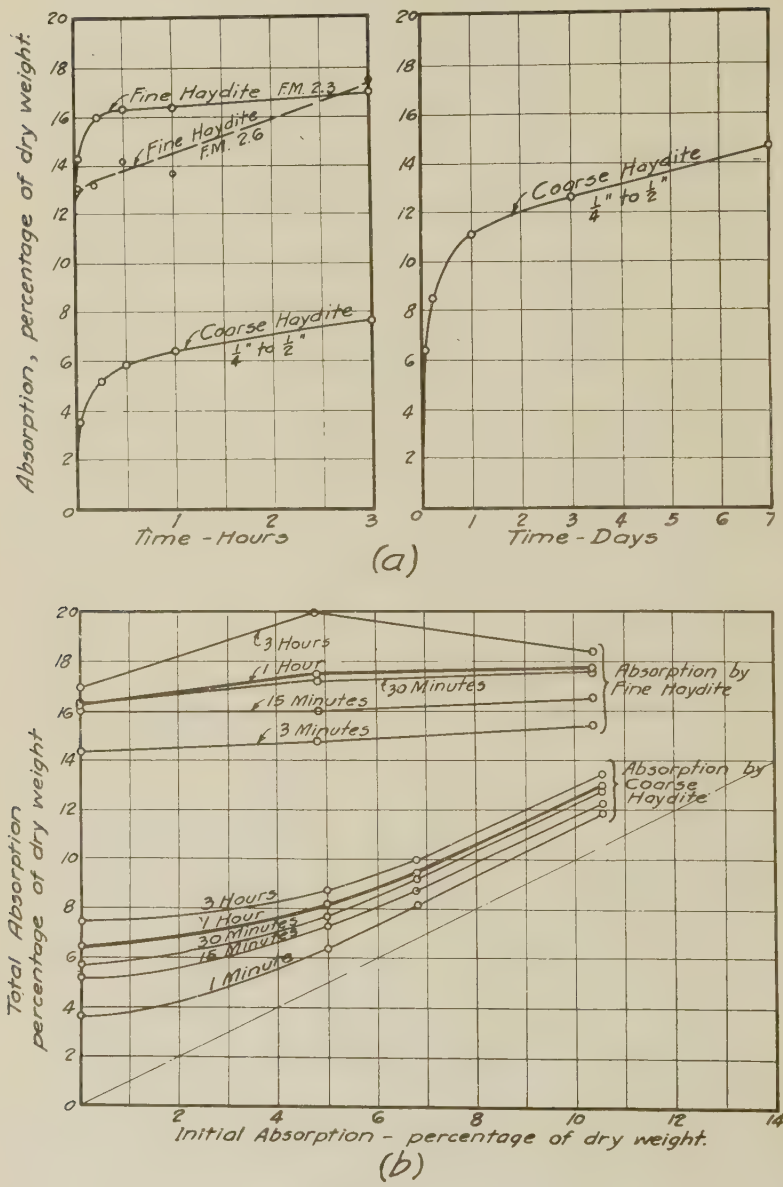

FIG. 1—(a) ABSORPTION OF WATER BY INITIALLY DRY HAYDITE AGGREGATES FOR VARIOUS PERIODS OF IMMERSION. (b) ABSORPTION BY HAYDITES HAVING VARYING INITIAL MOISTURE CONTENTS

the coarse material. The fine material reaches its absorptive capacity more quickly than the coarse and is less affected by initial moisture conditions.

The effect of a variation in water-cement ratio due to error in absorption allowance may be seen from an example. In a one-bag batch of a 1:2:3 mixture, there would be roughly 245 lb. of Haydite. An error of 2 per cent by weight of aggregate in the absorption allowance would change the amount of free water by 4.9 lb. and the value of w/c by $\frac{4.9}{62.4} = 0.08$. With a water-cement ratio of 1.0 this will cause a variation in strength of 15 per cent or more.

There is little information regarding the period of time that aggregates should be immersed in water to produce an absorption equal to that taking place during the mixing and placing of concrete. Periods varying from 15 minutes to 3 hours have been assumed by various investigators, without great difference in result when ordinary aggregates were used. Observation of fresh concrete in forms indicates that insofar as water content fixes the voids in the concrete, the mass takes its final volume (neglecting subsequent shrinkage of the order of 0.1 to 0.2 per cent of volume) within 15 minutes after the concrete is placed. Changes in water-cement ratio due to further absorption by the aggregates may affect the process of hydration and thus affect the strength. An estimate of this effect has led to the use in this investigation of an absorption allowance corresponding to a one-hour immersion test. Values for one-hour absorption for material with various initial moisture contents are shown by the heavy curves of Fig. 1 (b).

It will be noted that Fig. 1 (b) refers to initial absorbed moisture, not total moisture content. The proportions of absorbed and free moisture in a sample will depend entirely upon how the moisture content has been taken on. If a wet sample is drying out the amount of absorbed moisture will be high; a sample just wet down will contain mostly free surface water.

CONSTRUCTION FEATURES

Relations Between Water-Cement Ratio and Strength: In a study of the relation between water-cement ratio and strength

for Haydite concrete, several series of cylinder tests were made, including mixtures with sand and gravel aggregates, sand and coarse Haydite, and fine and coarse Haydite. These were made of several proportions and consistencies and tested at ages of 7 and 28 days. Two groups were made with fine and coarse Haydite, one with oven-dried material, the other with moisture contents of 6 per cent in the coarse and 27 per cent in the fine material. In determining the water-cement ratios, absorption allowances have been used as follows: for sand and gravel, 1 per cent by weight; coarse Haydite, dry, 7 per cent, moist, 9 per cent; fine Haydite, dry 14 per cent, moist, 20 per cent. Data from the 28-day tests are plotted in Fig. 2. All of the points fall within a fairly narrow zone on the diagram, though there are definite differences in the average curves for the four series of tests. The All-Haydite concrete made with moist aggregates appears to be consistently stronger than that made with dry Haydite, and as strong as that made with sand and gravel. The difference in the Haydite concretes may be due to a better bond between the moist particles and the cement paste than that obtained with the dry particles, to differences in absorption not fully accounted for in the corrections applied or to differences in the water-cement ratio relation. All of these curves give strengths considerably above the values recommended in the Joint Standard Building Code of the American Concrete Institute for use with average materials. These rather high strengths call attention to the cement used, which was a new lot of standard Universal cement, passing the Standard Specifications for Cement current when the tests were made. Tensile strengths of standard Ottawa mortar briquets were: at the age of 7 days, 258 lb. per sq. in.; at 28 days, 370 lb. per sq. in.

It is recommended that in the design of Haydite concrete when very careful absorption determinations are not made and the work is done under ordinary conditions of supervision, somewhat lower strengths be assumed for a given water-cement ratio than those given in Fig. 2. The values recommended in the Joint Standard Building Code noted above, which are probably sufficiently conservative, are as follows:

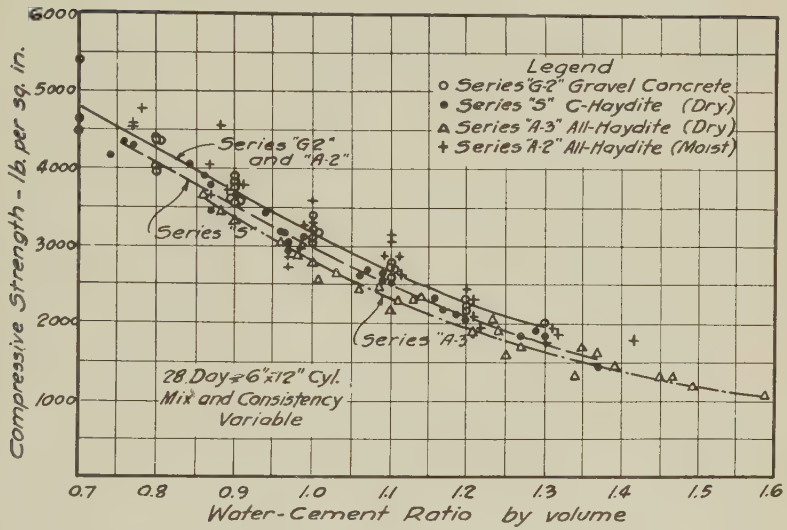

FIG. 2—RELATION BETWEEN WATER-CEMENT RATIO AND COMPRESSIVE STRENGTH FOR THREE TYPES OF CONCRETE

Water-Cement Ratio		Compressive Strength* lb. per sq. in.
By Volume	Gallons of Water per Sack of Cement	
1.10	8¼	1500
1.00	7½	2000
0.90	6¾	2500
0.80	6	3000

*From tests of 6 by 12 in. cylinders, moist cured for 28 days at 70° F., tested moist.

The indication in Fig. 2 that greater strength is obtained through the use of moist Haydite aggregates than with dry ones, even when a logical correction is made for differences in absorption, is borne out by several other groups of tests. This favors the practice of pre-wetting of aggregates in the stock-pile previous to placing them in the mixer, which has been done, however, for the primary purpose of securing better and more uniform workability and to prevent undue drying out of the concrete after

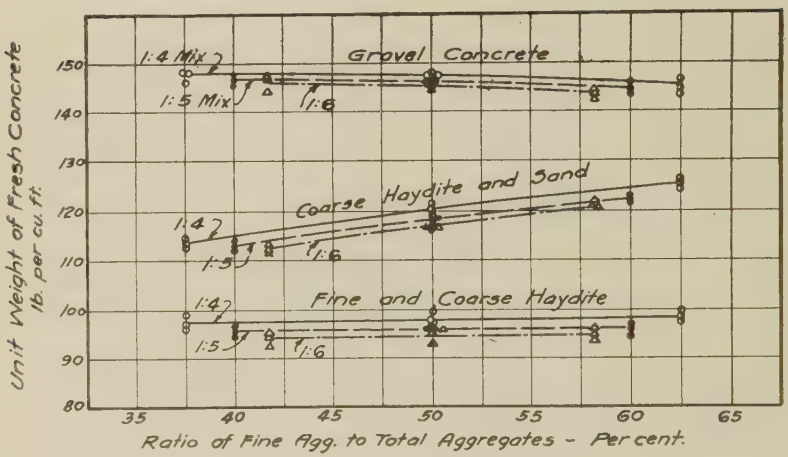

FIG. 3—UNIT WEIGHT OF GRAVEL AND HAYDITE CONCRETES

it was placed. Such pre-wetting, unless very systematically done, may increase the difficulty of applying proper absorption corrections where a close control of strength is required.

Proportions and Workability. Some users of Haydite aggregates have run into difficulty due to an attempt to use as large a proportion of coarse Haydite as would be used with 1½-in. gravel. It has been established by experience and tests that the amount of coarse aggregate usable decreases as the size of particle decreases, at least below the 1-in. size. While an aggregate of ½-in. size may contain the same percentage of voids as one of 1½-in. size, it is obvious that the size of the voids is smaller in the ½-in. material and will not accommodate sand grains without separation of the coarse aggregate particles. The proportion of coarse to total aggregates recommended by the Portland Cement Association in "Design and Control of Concrete Mixtures," 3rd. Ed. 1929, is 0.50 to 0.70 for coarse aggregate of maximum size of 1-in. or over; 0.40 to 0.60 for a maximum size of ¾-in.; and 0.30 to 0.45 for a maximum size of ⅜-in. Proportions of "C" Haydite (which is composed of material passing a ¾-in. round hole screen) varying generally from 40 to 60 per cent of the total were used in the tests represented by Fig. 2. Considering the resulting

workability obtained with the use of an excess of fine aggregate and also the accompanying increase in weight of the sand and "C" Haydite mixture, it is believed that a mixture of 45 per cent fine and 55 per cent coarse is the most desirable combination, at least with the sand and Haydite mixtures. For All-Haydite concretes it may be just as economical to use equal parts of fine and coarse material.

Data of C-Haydite and All-Haydite mixtures (see Series S and A-3 of Fig. 2) are given in Table 2 as a guide to proportions and accompanying slumps usable with various water-ratios. The materials used were in all cases initially dry. If moist aggregates are to be used, bulking and moisture content tests should be made, so that volumes of moist material containing solids equal to those of the dry materials may be used. The bulking effect is small for the coarse Haydite and usually will not exceed 5 or 6 per cent, but for the fine Haydite the bulking may be important. Thus the fine Haydite weighing 55 lb. per cu. ft. by dry loose measure, weighs 51 lb. per cu. ft. with 27 per cent of moisture present. This 51 lb. consists of 40.1 lb. of dry Haydite and 10.9 lb. of water. To obtain 55 lb. of dry Haydite in the mixture requires $\frac{55}{40.1}$ or 1.37 cu. ft. of the moist material. With this 37 per cent bulking in the fine aggregate and assuming a 5 per cent bulking in the coarse, for a mix of 1:2:3 concrete as listed in Table 2, the volume proportions with the moist materials should be 1:2.74:3.15. Similarly, the quantities required per cubic yard of concrete as given in Table 2 would be multiplied by the ratios of 1.37 and 1.05 for the fine and coarse materials, respectively.

The use of moist aggregates just described will naturally affect the water requirements. In a one-bag batch the 2.74 cu. ft. of fine aggregate contain 10.9 lb. of water per cu. ft. or 29.9 lb. This must be considered in computing the amount of water for mixing and absorption requirements.

The quantities of materials in Table 2 contain no allowance for waste or for settlement of material in forms. As explained, the aggregate quantities must be increased for bulking when moist aggregates are used. If these proportions are used without

correction for bulking, a richer and stronger mix will result, and all quantities of materials, including the cement, will be increased. The amount of such increase, in per cent, is roughly equal to the per cent bulking of the fine aggregate times the ratio of fine to total aggregates.

Table 2 shows a range of workabilities as shown by values of slump from 1 to 10 inches. For making test beams with fairly heavy reinforcement, very satisfactory placing of the concrete was accomplished with slumps of 6 and 7 inches. Good surfaces were obtained next to the forms and there was practically no honey-combing or segregation of the materials. For slabs and large beams slumps of 4 to 6 inches should give satisfactory workability.

Unit Weight of Concrete: Data on unit weight of freshly placed concrete as found from test cylinders are given in Fig. 3. It is seen that the weights of gravel and All-Haydite concretes do not vary greatly with changes in proportions and consistencies corresponding to those of Table 2. The values shown in Fig. 3 are for concrete made with dry aggregates. The weight of All-Haydite concrete made with moist aggregates was 3 to 6 lb. per cu. ft. greater than that of Fig. 3, which is further evidence that the total absorption of moist aggregate is greater than for that initially dry. The increase in weight of "C"-Haydite concrete with increasing amounts of natural sand is self-explanatory.

DESIGN CONSIDERATIONS

General Considerations: Of the several phases of concrete design those of primary importance are—first, the selection of a concrete strength, second, the determination of the necessary and usable proportions of materials, and third, the actual design of the structural members. Data pertaining to the first and second phases have been presented and further discussion of economy as it relates to them would necessarily involve relative prices of materials, relative quantities of the different materials which could be used to produce a desired strength and consistency of concrete, and proportional costs of raw materials and concrete in place. Current local prices and the needs of individual jobs will govern the comparisons to be made and therefore this section

will be devoted entirely to the factors which affect the design of the structural members. These factors are lightness in weight and low modulus of elasticity.

In the following analysis the symbols and notation are those in general use, as defined, for example, in the A. C. I. Joint Standard Building Code, Section 602. In addition, use has been made of the relation *Resisting Moment* = Kbd^2 for balanced reinforcement, also the subscript g has been used with terms referring to gravel concrete.

It may be noted that the comparisons to follow involve values of strength and modulus of elasticity from tests of cylinders rather than of beams. The limited amount of beam test data available are in accord with the analyses given; Haydite concrete beams show larger values of k and consequent smaller values of j, and increased strains and deflections at a given load, as compared to gravel concrete beams. Haydite concrete beams tested in studies of diagonal tension showed no initial failures at the extreme fibre in compression, even though percentages of longitudinal reinforcement (structural grade) as great as 2.8 were used, and tensile failure of the steel was developed. Obviously, beam and slab tests corresponding to the range of designs considered here would be impracticable, and such tests have not been made. Instead, the authors have felt justified in determining properties of the material and in applying the results by means of well-established theory of the behavior of such members.

Effect of Lightness in Weight: Unit weights of concrete made of gravel and sand, coarse Haydite and sand, and of fine and coarse Haydite are shown in Fig. 3. For ordinary mixtures "C"-Haydite concrete will weigh 80 per cent, and All-Haydite concrete 67 per cent, of the weight of gravel concrete. The effect of a reduction in dead load depends upon the percentage of dead to total load and upon the manner in which the designer may take advantage of the reduced load. His beam sizes, spans, or slab thicknesses may be limited by considerations other than stress, in which case it may not be possible to obtain full advantage.

Comparison has been made in Table 3 of the three kinds of concrete (gravel, "C"-Haydite, and All-Haydite) for ratios of dead load to total load varying from 60 to 30 per cent, upon the conditions that the resisting moment which must be developed is

proportional to the load per sq. ft. of floor area, and that b and d for slab or beam are the same for all three kinds of concrete. The figures shown are ratios of total loads to be carried and are equal to the ratios of resisting moments to be developed when the span is the same for all three concretes. Values of j for "C"-Haydite and All-Haydite concretes with balanced reinforcement are shown in the following section to be approximately 97 and 95 per cent respectively of j for gravel concrete. Haydite concretes are shown to require higher percentages of steel for balanced reinforcement as a consequence of higher values of n. Therefore in the comparison of Table 3, which imposes constant span and depth of slab, a decreased bending moment due to decreased load results in a lowering of the percentage of steel required for the Haydite slabs and brings the values of j for Haydites nearer to the value for gravel than is indicated by the proportions of 97 and 95 per cent. The relative percentages of steel required for the three concretes are thus shown to be approximately equal to the values given in Table 3 of relative percentages of resisting moment which must be developed.

The effect of taking advantage of the reduced weight of Haydite concrete by reducing the depth of the slab is to produce an additional secondary reduction in the values given in Table 3 of from 1 to 4 per cent, the higher percentage being for the greatest percentage of dead to live load. In a comparative design of gravel and Haydite concrete in which d is varied and balanced reinforcement is maintained the additional effects of concrete strength and variation of E enter the problem. These effects are discussed separately in the following section.

The percentage of reduction in column loads to be carried when Haydite concrete is used in place of gravel concrete is somewhat greater than those indicated for slabs in Table 3, due to the reduction factor which is applied to the live loads under many building codes. The effect of such a live load reduction factor becomes greater as the number of stories between the column to be considered and the roof is increased. Since the column is designed for the remaining live load and the dead load, a decrease in the latter becomes quite important.

A considerable economy may result from dead load reduction under certain conditions of design due to the ability to use a cheaper type of foundation than would have been required for the heavier dead load. Complete data concerning the individual job would necessarily have to be available for a determination of this possibility.

Modulus of Elasticity of Haydite Concretes: Experimental values of initial moduli of elasticity of concretes made with gravel and sand, coarse Haydite and sand, and fine and coarse Haydite are shown in relation to compressive strength in Fig. 4 (a). Each value is the average of 3 tests. Mixes varied from 1:4 to 1:6, percentages of fine aggregate to total aggregate from 37.5 to 62.5, and slumps from 1 inch to 10 inches. It will be seen that for each kind of concrete the variation in E with strength may be represented by a straight line for strengths between 2000 and 4000 lb. per sq. in. It will also be noted that the moduli for "C"-Haydite and All-Haydite concretes average about 75 and 55 per cent, respectively, of the values for gravel concrete.

Fig. 4 (b) shows the relation between the moduli found by test and the values which are obtained by using the A. C. I. building code value of $1000f'_c$ for gravel concrete and values 75 and 55 per cent as great for "C"-Haydite and All-Haydite concretes, respectively. As another approximation, values of constant moduli of 3,400,000 for gravel, 2,500,000 for "C"-Haydite, and 1,900,000 for All-Haydite concrete are shown in the figure for comparison with the experimental and A. C. I. values. The three relations between E and strength will be used later in comparative studies.

For a more complete study of the possibilities of variation of secant moduli and to give information concerning relative deformations of the three concretes, the stress-strain curves of Fig. 5 are presented. These are typical curves taken from individual 6 by 12-in. cylinders of varying mix and consistency. Curves were obtained by means of an attached extensometer and a semi-autographic recording device. A constant ultimate unit deformation of about 0.0015 was found for gravel concrete of all strengths except those considerably below 2000 lb. per sq. in., this value being in agreement with numerous previous tests.

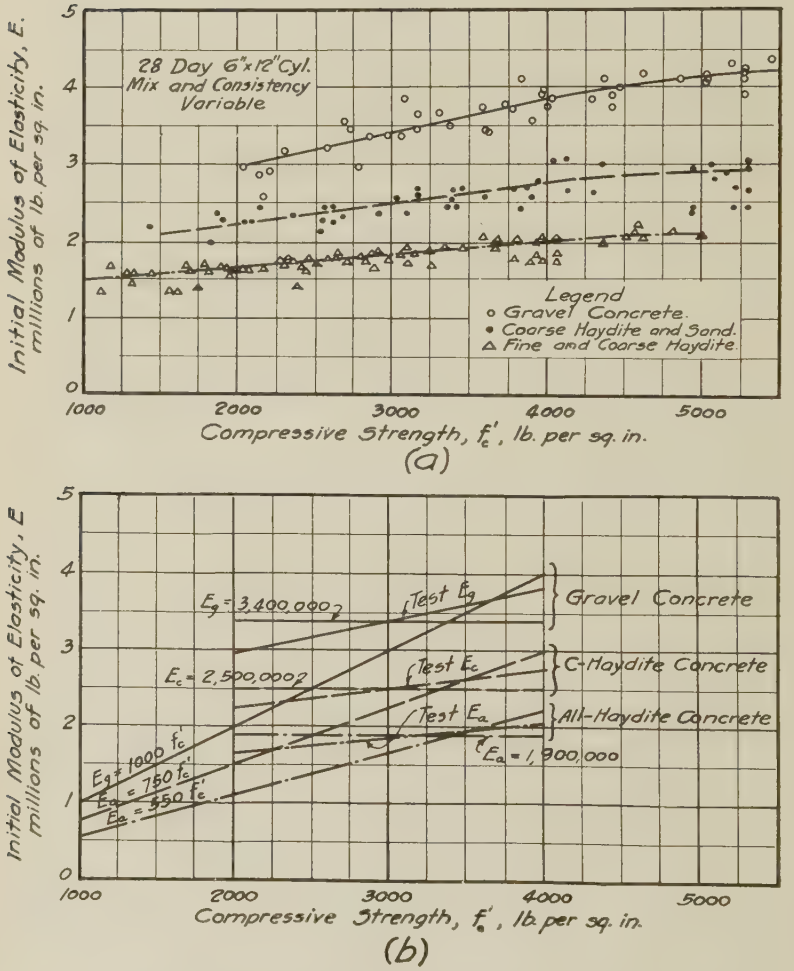

FIG. 4—RELATION BETWEEN INITIAL MODULUS OF ELASTICITY AND COMPRESSIVE STRENGTH FOR THREE TYPES OF CONCRETE

Ultimate unit deformations of the Haydite concretes are shown to be greater than those of gravel concrete, the proportional increase being greater for the concretes of higher strength. Deformation of All-Haydite concrete shows an increase over that of "C"-Haydite concrete similar to the increase in deformation of "C"-Haydite over that of gravel concrete. A consideration of the nearly straight stress-strain curve for high-strength gravel concrete will show that concretes having initial moduli 75 and 55 per cent as great must necessarily receive higher deformations in order to develop the same stress as the gravel concrete.

The curves of Fig. 5 have been replotted in Fig. 6 with the abscissas for the Haydite concrete reduced by the differences in horizontal intercepts of the tangents which represent the initial moduli of these concretes and gravel concrete. In other words, all curves have been brought approximately to a common tangent, that for an intermediate grade of gravel concrete. The curves as represented thus are scarcely more varied than is to be expected from a group of individual cylinders made with a single kind of aggregate. The similarity of these curves leads to the conclusion that for deformations up to 50 per cent of the ultimate deformation the relations of secant moduli of Haydite and gravel concretes are essentially the same as those of initial moduli. A further conclusion is that the primary difference in deformations is the difference in "elastic" deformation (deformation up to the line for initial modulus) as indicated by the ratios 75 and 55 per cent, and that the difference in "plastic" deformation (remaining deformation) is slight and of secondary importance. Since the "plastic" deformation gives an indication of the rate of breaking down of the structure it would seem that the Haydite particles themselves do not affect the rate of internal local failure and final complete rupture of plain concrete in compression.

Effect of Low Modulus of Elasticity on Design of Beams and Slabs: Comparative properties and design factors of rectangular beams and slabs have been computed and tabulated for gravel, "C"-Haydite and All-Haydite concretes having compressive strengths of 2000, 2500, 3000 and 3750 lb. per sq. in., using values of E from Fig. 4 (b). While a comparative design based upon the test values of E should probably give the truest indication of

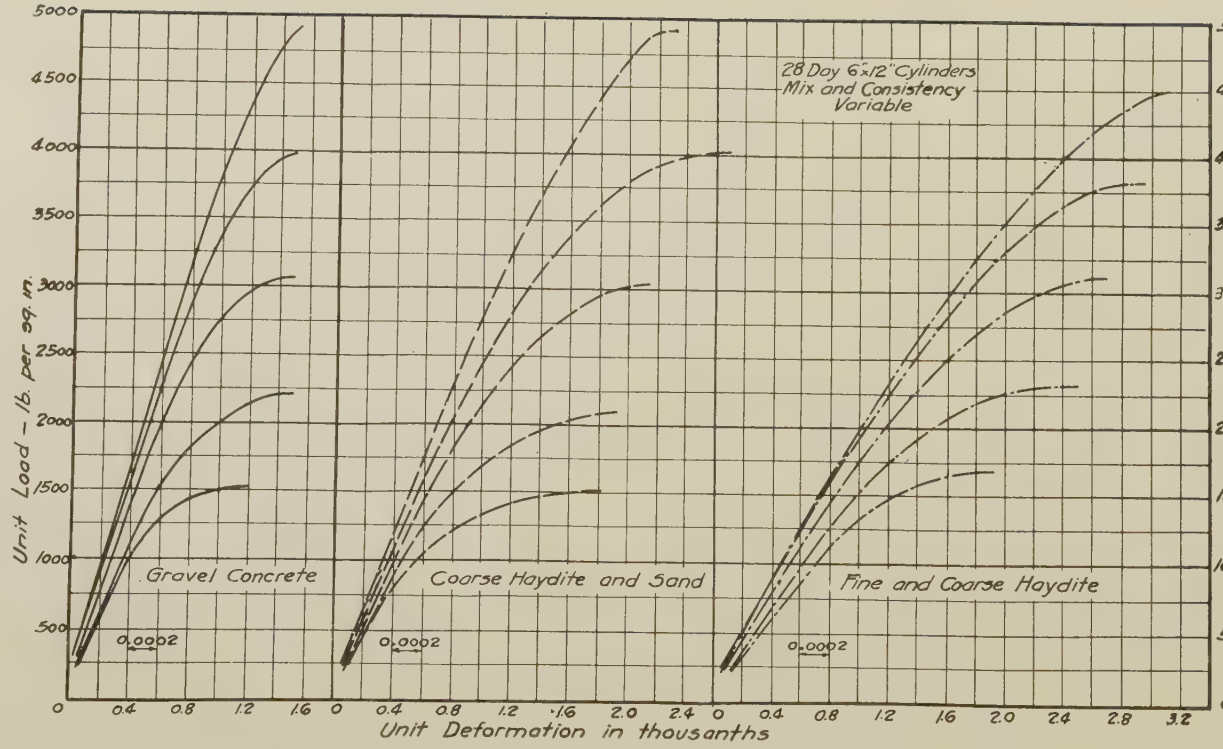

FIG. 5—STRESS-STRAIN CURVES FOR THREE TYPES OF CONCRETE

the differences in the concretes and their resulting behavior in flexure, the designer must necessarily use a codified value of E, and therefore the comparisons given in Tables 4, 5 and 6 are based on three different assumptions, respectively; (1) using test values of E, (2) using three proportions of the A. C. I. building code value of E, and (3) using constant value of E for each material. It is to be noted that the comparisons made in these tables are for the purpose of determining the effect of variation in E only and do not include the additional effect of lightness in weight in reducing the load to be carried and the section required.

In section A of Table 4, which is based upon experimental values of E, balanced reinforcement, $f_s = 20{,}000$ lb. per sq. in., and $f_c = 0.40\, f'_c$, the factors, n, k, j, p, and K are given for all three kinds of concrete. It will be seen that the lowered E and increased n for Haydite, while causing a slight decrease in j and a considerable increase in k and p, have the effect of increasing considerably the resisting moment factor K. The slab and rectangular beam comparisons which follow in the table are based upon various design limitations.

In section B, Table 4, under the heading "Slab Comparison Based Upon Constant Resisting Moment, b constant, d varies," are given figures which are intended to show the net effect of the changed design factors for Haydite concretes. These have been computed as follows:

Slab with Variable Depth, d.

With balanced reinforcement,

$$R.\ M.\ (\textit{Resisting Moment}) = Kbd^2 = 12\ Kd^2$$

$$d = \left(\frac{R.\ M.}{12\ K}\right)^{\frac{1}{2}}$$

For a constant resisting moment the ratio of depth, d, required for Haydite concrete slabs to depth, d_g, required for gravel concrete is,

$$\frac{d}{d_g} = \left(\frac{K_g}{K}\right)^{\frac{1}{2}}$$

Ratios of $\frac{d}{d_g}$ for "C"-Haydite concrete are shown in Table 4 to vary from 92 to 91 per cent and for All-Haydite concrete to

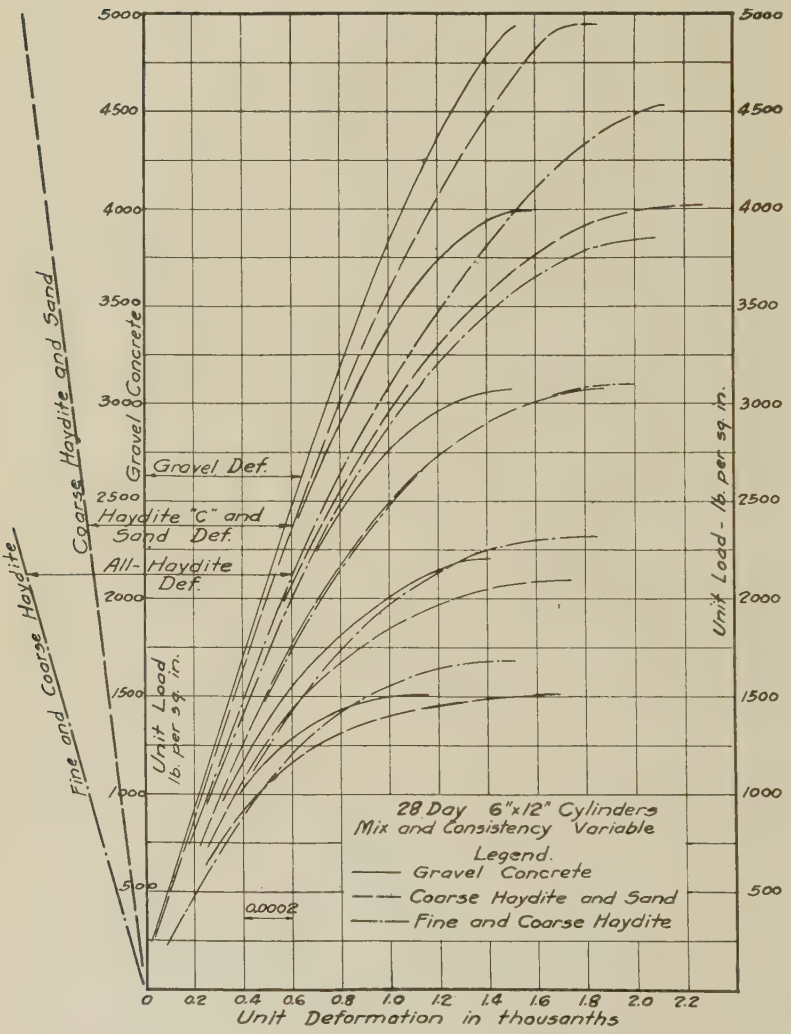

FIG. 6—MODIFIED STRESS-STRAIN CURVES FOR THREE TYPES OF CONCRETE

vary from 84.5 to 87.5 per cent. Percentages of total volume of concrete required would be from 1 to 3 per cent higher than these percentages of depth due to a constant thickness of covering.

Ratios of steel areas, A_s, required for Haydite slabs to steel areas, A_{sg}, required for gravel concrete are net ratios based on the increased p required for balanced reinforcement in Haydite and the reduced d as shown by the ratio $\frac{d}{d_g}$.

Thus:

$$\frac{A_s}{A_{sg}} = \frac{d}{d_g} \cdot \frac{p}{p_g}$$

Percentages of $\frac{A_s}{A_{sg}}$ (Table 4, part B) show for this comparison a requirement of from 111 to 110 per cent of steel area for "C"-Haydite concrete and from 123.5 to 121.5 per cent for All-Haydite concrete. The total effect is then to develop the same resisting moment with "C"-Haydite concrete with d reduced 8 to 9 per cent and A_s increased 11 to 10 per cent, and with All-Haydite concrete with d reduced 15.5 to 12.5 per cent and A_s increased 23.5 to 21.5 per cent.

Section C of Table 4, which is headed "Slab and Rectangular Beam Comparison Based upon Constant b and d for All Concretes," applies to the case in which a possible reduction in depth of slab is not utilized. It shows that with "C" Haydite concrete an increase of 18 to 17 per cent in resisting moment is obtained by the use of 21 to 20 per cent more steel, and that with All-Haydite concrete an increase of 39 to 31 per cent in resisting moment is obtained by an increase of 46 to 39 per cent in steel. The exact value of the increased carrying capacity or possibility of increased span length which is purchased in this case by the use of a higher percentage of steel is not at once easily determined as a simple percentage. If, however, no increase in resisting moment is desired, a constant resisting moment with constant depth of section may be provided with a Haydite concrete slab by the use of slightly more steel than that required by gravel concrete. This is due to the slight difference in j for the two materials, an effect due only to variations in modulus of elasticity. The com-

pensating effect of a reduction in weight in reducing the steel required with Haydite concrete is considered in Section 12.

In Section D of Table 4 comparisons of rectangular beams are based upon the condition that it is possible to reduce both b and d and that b and d for Haydite concrete beams are proportional to b and d for those of gravel concrete. Calculations were made as follows:

Rectangular Beams.

With balanced reinforcement,

$$\begin{aligned} R.\ M. &= Kbd^2 \\ b &= Constant \times d = Cd \\ bd &= Cd^2 \\ R.\ M. &= CKd^3 \\ d^2 &= \left(\frac{R.\ M.}{C\ K}\right)^{2/3} \end{aligned}$$

For a constant resisting moment,

$$d^2 = Constant \times \left(\frac{1}{K}\right)^{2/3}$$

$$\frac{bd}{(bd)_g} = \frac{d^2}{d_g^2} = \left(\frac{K_g}{K}\right)^{2/3}$$

These area ratios, $\frac{bd}{(bd)_g}$ for "C"-Haydite concrete are shown to vary from 89 to 90 per cent and for All-Haydite concrete to vary from 80 to 83.5 per cent of gravel areas.

Net ratios of steel areas, A_s, required for Haydites to areas, A_{sg} required for gravel concrete are 107 to 109 per cent for "C"-Haydite and 117 to 116 per cent for All-Haydite concretes. For these computations,

$$\frac{A_s}{A_{sg}} = \frac{bd}{(bd)_g} \cdot \frac{p}{p_g}$$

giving ratios of steel areas based on the reduced beam section as was done in the case of slabs of variable depth.

The comparative design ratios given in Table 5 using proportional A. C. I. Code values of E, and in Table 6 using constant values of E, were all computed in the manner described for Table 4.

It is to be noted that the comparative design ratios in Tables 5 and 6 do not differ greatly from those based on test values of E in Table 4, the largest difference occurring with the proportional A. C. I. Code values for 2000-lb. concrete where the greatest divergence in E is to be found (see Fig. 4 (b)). Actual percentages of steel, however, vary considerably for the lower strength concretes.

Combined Effect of Lightness in Weight and Low Modulus of Elasticity on Slab and Beam Design. In general a design in Haydite concrete will permit advantage to be taken of reduced dead load and must necessarily be made on the basis of actual values of E. Comparative design ratios are shown in Table 7 based on proportional A. C. I. Code values of E, for all concrete strengths, and for a range of ratios of dead load to total load from 0.50 to 0.20. Percentages of resisting moment required for Haydite to resisting moment required for gravel, $\frac{R.\ M.}{(R.\ M.)_g}$, have been taken from Table 3. Percentages given in section B of Table 7 for slabs with balanced reinforcement show a requirement for "C"-Haydite concrete of 88 to 91 per cent of the depth of gravel concrete slabs with corresponding values of 105 to 108 per cent of the steel areas for gravel concrete. For All-Haydite concrete similar percentages of depth are 80 to 85, with 111 to 117 per cent of steel. The analysis for variable resisting moment is similar to that given for Table 4.

Thus for a variable resisting moment, $R.\ M.$,

Slab comparison:

depth ratios, $$\frac{d}{d_g} = \left(\frac{K_g}{K} \cdot \frac{R.\ M.}{(R.\ M.)_g}\right)^{1/2}$$

and steel ratios, $$\frac{A_s}{A_{sg}} = \frac{d}{d_g} \cdot \frac{p}{p_g}$$

Rectangular Beams Comparison:

concrete area ratios, $$\frac{bd}{(bd)_g} = \left(\frac{K_g}{K} \cdot \frac{R.\ M.}{(R.\ M.)_g}\right)^{2/3}$$

steel ratios, $$\frac{A_s}{A_{sg}} = \frac{bd}{(bd)_g} \cdot \frac{p}{p_g}$$

Rectangular beam comparisons given in section C of Table 7 show area requirements for "C"-Haydite concrete of 85 to 89 per cent with corresponding steel requirements of 101 to 106 per cent, and area requirements for All-Haydite concrete of 74 to 79 per cent, with steel requirements of 103 to 110 per cent, as referred to gravel concrete requirements.

Having obtained the reduced depths shown in Table 7 a further reduction of required resisting moment (due to this decrease in dead load) might be applied thus effecting a further slight reduction of all concrete and steel areas for Haydite concretes.

T-Beams and Beams With Compressive Reinforcement: For a comparison of T-beams of different concretes, since the depth is usually assumed or limited by shear or architectural considerations, only beams of the same stem size will be compared. In general the decrease in bending moment due to reduced dead load for Haydite concretes will be somewhat greater than the decrease in values of j, resulting in a slight saving in steel. A single illustration is given in Table 8 for the design at the center of a T-beam, the problem being taken from "Design and Cost Data for the Building Code," Arthur R. Lord, Proc. A. C. I., Volume 24, 1928, p. 546, problem 2.

In Haydite beams of the same size as gravel the efficiency of compressive steel is increased due to two causes, greater values of n and larger proportions of f_c to be multiplied by these values of n in determining the ability to develop compressive stress in the steel. The larger proportions of f_c result from increased values of k for Haydite concretes and in quantity will depend upon d when the distance from the compression surface to the compression steel is constant.

Shear and Bond: As a result of beam and pull-out tests* to determine bond values and beam tests* to determine diagonal tension resistance of concretes of gravel, "C"-Haydite, and All-Haydite, it was concluded that the same working stresses may be applied to all three concretes for shear and bond.

Deflection: While relative deflections of homogeneous beams of constant size and span will be inversely proportional to their

*Proc. A. S. T. M., Vol. 30, Part II, 1930. "Tests of Plain and Reinforced Haydite Concrete."

E values the same will not be true of non-homogeneous beams of reinforced concrete. This is apparent from a study of Maney's equation† which gives deflection, D, as a function of the separate deformations of the steel fiber, ϵ_s, and the concrete fiber, ϵ_c,

$$D = K\frac{l^2}{d}(\epsilon_s + \epsilon_c)$$

Tests show that beams made with gravel, "C"-Haydite and All-Haydite concrete having relative values of E of 1.00, 0.75 and 0.55, developed relative deflections under a given load of 1.00, 1.15 and 1.30, respectively. This is readily understood by reference to the formula, in which the concrete deformation increases as E decreases, while the steel deformation is only slightly affected by variations in the stiffness of the concrete.

Column Design: In applying a column formula of the type $\frac{P}{A} = f_c[1 + (n - 1)\ p]$ it is obvious that an increase in n for a constant value of f_c and p would result in increasing the working load and that the higher the percentage p the greater would be the increase in working load. A reinforced concrete column made of Haydite concrete of a given strength can not be expected to carry a greater ultimate load than a similar gravel concrete column, identically reinforced. It is apparent that this type of formula embodying n will not apply to a series of concretes having widely differing values of n for identical strengths. Tests of columns of gravel concrete, "C"-Haydite concrete, and All-Haydite concrete covering plain columns, tied columns having 1.5 per cent and 4 per cent longitudinal steel, and spirally reinforced columns having 1 per cent spiral and 1.5 and 4 per cent longitudinal steel have shown that approximately the same relationships may be expected between load carried, ultimate concrete strength and yield point of reinforcement for all three kinds of concrete regardless of the values of E.

In view of the above considerations it seems advisable in the design of axially loaded Haydite columns to make a simple substitution of concretes, taking no account of a reduction in E, and making only such reduction in dead load as the substitution permits. The above equation indicates a distribution in stress

†Proc. A. S. T. M., Vol. XIV, Part II, 1914. "Relation between Deformation and Deflection in Reinforced Concrete Beams." by G. A. Maney.

between the concrete and the steel at working loads which has little real significance. For cases of eccentrically loaded columns in which the bending moment induced results from a rigid connection with a girder or slab, the low modulus of elasticity of the column may be of considerable advantage. As recently noted by Prof. Hardy Cross, when a heavy stiff girder is supported by relatively light columns, the bending moment induced in the column varies almost directly with its stiffness. Such a column may be difficult to design, since any attempt to increase the resisting moment is likely to increase the stiffness and consequent bending moment. A gravel concrete girder supported on Haydite concrete columns might thus represent a logical and sensible design.

SUMMARY

The principal conclusions to be drawn from the foregoing discussion may be summarized as follows:

The relation between compressive strength and water-cement ratio of Haydite concrete does not differ greatly from that for gravel concrete, all test results falling within a narrow zone as shown in Fig. 2. Concretes made with initially moist Haydite were consistently a little stronger than those made with dry Haydite aggregates. Due to their gradation and surface texture, Haydite aggregates in general required a larger water-cement ratio than gravel aggregates to produce a desired workability with a given mix, as indicated by slump and flow tests.

The determination of the water-cement ratio involves an accurate correction for the amount of absorbed moisture. The total absorption of moisture in a given period varies with the initial moisture condition of the Haydite aggregate, and is greater if the material is initially moist than if it is dry.

It is recommended that to secure workability the proportion by volume of coarse Haydite, of the sizes described herein, shall not exceed 55 per cent of the total aggregate. With this proportion, the unit weight of the usual range of structural concretes will be 115 to 120 lb. per cu. ft. for "C"-Haydite concrete and 95 to 100 lb. per cu. ft. for All-Haydite concrete.

The modulus of elasticity of "C"-Haydite concrete is about 75

per cent and that of All-Haydite concrete about 55 per cent, of that for gravel concrete.

With regard to the design of reinforced slabs and beams, there are two features of Haydite concrete that are important, the lightness in weight and the low modulus of elasticity. The first will permit considerable reductions in dead load over ordinary concrete, thus permitting a reduction in size of members or an increase in span, as well as decreasing loads on columns and footings.

The effect of low modulus of elasticity in a reinforced concrete beam or slab is to lower the neutral axis and to require a higher percentage of steel for balanced reinforcement. However, the depth of member may be decreased so that the saving in concrete quantities will offset the increase in steel requirements.

Combining the effects of light weight and low modulus of elasticity and taking advantage of possible reduction in slab depth, it is found that the substitution of "C"-Haydite for gravel concrete will permit a decrease of 12 to 9 per cent of concrete with an increase of 5 to 8 per cent of steel. With All-Haydite concrete there may be 20 to 15 per cent reduction in concrete with 11 to 17 per cent increase in steel. In rectangular beam design the conditions are even more favorable to the use of Haydite concrete.

The working stresses for bond and diagonal tension apparently may be taken as the same percentage of the compressive strength as is usually recommended for ordinary concrete.

The values of modulus of elasticity found for gravel concrete do not agree particularly well with the design values specified by the A. C. I. Joint Building Code, except at strengths of 3500 to 3750 lb. per sq. in. Use of the Code formula, modified by the introduction of 75 and 55 per cent for "C"-Haydite and All-Haydite concretes will produce considerable error for concretes of very high or very low strengths.

Despite the implications of the current column formulas, such as that of the Joint Building Code, the low modulus of elasticity should not be used to justify any increase in working stresses in Haydite columns over those for gravel concrete. Using concrete

of equal compressive strength, equal ultimate column strengths will result. The smaller stiffness of Haydite columns may be of advantage in decreasing column moments in rigid frames and like structures.

Because of the variation of construction costs in different localities, no attempt has been made to carry the foregoing studies through to the ultimate cost of any structure. However enough has been given to indicate the variation in quantities to be expected in certain common structural members. Other less tangible features of the Haydite concrete structure may lie in the possibility of increased building heights, the use of cheaper types of footings, the possibility of greater panel sizes, and the utilization of insulating properties of the material. The saving of weight in a structure such as in a bridge floor or in a longspan roof is of very obvious advantage. Both the properties of the material and its economy in design remain to be explored more fully.

Blast Furnace Slag as Concrete Aggregate

Report of Committee 201, Aggregate Specifications

Former Institute Committee E-5, Aggregates, assigned its subcommittee on Slag, H. J. Love, Chairman, to report a summary of available information on Blast Furnace Slag as Concrete Aggregate. The report here presented, as the result of that assignment, has been approved by the successor Committee 201, Aggregate Specifications, H. F. Clemmer, Chairman, and is here offered for the information of Institute members and others and discussion invited.—Editor

1. Definition of blast furnace slag

"Blast furnace slag is the non-metallic product, consisting essentially of silicates and alumino-silicates of lime, which is developed simultaneously with iron in the blast furnace." (Proc., Amer. Con. Inst., page 524, 1925).

2. Introduction

The technical committees of practically all the national organizations interested in construction materials have approved the use of slag aggregate in specifications or reports, including the following:

Amer. Concrete Institute; Amer. Soc. for Testing Materials; Amer. Railway Engineering Assn.; Amer. Soc. for Municipal Improvements; Associated Tile Manufacturers; National Paving Brick Manuf. Assn.; Portland Cement Assn.; Asphalt Institute; Amer. Assn. of State Highway Officials; Federal Specifications Board; U. S. Bureau of Roads (Dept. of Agriculture); U. S. Bureau of Standards (Dept. of Commerce); State Highway Departments of Alabama, Delaware, Dist. of Columbia, Florida, Georgia, Kentucky, Maryland, Mississippi, Missouri, New York, New Hamsphire, South Carolina, Ohio, Pennsylvania, Utah and West Virginia.

Although the tonnage of slag used is only about 4 per cent of the estimated total of all aggregates, this amount is confined almost exclusively to the large centers of population having steel mills, so that the use of slag becomes more important than is

indicated by its comparative tonnage. With this in mind, the Committee has made first-hand investigations of the properties and uses of blast furnace slag as revealed in (a) Actual service in the field and (b) Test data and technical literature. The latter have been made available to the Committee by the National Slag Association through its symposiums, which have been issued regularly during the last two years for the benefit of national technical societies engaged in formulating specifications.

On one inspection trip, 115 miles of slag concrete pavement were inspected, in addition to slag concrete factory buildings, office buildings, residences, bridges, water tanks, boiler stacks and fences. The latter item, fences, included the mile-long cast-in-place fence along the property of the Carnegie Steel Co., Youngstown, O., which has been standing for 13 years. Eight bridges were inspected on this trip, including the 16-year old North Howard bridge at Akron, O., the 15-year Lake Milton bridge west of Youngstown, O., the 14-year West Summit St. bridge at Warren, O., the North Hill Viaduct in Akron, and Lanternman's Falls bridge in Youngstown.

The interest shown in slag aggregate is evinced by papers published in the Proceedings of the American Concrete Institute:

"Slag as Concrete Aggregate," by Sanford E. Thompson, Vol. 13, p. 107.
"Tests of Slag as the Coarse Aggregate in Concrete," by P. J. Freeman, Vol. 14, p. 95.
"Fire Tests of Concrete Columns," by Walter A. Hull, Vol. 14, p. 138.
"Fire Tests of Concrete Columns," by Walter A. Hull, Vol. 16, p. 20.
"Flexural Strength of Plain Concrete," by Duff A. Abrams, Vol. 18, p. 20.
"Report of Fire Resistance of Concrete Building Units," by A. C. I. Committee P-5, Vol. 19, p. 331.
"Proportioning Concrete Materials," by George W. Hutchinson, Vol. 21, p. 148.
"Concrete Pavement Design," by L. W. Teller and J. T. Pauls, Vol. 22, p. 314.
"Tests of Retempered Concrete," by H. F. Gonnerman and P. M. Woodworth, Vol. 25, p. 344.

In addition to these papers, the Institute recognized slag aggregate in the following specifications:

"Proposed Specifications for Sidewalks and Floors," 1919.
"Standard Building Regulations for Reinforced Concrete," 1920.
"Standard Specifications for Monolithic Concrete Sewers and Reinforced Concrete Pipe Sewers," 1920.

"Standard Specification for Cement Concrete Pavements," 1924, revised in 1925.

"Tentative Purchase Specifications for Concrete Aggregates," 1929.

3. Processing blast furnace slag

The processing of slag really begins in the blast furnace, where the iron and slag are produced simultaneously. Layers of coke, flux stone and ore are placed in the furnace through an opening in the top, and the mass subjected to a blast of hot air. During combustion of the coke, the gangue or dross of the ore separates from the metallic iron and combines with the flux stone, and it is this combination, along with certain non-combustible material in the coke, which forms blast furnace slag. At the base of the furnace the molten slag and iron automatically separate due to difference in specific gravity, the slag floating on the iron. The slag is drawn off between iron flushes through the "slag notch" in the side of the furnace above the level of the molten iron. The iron is drawn off through a lower hole (the "iron notch") on the other side of the furnace, followed by any slag which has accumulated since the last slag flush.

Methods of Cooling

Slags are of two classes with regard to method of handling on leaving the furnace:

1—Slag which is brought from molten to solid form entirely through the agency of atmospheric air, known as air-cooled blast furnace slag.

2—Slag which is changed from molten to solid form by means of water or other rapid-cooling agency, known as granulated slag.

Although by far the greater portion of commercialized slag is in the air-cooled form, granulated slag finds an extensive use for the following purposes:

Fills, including backfilling.
Subgrade soil corrective in pavement construction.
Sub-base (blanket) course under all types of pavement.
Bedding course under brick pavement.
Granulated slag roads.
Aggregate in concrete products of all kinds.
Soil corrective in agriculture.
Raw material in manufacture of portland cement.

In Europe slag has been granulated by water, steam, and air under pressure, but American practice invariably makes use of

water. The molten slag is conducted in runners to a pit containing a small amount of water, where it may be struck by a stream of water under pressure, or may be granulated merely by falling into the pit. It can then be removed immediately with grab-buckets. Except for chemical composition, granulated slag is an entirely different product from air-cooled slag, being highly porous, easily crumbled in the hand, and occurring in sharp grains. It is gray or yellow in color. Except for concrete products, it is little used as concrete aggregate.

Methods of Disposal

Commercial slag aggregate for concrete is produced from air-cooled slag. From the furnace the molten slag may follow one of two courses: It may flow through runners direct to small pits alongside the furnace (known as the pit system of disposal), or it may be poured into large ladles mounted on standard railway trucks and conveyed to a more distant point for disposal. The latter operation, in turn, may take one of two methods:

1—The slag may be poured from the ladles into large, well-defined pits served by permanently-located pouring and loading tracks, from which it is regularly excavated (known as the modified pit system).

2—The slag may be poured from the ladles over a large plot of land with no very definite attempt to control width or depth of the solid slag so formed (known as the bank system).

Modern practice follows for the most part either the pit or modified pit system, each of which has its peculiar advantages. The pit system calls for a small percentage of the area demanded by the modified pit system, but that area must be alongside the furnace, which is not always feasible. The modified pit system, covering a larger area, has the advantage of providing greater storage facilities for the slag, so that the crushing and screening plant need not be running continuously as with the pit system. The bank system calls for large areas of land and has other disadvantages making for its disuse.

The molten slag is poured into the pits in a thin layer, which brings about a rapid drop in temperature and the solidification of the material. Succeeding layers retain some heat in the mass and a tempering action takes place, resulting in a hard, tough

product suitable for processing into concrete aggregate. When one pit has been filled by successive pourings, the filling of another begins, while a power shovel may enter the full pit and excavate the solidified slag. Where the pit system is in use, the shovel follows the filling of the pit very closely, but in large modified-pit layouts six months may elapse between filling and excavating. The time the slag lies in pits before use depends on the size of the pits and the demand for the product. At one time it was thought advisable to specify that the slag lie in the pits for a definite period of "aging," but tests and observations[15]* have shown this to be unnecessary, and now there are excavated and used annually in Ohio alone 1,250,000 tons of slag less than two weeks old. The total production for commercial purposes throughout the United States approximates 10,000,000 tons annually, about thirty per cent of which is used as concrete aggregate.

Crushing and Screening Operations

The process of cooling in layers provides planes in the slag mass which assist materially in excavation, and blasting is very seldom resorted to. The slag as excavated is loaded into dump cars and carried to the crushing and screening plant, where it passes through the processes typical of a plant preparing crushed aggregate for the market. There is one exception, however,—the slag is passed over magnetic separators during the operation in order to remove any small pieces of metallic iron carried over into the slag at the furnace. These are returned to the steel companies and reclaimed. After the screening operation has been completed, the slag is chuted to bins from which railroad cars or motor trucks may be filled.

4. Physical and chemical characteristics of slag

Air-cooled blast furnace slag as produced for commercial purposes is a rough, angular aggregate varying in color from light to dark gray, depending upon the character of the materials charged to the furnace. The roughness is due to its cellular structure, and the degree of roughness varies as the cells are large or small, many or few. These cells are formed by gases occluded in the slag at time of cooling, and are generally non-communicating; hence the term "cellular" or "vesicular" is more applicable than the term "porous." As excavated from the pit or bank,

*All references are to the bibliography at end of report.

slag breaks into roughly cubical pieces containing practically no flat pieces or slivers. This angularity, combined with its rough surface texture, gives slag a larger surface area per unit of volume than is usually found in concrete aggregates.

When fresh, there is a perceptible odor from blast furnace slag due to the small amount of sulphur compounds which it contains (1.00-1.75 per cent), but later this almost entirely disappears. Since it has passed through the high temperatures of the blast furnace, slag is a particularly clean material, and it is dug from pits in which nothing but slag is placed. It is also clean from the standpoint of adherent dust-coating, since this is readily removed during the screening operation.

Specific Gravity

The apparent specific gravity of air-cooled blast furnace slag as determined by the standard method averages about 2.25, although samples will be found ranging from 1.80 to 2.80 due to the cellular structure of the material. The true specific gravity of the solid material is fairly constant between 3.00 and 3.10.

Weight per Cubic Foot

The difference in specific gravity of various pieces of slag inevitably affects the weight of the aggregate per cubic foot,—if the unit of volume contains a large percentage of either light or heavy pieces, the weight may vary from 65 to 100 lb. per cu. ft. in the concrete aggregate sizes. The higher weights are relatively rare and represent only a very small per cent of the total tonnage. In general, the highest weight in the concrete aggregate sizes is about 85 lb. The foregoing weight values are based on the aggregate compacted in a dry condition; if the material is weighed loose, the values will be approximately 10 lb. per cu. ft. lower.

Voids and Absorption

Void determinations by the water displacement method show a void content of 40-45 per cent (average 42 per cent) in slag sized for concrete aggregate. If the determination is made by calculation from the specific gravity and weight per cubic foot, the result will be approximately the same if the specific gravity has been based on a representative sample. The presence of light or heavy pieces in practically all blast furnace slags makes

most specific gravity determinations of doubtful value and also greatly affects the absorption determination, since a few pieces of such slag will affect the absorption appreciably. Furthermore, the small sample chosen for absorption and specific gravity determinations may contain a much larger percentage of light or heavy pieces than the stockpile, bin or car of which it is supposed to be representative. Absorption tests show an average of about 4 per cent by weight with a high and low range of 25.0 to 0.25 per cent, with the great majority lying within the field of 2-4½ per cent absorption. Although these average figures appear somewhat high in comparison with other aggregates, the actual amount of water absorbed may be no greater than that indicated by a lower percentage on other aggregates, due to the latter having specific gravities averaging 20 per cent higher than slag. For example, a slag of specific gravity 2.21 and an absorption by weight of 6 per cent has the same absorption *by volume* as an aggregate of specific gravity 2.65 and an absorption by weight of 5 per cent.

The absorption which takes place in the first 30 minutes is usually that considered in proportioning slag concrete, and allowance must be made for this amount if the mixing water is to be kept under control.

Hardness and Toughness

Hardness and toughness factors have been found meaningless when applied to slag aggregate, and are no longer required in specifications.

Resistance to Abrasion

Testing slag for resistance to abrasion in the Deval machine is subject to the same difficulties as the specific gravity and absorption determinations. The small sample may contain many more of the light or heavy pieces than the pile from which it was taken, and these pieces will materially affect the test results. It is further believed that neither stone nor slag is adapted to such a test, since the sharp edges are rapidly broken off and appear as "loss by abrasion," even though such breakage represents a large part of that which occurs throughout the duration of the test. That this actually happens has been proven by tests on slag,[1] in which the sharp edges were first worn off in the machine, and the

material then subjected to the standard Deval test. The results showed that a slag which averaged 13.2 per cent loss in the natural state averaged only 8.2 per cent loss with the sharp edges removed. The standard Deval test, which is used only on large-sized pieces of aggregate, gives test results on slag varying from 2½—43 per cent, but the average loss lies within the limit of 12—16 per cent.

The modified Deval abrasion test, in which steel balls are introduced as an abrasive charge, is used in Ohio for testing the concrete aggregate sizes. The wear is proportionately greater, averaging about 25 per cent loss with a range of 15-38 per cent.

The abrasion factor as a specification requirement on slag is being eliminated from most specifications, following the path of hardness and toughness factors. The inaccuracy of the Deval abrasion test as applied to slag is strikingly brought out in data recently presented to the American Association of State Highway Officials. These data were obtained by 17 well known laboratories coöperating in tests of slags from four different sources. In order to insure uniformity of the samples, they were selected from each source by A. S. Rea, Chief Engineer of Tests, Ohio Highway Dept., and shipped to the respective laboratories for testing. The abrasion tests were run according to the Standard Deval method (A. S. T. M. Serial Designation D 2-26). When the results were reported, a decided variation among laboratories was evident. In the following table is summarized (a) The maximum, minimum and average of all laboratories for each slag, (b) The maximum variation from the average shown by any one laboratory, and (c) The mean variation from the average. The latter was arrived at by totalling the individual variations from the average, and dividing the sum by seventeen.

Slag	Abrasion Loss			Variations from Average Per Cent	
	Max.	Min.	Ave.	Maximum	Mean
A	23.0	9.1	13.6	69	15
B	21.5	7.8	13.2	62	14
C	18.3	5.1	12.9	60	15
D	6.6	1.0	4.7	78	18

These large variations from the average were not confined to any one laboratory; in general variations of 10 per cent or more

were obtained with all four slags in most of the laboratories.

To determine whether abrasion test results could be duplicated in the same laboratory, seven of the 17 laboratories were asked to run check samples. These consisted of samples designated Slags E, F, G and H, which were selected by Mr. Rea at the same time and from the same source as Slags A, B, C and D, respectively, although this fact was not known to the cooperating laboratories.

Considered as a separate series of tests, the results obtained on Slags E, F, G and H by the seven laboratories show equally as much variation between laboratories as did Slags A, B, C, and D. Tabulated in the same manner as the results from the latter, Slags E, F, G and H showed the following variations:

Slag	Abrasion Loss			Variations from Average Per Cent	
	Max.	Min.	Ave.	Maximum	Mean
E	14.5	3.9	11.7	67	22
F	15.1	9.8	12.6	22	12
G	13.7	4.1	11.4	64	21
H	6.0	0.4	4.0	90	30

In view of the foregoing, it is evident that the Standard Deval abrasion test will not develop concordant results on uniform samples of blast furnace slag, and therefore should be omitted from specifications for slag aggregate.

Crushing Strength

The crushing resistance of slag is about that of the more common aggregates,—approximately 9,000-12,000 lb. per sq. in. —but this factor is of minor importance since it is well above the strength required in concrete.

Cementation Value

The cementation value of blast furnace slag, as measured by the cementation test (described in U. S. Dept. of Agriculture Bulletin 347) varies according to the chemical composition, slags containing a large percentage of calcium oxide having a greater cementing value. Thus there is record of cementing values on blast furnace slag from 3 to 600, indicating the number of blows withstood by a cylinder made of a mixture of finely ground slag and water, the weight of the hammer being 1 kgm. and the height of fall 1 cm.

Melting Point

With regard to the melting point of slag, tests have shown it to be fluid between 2300-2600° F., viscous at 2200° F., and solid at 2100° F. or lower.

Chemical Composition

Chemically, blast furnace slag is made up of calcium oxide (CaO), alumina (Al_2O_3), silica (SiO_2), and magnesia (MgO); there are also small quantities of iron oxide (FeO), manganese oxide (MnO), and sulphur compounds. The chemical composition is entirely dependent upon the nature of the materials charged to the furnace,—the lime and magnesia in the flux stone, the alumina and silica in coke and ore. Although this brings about a difference in chemical analysis for slags from different sources, the slag from any one source maintains a marked degree of uniformity. Thus, monthly analyses of slags from 24 sources in Ohio, Pennsylvania and Kentucky over a 12-month period in 1927 showed mean variations from the average as indicated in the following tabulation:

CONSTITUENT	AVERAGE OF ALL TESTS	MEAN VARIATION FROM AVERAGE
	Per Cent	Per Cent
SiO_2	36.44	2.38
Al_2O_3	12.73	2.13
CaO	41.28	1.83
MgO	6.50	1.20

The relatively high variation in magnesia content (1.20 in 6.50) is due to the use of magnesian limestone or dolomite as flux at some furnaces, while others use nothing but limestone. The general range in chemical composition of blast furnace slag is within the following limits:

SiO_2	32–40 Per Cent
Al_2O_3	10–17 "
CaO	30–49 "
MgO	3–14 "
FeO	.5–2 "
Sulphur	1–2 "

Petrographic Composition

Petrographically, slag is composed mainly of silicates, such as di-calcium silicate and calcium alumino-silicate. There have also been found melilite, periclase, spinel, forsterite, pyroxene,

cordierite, mullite, christobilite, tridymite, anorthite, gehlenite, olivine and akermanite.

5. Properties of slag concrete

Weight

The weight of slag concrete varies from 127 to 150 lb. per cu. ft. according to the mix used and the weight of the slag aggregate itself. Rich mixes containing more of the relatively heavy cement and sand naturally weigh more than the leaner mixes. The figure of 135 lb. per cu. ft. may be taken as average for the intermediate mixes (1:2:3, 1:2½:4 etc.) when a medium-weight slag (70-80 lb. per cu. ft. compact) is used as coarse aggregate.

Absorption

The absorption of any concrete is more affected by the mortar, the cement content, the water content, and the density of the concrete than by the type of aggregate used. The average of all available absorption tests on slag concrete show a value of 5.5 per cent by weight. As in the case of absorption determinations on slag aggregate, this value is not as high as it may appear, since any stated weight of water absorbed will show up as a larger percentage of absorption in slag concrete than in other concretes weighing 10-15 lb. per cu. ft. more. Five and one-half per cent absorption in slag concrete corresponds to 5 per cent absorption in the heavier concretes.

Bond

When "bond" is spoken of in connection with concrete, it may mean either of two properties: (a) Adhesion between concrete and reinforcing steel, or (b) Adhesion between mortar and aggregate. Bond of steel with concrete, being almost entirely a function of the mortar, is the same for slag concrete as other concretes.

With respect to adhesion of mortar and aggregate blast furnace slag possesses several advantages. The rough pitted surfaces and the angularity of the fragments each aids the mortar in obtaining a high degree of bond, so that tests on slag concrete very seldom show failure of the bond between mortar and slag. Such a bond is never the weak point in a slag concrete. Quoting Sanford E. Thompson[3] on this subject:

Inspection of the crushed specimens (of slag concrete) where breaks occur through the pieces shows a very strong bond between the mortar and the pieces of slag. While this probably is due in part to the rough nature of the surface of the slag, it is evident from inspection that a chemical action has taken place between the slag and the mortar. This is shown by a circle of a different color around the edges of the sections of slag.

Durability

The durability of slag concrete has been tested in thousands of structures over a period of 50 years, including buildings, machinery foundations, bridges and pavements. The durability of the aggregate itself has been proven by its successful use as ballast, road material and sewage filtering medium, and also by various test methods. The most prominent of the latter are the sodium sulphate test and the freezing and thawing test. Raymond Harsch[4] has reported sodium sulphate tests on slags from 32 sources in the United States, all the samples being unaffected after 5 cycles of the test.

C. C. Hommon[5] selected thirty-seven samples of slag which had been used as sewage filtering media in as many beds throughout the eastern and southern states. Ten pieces from each of these samples were subjected to 20 cycles of the sodium sulphate test. Although the material had been exposed to the effects of sewage and weather for periods varying from 1 to 21 years, this admittedly severe test had little effect on them, as shown in the accompanying table. The four samples which showed any effect whatever were aged respectively 6, 8, 12 and 14 years. The following table, which includes stones and gravel sampled and tested during the same investigation, shows the results of the tests:

AGGREGATE	NUMBER OF PIECES				PIECES UNAFFECTED
	Tested	Checked	Chipped	Split	Crumbled	Per Cent
Slag	340	0	0	0	0	100
Limestone	20	0	0	0	0	100
Granite	30	0	0	0	0	100
Traprock	10	0	0	0	0	100
Slag	30	1	1	1	0	90
Granite	10	0	0	1	0	90
Slag	10	0	0	2	0	80
Feldspar	10	2	0	0	0	80
Gravel	10	0	0	2	0	80

Limestone	10	2	0	2	0	60
Limestone	10	3	0	0	2	50

In tests by George B. Gascoigne[6], six slags from as many sources were subjected to 10 cycles of sodium sulphate, with result that three pieces of slag out of 36 split, but none of the others were affected in any way. In addition, three of the slag samples were carried to 20 cycles; of the 18 pieces tested at 20 cycles, 6 were unaffected, 4 showed checking, 4 splitting and 4 cracking, but none of the pieces crumbled.

The most extensive series of sodium sulphate tests on record has been carried out by Fred Hubbard[7] on slags from 44 sources in Ohio, Pennsylvania, Maryland and Kentucky. Each of the 422 samples tested underwent 5 cycles of sodium sulphate without showing any signs of checking or cracking, representing a total of 4220 separate pieces of slag. In addition, 358 of the samples (3580 pieces) were carried through to 20 cycles. Of these, 3550 remained intact, denoting a remarkable resistance to the severe action of expanding sodium sulphate crystals. The 30 pieces which did not sustain 20 cycles without some breakdown showed a clean splitting off of one or more fragments in practically every case, there being only three pieces in which there was any crumbling of the material. In terms of percentage, this amounts to 0.08 per cent crumbling material—a negligible quantity.

Freezing and thawing tests of slag have been reported by Edward Orton Jr.,[8] showing a loss of only 0.65 per cent after 30 alternations. G. B. Gascoigne's[6] report also includes the results of such tests, carried to 100 cycles on 2-3 in. pieces as shown in the following table:

AGGREGATE	PIECES TESTED		CONDITION FOLLOWING TEST			
	No.	Weight, Gm.	Pieces over 1″ No.	Pieces over 1″ Weight, Gm.	Fines under 1″ Weight, Gm.	Fines under 1″ Per Cent by Wt.
Slag—1	27	3250	28	3168	82	2.5
Slag—2	22	2993	25	2864	129	4.3
Slag—3	39	3320	40	3209	111	3.3
Slag—4	20	3780	29	3594	186	4.9
Slag—5	18	3966	27	3877	89	2.2
Slag—6	25	3147	29	2935	212	6.7

Tests at the U. S. Bureau of Standards[9] included not only freezing and thawing, but boiling and drying, sodium chloride, and sodium sulphate. Each aggregate was from a different source—6 slags, 3 granites, 4 traprocks, 4 sandstones, 7 limestones and 12 gravels. At the time of the last report, 24 cycles of freezing and thawing had been completed on 28 of the 36 aggregates, and 40 cycles of the other three methods on all 36 aggregates. The report states in part:

> Of the types of aggregates used in these tests, the limestones are apparently showing the greatest disintegration. With few exceptions, by far the greater number of pieces of gravel are sound. Granites have not been affected, and only occasional pieces of trap, sandstone and slag have shown signs of breaking up under these tests.

Probably the best test of the durability of any aggregate is its behavior when used as a filtering medium in sewage beds. Here the surface pieces receive every possible temperature extreme, in addition to alternate freezing and thawing, alternate wetting and drying, and the destructive effects of the sewage itself, which is often increased by the presence of industrial wastes such as acid pickle-liquor from steel mills, tannery wastes, etc. Yet the recent survey of C. C. Hommon[5] showed very little disintegration of the slag filtering medium in 37 sewage beds, 16 of which had been in service for 10-21 years. This survey covered all the slag filter beds which could be found in the United States, and particular attention was paid to the three possible forms of disintegration—splitting, crumbling and flaking. At 29 of the plants, crumbling and flaking were either not present or it was necessary to examine very closely to find them. At 26 plants the same condition obtained with regard to splitting. At the plants where splitting and crumbling could be found, the total amount was comparatively small and would have no effect on the operation of the filters. Although more pieces of slag were affected by flaking, the total amount of such flaking did not represent any greater disintegration than by splitting and crumbling.

The durability of slag under sewage bed conditions has been tested by George. H. Gascoigne.[6] Samples of the material were placed in colanders on the surface of an operating sewage bed within range of the spray from the distributing nozzles. The

samples were left on the bed from Jan. 1927 till Feb. 1928, in which time there were 37 days during which the temperature at all times was below freezing point. The minimum atmospheric temperature was —8° F. and the maximum 99° F. Alternate wettings and dryings occurred on the bed 40-50 times daily during the period. The original size of the aggregates was 2-3 in., and the following table shows the results of the test. The fine material below $\frac{3}{16}$ in. (lost through the holes in the colander) was not calculated:

AGGREGATE	PIECES TESTED		CONDITION AFTER TEST		
	No.	Weight, Gm.	Pieces over 1″	Fines $\frac{3}{16}$″ –1″ Weight, Gm.	Per Cent by Wt.
Slag—1	20	3117	20	0	0
Slag—2	20	2939	20	22	.7
Slag—3	20	1938	20	10	.5
Slag—4	20	3969	20	5	.1
Slag—5	20	3336	20	18	.5
Slag—6	20	2970	20	5	.1

In view of the behavior of slag in the accelerated durability tests just outlined, it would seem superfluous to state that it is a durable and stable material, but there is one small point in this connection which may need clarification. L. G. Carmick's[10] investigations show that slag which is solid at atmospheric temperatures (in other words, as delivered on the job) will remain entirely stable and durable, but occasionally there is produced a small quantity of "limy" slag which crumbles to powder during cooling if it is not processed correctly. It has been found that slow cooling will cause the calcium orthosilicate in certain slags to pass through three forms (alpha, beta and gamma), the last of which involves a volume increase of about 10 per cent and disintegration of the slag. However, if the general practice is followed and the molten slag is poured in thin layers so as to chill quickly and solidify it, the calcium orthosilicate is arrested at the beta form, which is entirely stable and involves no volume change. Tests have proved that any disintegration which takes place does so before the slag has cooled, hence no slag likely to crumble will be found in the finished commercial product. The small amount of fine material developed in the pits by crumbling is removed by the screening opera-

tions, and furthermore has reached its final form and is entirely inert as proved by tests. C. C. Hommon[5] reports a case where hot slag which was visibly crumbling was immersed in water and the crumbling was completely arrested. Further, the cooled slag withstood 5 cycles of sodium sulphate successfully. He also cites the instance of a large piece of slag, part of which had crumbled during cooling; the solid material remaining after cooling withstood 20 cycles of sodium sulphate. The final proof of the relative unimportance of crumbling slag is the fact that there has never been any crumbled or disintegrated slag found in slag concrete.

Like slag aggregate, slag concrete receives its most severe durability test in connection with sewage disposal beds. Concrete is used for the walls and floors of the beds, and also for primary and secondary settling tanks. All these receive the weathering that any exposed concrete is subject to, and in addition the wetting and drying, freezing and thawing caused by the conditions under which such plants are operated. The character of the sewage itself probably has a decided effect in bringing about disintegration, but slag concrete has been used with entire satisfaction for such construction in 19 sewage beds in the United States, including the temperature ranges to be found in New York, Pennsylvania, Ohio, Alabama and Tennessee.

A report of the A. S. T. M. Committee on Concrete Aggregates[11] makes the following conclusive statement with regard to the durability of slag concrete:

> A large amount of test data has shown this material to be acceptable as concrete aggregate, and there is also a large amount of data from the field in testimony of the permanence and durability of slag concrete structures.
>
> No restriction has been placed upon the sulphuric content of slag, for the reason that inspections made by members of the Committee of reinforced slag concrete structures in the course of demolition showed no corrosion of reinforcement that could be attributed to the slag, nor is there any published evidence that such corrosion has been observed so far as the Committee is aware.

The last sentence of the foregoing statement by Committee C-9 answers a question which has often been raised by engineers: "Does slag concrete have any corrosive effect on steel reinforcement?" There has never been a case where slag has been shown

to have affected the reinforcing steel in any way, and many concrete authorities have expressed a decided belief that such action cannot happen. If the concrete is dense and the steel placed at a proper depth from the surface, every possible protection has been afforded, and the steel will be unaffected.

If slag has any corrosive effect on steel, it would have come to light in connection with other uses of the material than reinforced concrete, where the steel is protected from air and moisture. For example, in sewage disposal beds the feeder and riser pipes are covered with slag to a depth of 5-8 ft., and liquid sewage is applied continuously, giving rise to the very conditions which should produce decided deterioration—air, moisture, and even acids. The liquid running down over the slag and thence over the piping undoubtedly produces a more severe condition tending to affect the iron than exists in reinforced concrete, and yet there is a total of 37 slag sewage disposal beds in the United States with service histories up to 21 years, in none of which are there any recorded data that the pipes deteriorated more quickly than usual. This is in spite of the fact that in several cases stone and slag beds have formed units of the same plant, with the opportunity to compare the behavior of each.

The Masonry Committee of the Amer. Railway Engineering Association[12] has also recorded its inability to find instances of corrosion of steel in slag concrete:

> The extensive use of slag concrete over a period of years has demonstrated its permanence for buildings, retaining walls, bridges and foundation work where the structure is exposed to ordinary conditions. No case has been brought to notice where embedded steel became corroded in slag concrete.

The U. S. Bureau of Standards[1] has conducted tests to determine whether there is any corrosive effect of slag, and made the following report:

> To the extent of the tests there was no sign of disintegration due to sulphide sulphur or other causes. In the past there has been some hesitation on the part of engineers to permit the use of slag aggregate without certain special limitations on the material such as weight per cu. ft. and sulphur content. Experience has shown, however, that there is probably no greater need for such restrictions in the case of blast furnace slag than for other commonly used and accepted aggregates.

Sanford E. Thompson[14] made an investigation of slag concrete structures in a number of cities in order to determine the durability of the material, and reported:

I have made chemical and physical tests and also visited several cities where slag concrete has been used for a number of years. As a result of careful examination of various structures made with slag concrete, and interviews with users of slag concrete, I find no evidence of disintegration where portland cement was used. In certain cases with puzzolan cement, the concrete is not in first-class condition, but this is to be expected with any puzzolan cement concrete laid in air. No authentic cases of deterioration of slag concrete made with portland cement, or of rusting of steel embedded in such concrete, have been discovered.

Tests at the Pittsburgh Testing Laboratory[15] showed no corrosion of steel in 5-year old concrete made with slag aggregate from 9 sources in the United States. Slight rust spots were found where air pockets had formed, but these were common to all the aggregates used in the tests—limestone, dolomite, trap-rock, granite, gravel and blast furnace slag.

A. T. Goldbeck[19] is one of the many concrete authorities who have been unable to find a case of slag concrete corroding steel reinforcing, and states:

I know of no cases of well-defined corrosive action of reinforcing steel in slag concrete. I examined, some 8 years ago sections of reinforcing steel removed from a concrete slab in our presence at the Swedeland (slag) plant in Pennsylvania. The sections removed were about three feet long. Two of them were perfectly sound, one end of the third rod had a few pits, showing no rust, but the surfaces were perfectly bright. Since the slab removed had been situated between electric railroad tracks and since there was considerable moisture present, I have always felt that this pitting might have been due to electrolytic action. We were told that this slab had been constructed 11 years previous to the time of our inspection.

Other statements regarding the durability of slag concrete have been made by Wilbur J. Watson, consulting engineer, Cleveland, Ohio[17]; A. D. Bender of Cleveland Macadam Co.[18]; John M. Goehring of Duquesne Slag Products[18]; L. W. Walter of the Erie Railroad[20]; F. Tschudy of the Tennessee Coal, Iron & R. R. Co.[18,21]; C. S. Hill of Eng.-News Record[22]; and W. S. Harger, of the New York State Highway Dept.[23].

Resistance to High Temperatures and Fire

When portland cement concrete is subjected to high temperatures such as commonly occur in building fires, the type of aggre-

gate used may have a decided influence on the resistance of the concrete to deterioration. Blast furnace slag experiences no disruptive change of volume under such conditions because of its low and uniform thermal expansion at all temperatures.

One of the earliest fire tests on record was that conducted by the British Fire Prevention Committee[24] in 1906, consisting of a fire endurance test followed by a hose stream test, on a loaded floor. The slag concrete bay in the floor was reported as showing slightly less buckling and much less cracking than other bays containing gravel, granite, clinker and brick as aggregates. Only the bay containing coke breeze as aggregate was in better condition.

Later tests by the British Fire Prevention Committee[25] in 1917-19 included as aggregates, two blast furnace slags, six gravels, seven sandstones, four limestones, eleven granites, five bricks, two coke breezes, two pan breezes and three coal clinkers, in both plain and reinforced concrete slabs. Fire and hose stream tests were made on the loaded slabs, and thermal conductivity values determined. The report of the tests states:

> Coarse aggregates of clean broken bricks and burnt clays gave the most satisfactory results from strength and resistance to fire. Blast furnace slag appeared to be almost as good. Pan breeze and clinker were fairly satisfactory. The gravels, sandstones, granites and other highly siliceous aggregates were unsatisfactory, while the fine-grained igneous rocks, such as basalt, gave satisfactory results. The limestones were better than the siliceous aggregates. In parallel with the tests of plain and reinforced concrete slabs, the heat conductivity of the various concretes was measured. The coarse aggregates in the slabs which did not attain to 1200° F. were slag, limestone, basalt, andesite, coke breeze, broken brick and whinstone. The highest temperatures at points near the top of the slabs were attained with concretes having as coarse aggregates siliceous gravels, calcareous gravel, coke breeze and quartzite.

W. A. Hull[26] reports fire tests on loaded concrete columns which were later tested in compression. Part of his conclusions follows:

> The results contribute additional evidence that gravels of 3 distinct types, all high in quartz, give less satisfactory results under fire conditions than concretes from limestone, traprock and blast furnace slag aggregates. Columns of these types from traprock and blast furnace slag concrete show no tendency to spall or crack to any important extent under the conditions of the standard 4-hour fire test. In all cases, columns from traprock and slag aggregates have

shown themselves capable of bearing considerably more than twice their respective working loads before cooling, following the 4-hour fire test. The observation that neither the traprock nor the slag concrete appears to have any tendency to spall or any other malignant tendency under the conditions of these tests is important and reassuring.

Fire tests of concrete building units at the Underwriters' Laboratories[27] in Chicago resulted in the conclusion that "Coarse aggregates of limestone, calcareous pebbles, cinders or crushed slag perform with comparative similarity under standard fire exposure conditions."

Tests of German concrete aggregates by Dr. Kurt Endell[28] included blast furnace slag, granite, basalt, limestone, quartz, quartzose and burnt brick, and resulted in the following report:

Quartz and granite expand up to 930° F. and then undergo an alteration which is accompanied by cracking of the material. Basalt and blast furnace slag show a smaller expansion due to heat and one which proceeds uniformly. The practical results of the investigation show that for heat-resisting structures quartz-containing mixtures should not be used, but aggregates composed of blast furnace slag, basalt and limestone should be employed because of their slow and uniform expansion.

In October, 1925, at Birmingham, Ala., a small house built of slag concrete tile was filled with inflammable materials and ignited. While the walls were white hot a hose stream was turned on it, but the State Fire Marshall, Chester E. Johnson[29] reports:

On inspection of the building no cracks of any nature were found, nor was any disintegration or crumbling of the tile apparent. On breaking through the wall and examining the interior webs of the tile, no cracks or other evidence of failure were found. The ceiling was undamaged, and the concrete tile roof showed no evidence of having been affected. The units plainly demonstrated their fire-resisting qualities and are to be highly recommended for use in the construction of permanent and fireproof structures.

Exactly 1 year later the same type of tile underwent a severe test of its fire-resisting properties in actual construction. During the building of the Calvary Baptist Church in Tuscaloosa, Ala., using slag concrete tile, the structure was destroyed by fire except for the tile, which withstood the flames in an extraordinary manner. Quoting from the report in *Concrete:*[30]

Fortunately for the underwriters and the congregation, the concrete tile walls resisted the flames in a remarkable manner. The blaze gained rapidly, probably having made considerable headway before discovery. Then

for two and a half hours the structure burned fiercely, consuming timbered and wooden interior, scaffolding, floors and finally the roof, which was supported by unprotected steel trusses. The walls were relatively quite high for their length, but this fact has no bearing except to accentuate their good behavior in the fire. There were five large arched windows in each side, as well as other large openings which provided plenty of draft and tended to weaken the walls. When the fire was finally subdued . . . two of the main walls had been carried down. These walls were forced over by the collapse of the roof trusses after having been deprived of the bracing effect of the previously collapsed floor members. The high front wall, one of the sidewalls, and the chimney remained standing. The chimney will doubtless be used in rebuilding the structure. The stucco apparently is in perfect condition except where blackened by smoke, although subject to the very severe test of having water from the fire hose thrown upon it while in an extremely hot condition. There was no discernible distortion of these walls at any point, a rather remarkable fact under the circumstances. No cracking or spalling of the units was found and the walls which were overturned broke up into a few large pieces of masonry apparently as strong as any first-class masonry not exposed to fire. As a result of the fire performance of the concrete tile in this fire, the same material was purchased for the rebuilding of the structure.

George H. Sanger[31] cites the use of slag concrete at the plant of the Northwestern Iron Co. at Mayville, Wis., as an example of its resistance to high temperatures:

In the last five years we have placed nearly 30,000 yards of slag concrete for various purposes and subject to a wide range of conditions and I have never known of a failure that could in any way be traced to the slag. In places where the concrete has been subjected to a considerable amount of heat, some few cracks have developed, but they were undoubtedly due to the expansion.

Our cooling pit at the pig machine probably represents the most severe conditions imposed upon any of our concrete. The pit is first filled with cold water, into which the pig machine discharges red-hot pig iron, which soon heats the water to boiling point; at the end of the cast the hot water is drawn off and the pit is refilled with cold water. As this cycle occurs every two hours the concrete is in a continual state of expansion and contraction, and is also in direct contact with the boiling water and steam. Thus far there have been no signs of spalling or surface cracks; the surface is apparently in as good condition as it was when the forms were first removed.

Compressive Strength

More data have been compiled on the compressive strength of concrete than on any other quality, although recently there has been a tendency to use other specific tests along with the compressive where the concrete is to undergo a particular type of

service. For example, pavement concrete is tested for transverse strength as well as compressive. However, it is believed by most concrete authorities that the compressive strength of a concrete is a very fair general indication of all-round quality.

Other conditions of test being equal, such as cement content, water-cement-ratio, etc., there is very little difference between the compressive strengths of concretes employing the more common mineral aggregates. This is illustrated in the results of tests at the laboratory of the Portland Cement Association[32], which included as aggregates 19 slags, 27 gravels, 36 limestones, 14 granites, 11 sandstones and 14 traprocks. Since each aggregate was selected from a different source, these tests should furnish a representative picture of the relative compressive strength of slag concrete. The mix was 1 part of cement to 4 parts of dry rodded mixed aggregates, which resulted in practically equal cement content throughout. Two combinations of aggregates were used: "A" containing 38 per cent sand and "B" 48 per cent. The coarse aggregates were graded differently in each of the combinations: "A" having 25 per cent No. 4-⅜ in., 50 per cent ⅜-¾ in., and 25 per cent ¾-1½ in., while the "B" grading was 25 per cent ⅜-¾ in. and 75 per cent ¾-1½ in. The cylinders were stored 14 days in the moist room, then in air till tested at 90 days, 5 cylinders being broken for each concrete containing a different aggregate. In the "A" grading, the average of all concretes was 4393 lb. per sq. in. Taking this value as 100, the averages of the individual aggregates were as follows: Limestone—103; Sandstone—101; Granite—99; Gravel—98; Slag—97; and Traprock—96. In the "B" grading, the general average was 4217 lb. per sq. in. Taking this value as 100, the averages of the individual aggregates were: Limestone—102; Traprock—101; Granite—99; Slag—98; Gravel—97; and Sandstone—96. It is apparent that the difference between aggregates is not sufficient to justify precedence of one over the other.

Stanton Walker[33] has reported other tests at the P. C. A. Laboratory on 7 different mixes varying from 1:2 to 1:6, the proportioning being on the same basis as before. Limestone,

granite, gravel and slag were the aggregates tested, and two curing methods were used: (a) In damp sand for 90 days, and (b) In damp sand for 14 days and the remainder of 90 days in air. In the damp sand curing, the average value for all mixes and all aggregates was 3940 lb. per sq. in. Taking this value as 100, the averages of the individual aggregates were: Granite —103; Limestone—100; Slag—98; and Gravel—96. In the air curing, the general average was 3626 lb. per sq. in. Taking this value as 100, the averages of the individual aggregates were: Limestone—102; Granite—101; Gravel—99; and Slag—97. Here again the difference between aggregates is so slight as to be negligible.

Not quite so close an approximation of compressive strengths is noted in further tests at the P. C. A. Laboratory reported by Duff A. Abrams[34]. The aggregates were slag, limestone, gravel and granite, tested at 1 year after storage in damp sand. The proportions were 1 part cement to 4 parts of dry rodded mixed aggregates. The general average was 4312 lb. per sq. in. Taking this value as 100, the averages of the individual aggregates were: Gravel—115; Slag—105; Limestone—91; and Granite—87.

Tests of the U. S. Bureau of Roads recently reported by W. F. Kellerman[35] included as aggregates 3 slags, 4 limestones, 1 sandstone, 1 traprock, 1 granite, and 7 gravels, in 4 distinct gradations. Two mixes were used, 1:1.6:3 and 1:2:4, based on dry rodded volumes of aggregates. Tested at 28 days after storage in moist air, the grand average strength for the richer mix was 3682 lb. per sq. in. Taking this value as 100,the averages of the individual aggregates were: Sandstone—113; Slag—101; Granite—99; Limestone—98; Gravel—97; Traprock—92. The grand average strength for the leaner mix was 2776 lb. per sq. in. Taking this value as 100, the average of the individual aggregates were: Sandstone—113; Limestone—100; Gravel—99; Granite—99; Slag—96; Traprock—94.

Raymond Harsch's[4] investigation for the U. S. Bureau of Roads included compression tests on slag concrete specimens. These were made with slags selected from 19 different sources in the United States, the mix being proportioned 1:2:3 based on dry rodded volumes of aggregates. For check aggregates one

gravel (average quality) and one limestone (above average quality) were used. Tested after 28 days damp sand storage, the average of all concretes was 3123 lb. per sq. in., 3-5 cylinders being tested for each aggregate source. Taking this average as 100, the slag concretes averaged 104, the stone concrete 95 and the gravel concrete 85.

Nine slags from as many sources were included in P. J. Freeman's[15] ten-year concrete tests, as well as two gravels, one traprock, one granite, and two limestones. The mix was proportioned 1:2:4 based on dry compact volumes of aggregates, and compression cylinders were broken at various ages up to 10 years. The strengths of all concretes were affected similarly by the type of storage, which was 35 days in damp sand followed by the remainder of 5 years in a warm dry laboratory. At 5 years, the cylinders were stored outside in the weather until 9⅔ years, when they were placed in damp sand until tested at 10 years. Mr. Freeman states in his report:

> All concrete, regardless of type of coarse aggregate, increased in strength when stored in dry air up to the age of 1 year, and after that time decreased in strength so long as the air storage continued. The strength of the concrete was regained after storage in the weather, and at the end of 10 years it has exceeded in strength the results obtained at 1 year.

Mr. Freeman's report also states that the compressive strength was not affected by:

> (a) Weight of the slag aggregate. The compact weight varied from 64 to 84 lb. per cu. ft.
>
> (b) Chemical analyses of the slags. The silica content varied from 31.53 to 36.72 per cent; the alumina from 11.81 to 14.11 per cent; the lime from 31.75 to 45.80 per cent; and the magnesia from 1.62 to 19.43 per cent.
>
> (c) Age of the slags. Some were only a few days old when used, while others had lain in banks for as much as 15 years.

At the end of 5 years in warm dry air, the general average of all concretes was 3939 lb. per sq. in. Taking this value as 100, the averages of the individual aggregates were: Slag—107; Granite—102; Traprock—94; Limestone—92; and Gravel—77, these values being the average of 27 specimens of slag concrete, 6 of gravel, 3 of traprock, 3 of granite and 6 of limestone. At 10 years, the general average strength was 5616 lb. per sq. in. Taking this value as 100, the averages of the individual aggregates were: Granite—103; Limestone—102; Slag—100; Trap-

rock—95; and Gravel—90. The values at 10 years were the average of nine specimens of slag concrete, five of limestone, two of gravel, two of granite and one of traprock.

Transverse Strength

The earlier beam tests of concrete made in a compression machine, consisted of supporting the beam at each end and applying the load either at the center point of the top surface or at the third points. Third-point loading was used in the P. C. A. Laboratory tests reported by Duff A. Abrams[34], the aggregates being slag, limestone, gravel and granite. The proportions were 1 part cement to 4 parts dry rodded mixed aggregates, which resulted in practically equal cement content throughout. At 7 days, the general average of all concretes (7 x 10 x 36 in. beams) was 423 lb. per sq. in. Taking this value as 100, the averages of the individual aggregates were: Slag—106; Limestone—104; Gravel—99; and Granite—90. At 28 days, the general average was 557 lb. per sq. in. Taking this value as 100, the averages of the individual aggregates were: Limestone —106; Slag—104; Gravel—98; and Granite—97. The foregoing figures are based on the average of 5 breaks, except the 28 day gravel value, which is on 25 breaks.

Later tests at the P. C. A. Laboratory used the same mix, method of test, and aggregates except that sandstone was included. These were reported by H. F. Gonnerman and E. C. Shuman[36]. At 7 days, the average strength for all concretes (7 x 10 x 38 in. beams) was 454 lb. per sq. in. Taking this value as 100, the averages of the individual aggregates were: Limestone—112; Sandstone—101; Slag—99; Gravel—98; and Granite —90. At 28 days, the average of all concretes was 609 lb. per sq. in. Taking this value as 100, the averages of the individual aggregates were: Limestone—115; Slag—102; Gravel—98; Granite—95; and Sandstone—92. These values are based on an average of 5 breaks, except the 28-day gravel value, which is on 15 breaks.

Center-loading tests of slag concrete have been reported by F. H. Jackson and J. T. Pauls[37] in connection with the Arlington Circular Track experiment of the U. S. Bureau of Roads. These were on 6 x 8 x 48 in. beams tested at 90 days in a 1:1½:3 field mix. The aggregates were 9 gravels, 10 stones and 3 slags. The

average of 2 beams for each aggregate showed a general average of 575 lb. per sq. in. Taking this value as 100, the average of the slag concretes is represented by 117, the stone concrete by 99 and the gravel concrete by 95.

During the construction of a 5½-mile section of the Cleveland-Meadville Road[38] in 1928, slag concrete beams were tested daily by the cantilever test at every age from 3 to 16 days, and thereafter intermittently until 26 days. The mix was 1 part cement to 5 parts of total aggregates (fine and coarse) measured loose, and the beams were 6 x 6 x 40 in. The machine used was a portable one developed by the Ohio Highway Dept., using a worm-and-gear for applying the load and a steel extension arm. The 3-day strength was 598 lb. per sq. in. Taking this value as 100, the average strengths at other ages were as follows:

Four day—110; 5—110; 6—111; 7—117; 8—129; 9—124; 10—125; 11—116; 12—127; 13—139; 14—126; 15—122; and 16 day—130. At 26 days the strength was 817 lb. per sq. in., or an increase of 36 per cent over the 3-day strength.

The average of all slag concrete pavements built by the Ohio Highway Dept. in 1928 shows the transverse values tabulated below. These data have been furnished from the files of the department through the courtesy of A. S. Rea and D. W. Leggett[39], and represent 370 tests of 6 x 6 x 40 in. beams. The mix throughout was the same as shown for the Cleveland-Meadville Road:

AGE AT TEST DAYS	NUMBER OF BEAMS	AVERAGE TRANSVERSE STRENGTH
3	1	598
4	4	653
5	7	655
6	4	611
7	102	656
8	11	696
9	8	734
10	7	675
11	4	675
12	10	715
13	4	766
14	102	732
15	2	805

16	2	743
21	17	762
28	85	801

For concrete base work the Ohio Highway Dept. uses a leaner mix of 1 part cement to 7 parts total aggregate (fine and coarse) measured loose. The average of 107 slag concrete beams tested during 1928 showed strengths of 446 lb. per sq. in. at 7 days, 544 lb. at 14 days, 641 lb. at 21 days, and 602 lb. at 28 days.

Tests at the Ohio Highway Dept. Laboratory in 1928 reported by A. S. Rea[40] indicate that the type of testing machine, or the type of specimen, or both, affects the results appreciably. The machine used by the Ohio Highway Dept. takes a 6 x 6 x 40 in. specimen, while the original machine developed by H. F. Clemmer and Fred Burggraf[41] takes a 6 x 8 x 30 in. beam. Five slags from as many sources were tested in 2 mixes, 1:5 and 1:5½, proportioned 1 part cement to a stated number of parts of total aggregate measured in a dry loose condition (cement content respectively 6.7 and 6.4 sacks per cu. yd. for the two mixes used). The five slags were chosen to represent the extremes found in commercial practice, ranging from 61 to 89 lb. per cu ft. (dry, loose weight). The weight per cu. ft. did not seem to be reflected in the transverse strength, since the heaviest slag had only a slight advantage in strength at 7 days and this disappeared at later ages. The results of the tests are shown in the following tabulation:

MIX	AGE AT TEST, DAYS	AVERAGE STRENGTH OF SLAG CONCRETES, MODULUS OF RUPTURE	
		Ohio Machine	Illinois Machine
1:5	7	672	548
	28	761	623
	90	861	709
1:5½	7	674	556
	28	744	607
	90	818	675

Slag concrete pavements built by the Pennsylvania Highway Dept. in 1928 were proportioned by either weight or volume. The average of 1312 beam tests of slag concrete, 6470 of stone concrete, and 618 of gravel concrete are shown in the accompanying tabulation reported by H. S. Mattimore[42]. The tests

were made on a machine using a wood extension arm, the specimens being 6 x 8 x 40 in.:

MIX	AGE AT TEST, DAYS	AVERAGE STRENGTH, MODULUS OF RUPTURE Slag	Stone	Gravel
*1:2:3	10	633	583	576
	14	656	631	596
	21	681	601	—
†1:2:3¼	10	617	589	477
	14	621	612	591

*By volume, with no compensation for bulking of sand
†By volume, with compensation for bulking of sand.
‡By weight, with compensation for moisture in sand.

The U. S. Bureau of Roads tests reported by W. F. Kellermann[35] were also made with the machine having the wood extension arm, the load being applied through a worm and gear arrangement. Four limestones, 1 granite, 1 sandstone, 1 traprock, 3 slags and 7 gravels were the aggregates in two mixes,—1:1.6:3 and 1:2:4, based on dry rodded volumes of aggregates. The three slags varied in compact weight from 65 to 82 lb. per cu. ft., but this weight variation could not be traced in the transverse test results. Each coarse aggregate was tested in 4 different gradings, but the gradations as used seemed to have no effect on the transverse strength. At 28 days the average of all concretes in all gradings in the 1:1.6:3 mix showed a value of 599 lb. per sq. in. Taking this value as 100, the averages of the individual aggregates were: Slag—106; Limestone—100; Trap—99; Granite—98; Gravel—96; and Sandstone—93. In the 1:2:4 mix at 28 days, the general average for all gradings was 502 lb. per sq. in. Taking this value as 100, the averages of the individual aggregates were: Limestone—104; Sandstone—103; Slag—102; Gravel—97; Trap—95 and Granite—95.

Resistance to Wear

The ability of pavement concrete to resist wear is not of primary importance, since no concrete road has ever become unsatisfactory purely from attrition. Since the wear on a concrete road

surface is very small, the pavement will have failed from other causes long before the wear can become a factor in its deterioration. The best-known laboratory test for wear of concrete is the Talbot-Jones, in which the inner circumference of a steel cylinder is lined with 8 x 8 x 5 in. concrete blocks and revolved 900 times in each direction after the addition of an abrasive charge of cast iron balls weighing 200 lb. Duff A. Abrams[43] reports the results of Talbot-Jones tests on concretes containing 13 slags, 24 gravels, 26 limestones, 12 granites, 6 traprocks, 7 sandstones, 2 flints and 1 marble, proportioned 1 part cement to 4 parts of dry rodded mixed aggregates (approximately equal cement content throughout). The average depth of wear, based on 10 specimens of each aggregate sample, showed the lowest value for granite concretes,—0.34 in. The average values for the other concretes were as follows: Traprock—0.40 in.; Marble—0.42 in.; Limestone—0.44 in.; Sandstone—0.45 in.; Flint—0.46 in.; Slag—0.48 in.; and Gravel—0.51 in. In later tests[44] designed to show the effect of cement content upon wearing resistance 8 mixes were used varying from 1:1 to 1:6, proportioned as above. Granite concrete showed the least average wear for all mixes,—0.44 in., followed by slag with 0.49 in., limestone with 0.51 in., and gravel with 0.54 in.

In the Circular Track Experiment of the U. S. Bureau of Roads[37] the Talbot-Jones test was used as a laboratory check on the wearing resistance of concrete which later was subjected to the actual service test of chain-tire traffic. The three slag concretes showed an average depth of wear in the Talbot-Jones machine of 0.25 in., the 10 limestone concretes 0.28 in., and the nine gravel concretes 0.30 in. The actual track test consisted of running two solid-rubber-tired truck wheels over sections of the various concretes. The wheels were loaded to 6,000 lb. and run over the track 55,000 times, but the wear from this operation was negligible so the wheels were equipped with tire chains and an additional 25,000 runs made. The average depth of wear for the nine gravel concretes was 0.31 in., for the three slag concretes 0.37 in., and for the 10 stone concretes 0.46 in. The best slag, with a wear of 0.27 in., made about the same showing as the best stone and gravel concretes. That this test was more severe than actual

traffic conditions is noted in the conclusions of the report, where it is stated:

It is realized that chain traffic on concrete highways is not dense enough except in isolated instances to cause any such wear of the surface of a pavement as was produced on the test sections. Wear, however, does take place at the unprotected edges of joints and cracks. It was believed that the relative resistance offered by the various sections to the chain traffic would be a fairly reliable index of the ability of the materials to resist the combined destructive influences of traffic, whether such influences produce wear at the joints or cracks or cause surface disintegration.

Toughness

Toughness in concrete is essential for whatever purpose it is to be used; buildings must withstand vibration and shocks, and pavements must be able to stand up under the impact of traffic. H. S. Mattimore[45] reports the results of impact tests on concretes containing slag, traprock, limestone, sandstone, slate and gravel, in 3 volumetric mixes,—1:1½:3, 1:2:3 and 1:2:4. The test machine consisted of a striking head, mounted on a frame, which was raised and released by a cam. The striking points were horse shoe calks with springs fitted to them to give ½ in. play so as to allow for wear of the matrix between the aggregate. The specimen was rotated by a dog attachment so that successive blows would be delivered to different parts of the surface. The effective blow was 29 lb. dropping 4 in. at the rate of 90 per minute.

The molded cylinders used in the test were made from the concrete going into the Lancaster Test Road built by the Pennsylvania Highway Dept. in 1919-20. Cores were also drilled from the pavement after 8-15 months. When tested under 5000 blows of the machine, the average loss in weight of the various specimens was as represented by the values in the following tabulation, which are expressed as "impact coefficients," a high coefficient indicating a high loss, and vice versa:

AGGREGATE	NUMBER OF CORES	1:1½:3 MIX		1:2:3 MIX		1:2:4 MIX	
		Drilled	Molded	Drilled	Molded	Drilled	Molded
Sandstone	35	115	114	115	140	90	82
Limestone	46	116	138	97	140	91	104
Slag	22	142	211	146	148	149	153
Gravel	14	191	161	168	152	212	165
Slate	16	191	193	145	134	156	137
Traprock	6	—	—	—	200	—	150

A summary of the foregoing tabulation for all mixes and both conditions of test shows an average coefficient of 133 for all concretes. Taking this value as 100, the averages of the individual aggregates were: Sandstone—83; Limestone—84; Slate —115; Slag—117; and Gravel—130, indicating an intermediate toughness for slag concrete. However, Prof. Curtis C. Myers'[72] tests at University of Cincinnati showed slag concrete tougher than either limestone or gravel concrete in a 1:2:4 mix. Five-inch cubes of concrete were first tested in the impact machine, which consisted of a swinging weight striking a blow equal to a 25-lb. weight falling 15 in., the load being concentrated on a 1-in. diameter striking point. The gravel concrete withstood 6 blows, the stone concrete 7 blows, and the slag concrete 10 blows before failure. Concrete beams were then tested in the machine using slag and stone as aggregates, and increasing the height of the blow each time. The stone concrete absorbed 8 blows before failure against 12 for the slag concrete, each of the last 4 on the slag concrete being more severe than that which caused failure of the stone concrete.

George W. Hutchinson[46] reports impact tests on limestone, slag and gravel concretes of equal cement content (6¾ sacks per cu. yd.) in which the testing machine consisted of a 10-lb. weight falling perpendicularly on the specimen from a constant height. The specimen was a 20-in. concrete disk 6 in. in diameter, supported on 3-point rubber-padded bearings, and the shock was transmitted through a 3-in. steel ball resting on the center of the top surface. The average of several hundred tests showed that limestone concrete had withstood 138 blows before failure, slag concrete 100 blows and gravel concrete 62 blows, but the author points out that there was equally as much variation within one type of aggregate as there was between different types.

Workability and Yield

Workability is defined as that quality in concrete which provides ease in mixing and handling, and allows the mixture to be readily placed without tangible voids, honeycombing or segregation.

Slag in common with other crushed aggregates, tends to give harsher mixtures than rounded aggregates because of its rougher

surface and higher voids, but this tendency can be largely overcome by attention to proper grading, and the use of a somewhat higher ratio of fine to coarse aggregate than would be required for rounded aggregates. This so-called "over-sanding" has been proven beneficial in every way, according to tests at the U. S. Bureau of Standards[47] with slag, limestone and gravel aggregates. The conclusions state:

> The tests showed (1) That for the various combinations of fine and coarse aggregates the amount of sand required to give a strength at least as great as that indicated by the normal water-cement-ratio strength-relation varied from about 33 to about 50 per cent of the total aggregate, (2) That the percentage of sand as determined gave a satisfactory workable mix, (3) That it was about the smallest percentage of sand which would give a workable mix, and (4) That these same percentages of sand gave higher strengths per barrel of cement per cu. yd. of concrete than did any other combinations of the same aggregates; that is, they gave approximately the maximum economy of cement.

The above conclusions are of great importance to the user of crushed aggregates, since they indicate that "oversanding" not only gives a workable mix but actually shows maximum economy in cement. This point can not be too highly stressed, because in the past arbitrary proportions of 1:1½:3, 1:2:4 etc. have been used with crushed aggregates in many cases where slightly more sand and less coarse aggregate would have greatly increased the workability, at the same time slightly increasing the strength and yield. This is brought out very forcibly in earlier experiments at the Bureau of Standards[48] reported in 1920. A limestone concrete in a 1:2:4 mixture was found to be harsh and segregating, while a 1:3:3 mix of the same materials not only gave satisfactory workability but higher 28-day strength, in spite of the fact that less cement was used per cu. yd. of concrete. Further tests showed that all mixes with the same proportion of cement to total aggregates had substantially the same strength, and that the oversanded mixes consistently used less cement.

Yield is the volume of concrete resulting from given quantities of cement and aggregates, and may be expressed in the following different ways:

1. The ratio of the volume of finished concrete to the volume of mixed aggregates, dry and rodded. Thus if a mix of 1 sack of cement and 4 cu. ft. of rodded mixed aggregates results in 4.4 cu. ft. of concrete, the yield is 1.10, or 110 per cent.

2. The ratio of the volume of finished concrete to the volume of the coarse aggregate, the latter being measured in any definite way. Thus if a mix of 1 sack of cement, 2 cu. ft. of sand, damp and loose, and 3 cu. ft. of coarse aggregate, damp and loose, results in 3.9 cu. ft. of concrete, the yield under these conditions is 1.30 or 130 per cent of the volume of the coarse aggregate as measured.

3. The volume of concrete of any proportions produced by one sack of cement. This is more often expressed as the reciprocal measure, viz: the number of sacks of cement contained in a cubic yard of concrete, and this number divided by 4 (to convert to barrels) is commonly referred to as the "cement factor." Thus if 6.4 sacks of cement are required for a cubic yard of concrete, the cement-factor is 1.6.

This last-mentioned method of expressing yield is now the one most commonly used, and it has the advantage of indicating the type or quality of concrete more definitely than the time-honored designation: 1:—:—, or parts of cement to parts of fine aggregate to parts of coarse aggregate. This fact is worth remembering in that recent discussions of the merits of different types of coarse aggregate have emphasized the necessity of comparing concrete mixtures on the basis of equal cement content, and when this is done with heed to the proper balance between fine and coarse aggregate for workability, the differences in concrete making properties of the different coarse aggregates become insignificant. Unfortunately this basis of equal cement content in comparative tests has not been generally used up to this time and most of the test data quoted in this report are of necessity taken from tests based on like proportions of cement and aggregates by volume or by weight.

Weight proportioning was used by Fred Hubbard[50] in comparative yield tests which he has reported using slag, limestones, traprock, gneiss and gravel as aggregates. The materials were proportioned on the basis of their respective dry weights, corresponding to a volumetric proportion of approximately 1:2:3 field mix. The gravel concrete showed the lowest cement factor, —6.80 sacks per cu. yd. of concrete, followed in order by gneiss with 6.91, traprock with 7.16, limestone No. 1 with 7.28, slag with 7.32 and limestone No. 2 with 7.32. In a leaner proportion

corresponding to approximately 1:2½:3½ field mix, limestone No. 2 and slag again had the same cement factor,—6.31 sacks per cu. yd. of concrete.

Slag as Fine Aggregate

Many more or less successful attempts have been made to introduce the finer sizes of slag (both air-cooled and granulated) as a substitute for natural sand in concrete, and a number of strong and durable structures have been and are being built in this way. Two prejudices had to be overcome before slag could be used as fine aggregate: First, the natural reluctance to change from a known to a practically unknown material; and Second, the fact that the resulting mix is somewhat lacking in workability. Laboratory and service tests have removed all doubt as to the strength and durability of concrete made with slag fine aggregate, while the workability of such a mix can be greatly improved by the addition of a portion of fine sand or a small amount of powdered slag, diatomaceous earth, hydrated lime, etc.

The control tests for the Circular Track investigation of the U. S. Bureau of Roads[37] showed satisfactory results for an all-slag concrete in compressive strength, transverse strength and resistance to wear. The transverse tests were made in the compression machine with center-loading, and the wear tests in the Talbot-Jones machine. Nine gravel concretes, 10 stone concretes and 4 slag concretes made with natural sand were included in these tests, as well as 1 all-slag concrete made with air-cooled slag screenings as fine aggregate. Taking the average of all concretes as 100 in each case, the relative values of the individual concretes in a 1:1½:3 field mix at 90 days were as shown in the accompanying table. With one exception, the all-slag concrete showed higher strengths and less wear than the concretes made with natural sand as fine aggregate:

KIND OF CONCRETE	COMPRESSION STRENGTH	TRANSVERSE STRENGTH	WEAR TEST
All-slag	104	133	68
Average of 3 slag concretes	101	112	88
Average of 10 stone concretes	105	97	97
Average of 9 gravel concretes	93	93	104

With reference to the foregoing table it should be stated here that the relation indicated by the laboratory wear tests was not borne out in the actual test on the track. The all-slag concrete showed more wear under tire-chain traffic than all the other concretes with the exception of one slag concrete and two stone concretes, which led F. H. Jackson and J. T. Pauls to state in their conclusions from the tests that "Slag or stone screenings are, in general, unsatisfactory as substitutes for natural sand as fine aggregates in concrete road construction."

Other tests on slag as fine aggregate have been reported by Curtis C. Myers[2] who found that an all-slag concrete withstood impact better than other concretes made with natural sand: and by Duff A. Abrams[52] who found that gravel concrete made with granite, slag, limestone and traprock screenings as fine aggregates were somewhat weaker (in compressive strength) than sand-gravel concrete.

The use of slag as fine aggregate has been largely confined to concrete construction around the steel plants. Fifty all-slag concrete houses were built at Youngstown, Ohio, in 1919 by the Carnegie Steel Co., and similar construction was used in recent additions to slag plants at Youngstown, East Toledo and Massillon, O. The Ford Hotel at Buffalo, N. Y., was built with an all slag concrete in 1923, and in 1916 four slag concrete bridges were built at Pottsville and St. Clair, Pa., using as fine aggregate equal parts of natural sand and slag sand.

Discussion of Progress Report of Committee 105

"Reinforced Concrete Column Investigation"*

BY HERBERT J. GILKEY†

A RECENT paper by Richart and Jensen[1] reports that Haydite concrete having an ultimate strength and bond resistance about equal to those of concretes from ordinary aggregates, has a modulus of elasticity that is decidedly lower. This fact means that the values of "n" are increased and that a correspondingly higher stress can be transferred to the steel for a given stress in the concrete.

From this very interesting fact it appears that Haydite concrete may have unique possibilities in the realm of columns and other reinforced compressive members. This point has been enlarged upon in a discussion of the Richart and Jensen paper[1].

It is probably too late to inject any phase of Haydite concrete into the present project even if it were deemed desirable to do so. It does appear that this aspect of the material has enough novelty and promise in it to warrant some sort of a separate experimental reconnaissance over the field.

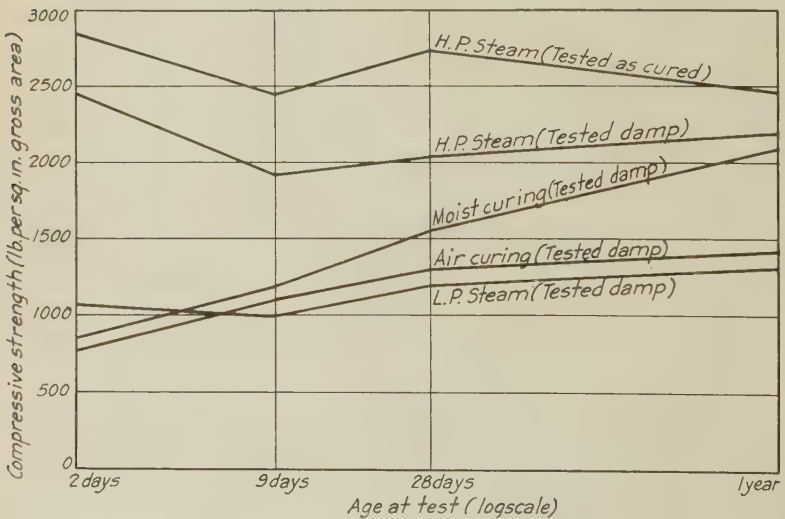
Discussion of Paper by P. M. Woodworth



"Some Tests of Concrete Masonry Cured With High-Pressure Steam"*

AUTHOR'S CLOSURE

This investigation has been completed with the testing of the one-year specimens. A summary of the results is contained in the accompanying table A and typical age-strength relations are plotted in the figure.

The outstanding feature of these tests is that concrete units cured with steam under 100-lb. pressure for 12 hr. and then in air at 50 per cent relative humidity, developed strengths which averaged about 15 per cent more at 2 days and about 5 per cent

*A. C. I. Journal, Feb. 1930, *Proceedings*, Vol. 26, p. 504.

Effect of curing on compressive strength of concrete masonry units

SOME TESTS OF CONCRETE MASONRY UNITS CURED WITH HIGH PRESSURE STEAM

TABLE A—*Compressive Strength of Vibrated Concrete Masonry Units*

Compressive tests of 5 by 3¾ by 12-in. concrete tile.

Cement from fresh warehouse stock.

Aggregate: Crume Brick Co. bank sand and crushed gravel graded 0-⅜-in.

Water: 8½ gal. per sack corrected for absorption of aggregate.

Mix: 1:4:6 damp, loose volume; 1:9.6 dry weight.

Concrete vibrated in molds for 50 seconds at 3600 r. p. m.

Specimens removed from molds 36 to 48 hr. after molding and air-cured until test.

Specimens capped with gypsum 6 hr. before testing.

Unless otherwise noted each value is the average of three tests made on the same day.

Values in parentheses are percentages of 28-day strengths of moist-cured tile.

more at 1 year than that of similar units moist-cured for a period of one year. These comparisons are based on units tested in a damp condition.

It appears that high-pressure steam-curing furnishes a means of developing relatively high concrete strengths at very early ages. The promising results obtained by this method of curing show the desirability of further study by manufacturers of concrete masonry units and other concrete products in order that its possibilities may be developed to the greatest extent.

Architectural Concrete—Forms, Molds and Surfaces

BY WILLIAM C. WAGNER*

Architecturally treated, exposed concrete as an exterior finish for buildings is a comparatively recent adaptation of the material, that requires, in addition to purely structural qualities, a smooth, durable finish and a definite sharpness of detail comparable to cut stone or carving. In our efforts to obtain the most satisfactory surfaces with this medium, we have revised many of our former opinions and extended our study to all agents and accessories that contribute to a concrete structure, for the uncertainty of success and the finality of the result make extreme care in preparation a mandatory consideration. Although the work is complicated by the nature of the material which places many limiting conditions on its uses, many of the faults of exposed concrete can either be eliminated or provided for by well studied design.

In building forms for architectural concrete there is no radical departure from the practice accepted for structural concrete, unless it be that they are lined with materials that control the character of the resultant surface. This discussion will therefore be confined to these materials and such variations from usual practice as are required to yield a satisfactory finish. Subsequent remarks may not receive complete concurrence from all who work with exposed concrete, because of such difference of opinion on the various points of procedure as result naturally from individual experience.

In a broad sense there are three types of wall treatment encountered in buildings—plain, ornamented and molded surfaces ——each of which required a different type of form lining.

*Morgan, Walls & Clements, Architects, Los Angeles, Calif.

FIG. 1—BANK OF BALBOA, BALBOA, CALIFORNIA—MORGAN, WALLS AND CLEMENTS, ARCHITECTS, LOS ANGELES. AN EARLY EXAMPLE OF EXPOSED CONCRETE STRUCTURE EMPLOYING PLASTER WASTE MOLDS AND ORDINARY BOARD FORMS

LINED FORMS FOR PLAIN SURFACES

For plain surfaces, forms are lined with a board of fibrous composition or with built-up wood panels, generally of three-ply construction and for ornamented and molded surfaces plaster casts and wood patterns are used.

To provide a rigid frame for attaching these linings, it is advisable to use 2-in stock. The use of 1-in. stock is questionable economy, because to overcome its tendency to buckle, more extensive bracing is necessary, with consequent additional expense of material and labor.

Fibre board is produced in large sheets which can be readily sawn to size; it is rigid and light in weight and it is easily nailed to forms or drilled to allow the passage of tie wires. Since its smooth surface is almost entirely impervious to water, it is neither necessary nor advisable to attempt a waterproofing treatment. The application of shellac has been tried with the result that when the forms were stripped, the shellac adhered to the concrete and peeled the surface from the fibre board. This was removed from the concrete with great difficulty.

When adjoining sheets of fibre board are butted tight water will cause the edges to rise and leave depressions in the concrete. Where design requires joints to suggest stone, this characteristic can be used to advantage by cutting the fibre board to the required stone sizes. If no joints are desired, such depressions can be prevented by allowing an expansion gap of not more than $\frac{1}{8}$ in. for full sheets. This gap will leave a small cement fin which can be brushed off easily and with no damage to the surface. Further precaution against surface marring can be taken by burnishing all edges that occur at exterior angles, by driving all nails flush only and by nailing the fibre board to the same form board wherever practicable. In instances where nails have been staggered the action of the form boards has been sufficiently opposite to cause the fibre board to buckle and leave a wavy concrete surface. Depending on the length of time it remains in the forms, fibre board is likely to lose its smooth surface and some of its rigidity, so that the advisability of using it for more than one pour will depend on its condition when released from the forms.

FIG. 2—WESTWOOD BRANCH, SECURITY-FIRST NATIONAL BANK OF LOS ANGELES—MORGAN, WALLS AND CLEMENTS, ARCHITECTS

WOOD FORMS

Except for occasional impressions from raised grain and the absence of fins and joint depressions, the surfaces obtained by the use of wood panels are comparable in texture to those resulting from fibre board. Grain impressions are not usually deep enough to be noticeable except in bright sunlight, but if they are objectionable the grain can be sealed. However, this might be relatively expensive, since the precaution is not necessary in the use of fibre board. When the edges of wood panels are planed smooth and butted tight there is no resultant swelling and it is not necessary to allow an expansion gap between panels. Therefore depressed joints can be obtained in one pouring operation only through the introduction of wood strips cut to required width of the stone joints. The advisability of using the same panels for subsequent pours can again be decided by their condition when stripped from the forms.

All wood milled for form lining should be as smooth as possible, kiln dried and entirely free of loose knots or other defects. Probably the best wood for this purpose is California white pine—generally called sugar pine—and eastern white pine because their uniform grain has a negligible tendency to rise under the action of water. Due to the compactness of the grain, waterproofing is sometimes not necessary for these woods. However,

FIG. 3—DETAIL OF WESTWOOD BRANCH BANK. A RECENT STRUCTURE FOR WHICH FIBRE-BOARD LINED FORMS AND PLASTER MOLDS WERE USED

they are soft and care must be taken not to damage their surfaces in puddling operations.

Paste fillers or shellac and varnish as seals for wood grain are not as satisfactory as lead and oil, because of the difficulty of obtaining a permanent bond that will prevent adhesion to the concrete. Since inferior grades have been known to stain concrete, a high grade of lead and oil should be used and unless the wood is painted on all faces, the water from curing operations will raise the grain by seeping under the lead and oil from the unprotected surfaces. If care is taken in stripping, wood molds can be cleaned and used for subsequent pours according to the repetition of detail.

PLASTER MOLDS

The term waste-molds is a descriptive designation of the plaster molds that are used to obtain ornamented surfaces and that are broken in stripping the forms—wasted so to speak. The amount of damage done to plaster molds in stripping depends on the nature of the ornament, and the extent of undercutting, but in no case can they be removed in a condition suitable for re-use—in fact they sometimes have to be chopped from the concrete. Only in instances where the design is extremely simple is there a possibility of stripping plaster molds without serious damage; and where the design presents such simplicity the molds would doubtless be wood.

From the approved clay models made under the Architects' supervision, plaster reverse molds are made. They are reinforced where necessary, and fitted with wood ties and bracing for building into the forms. In order to prevent the collapse of waste molds under the pressure of the concrete, it is advisable that they be not less than 1 in. thick at any point. Where a number of identical waste molds are required by the repetition of ornament, they are obtained by the use of a glue mold made from the reverse plaster mold. For safety in shipping, plaster molds should be well packed in sawdust.

Unless plaster molds are sized or fixed to prevent the absorption of moisture from the concrete, they may disintegrate and destroy the ornament, or the concrete may soften, spall and leave a rough surface. The application of two coats of thin shellac

has been found the best and cheapest method of sealing plaster molds and while there are several other methods used in an attempt at economy, there is none as simple or efficient as the use of shellac. A mixture of gasoline and melted paraffin which is sometimes used as a substitute for one coat of shellac, seals the mold when the gasoline evaporates and leaves only the paraffin in the pores. One coat of shellac is required after this operation. The difficulty of using the gasoline mixture lies in the fact that the gasoline must be luke warm in order not to congeal the melted

FIG. 4—PLASTER WASTE MOLD SET IN PLACE

paraffin—and heating gasoline is not the safest of operations. There has also been some experimentation with slightly colored lacquer as a substitute for the initial coat of shellac. However, since the best results have been obtained with shellac and inasmuch as one coat of thin shellac has always been required to complete the waterproofing, it seems advisable to use shellac as the sole fixing agent.

Wherever pointing or patching of any kind is necessary for any type of form the best agent is a mixture of plaster of paris and shellac. This mixture sets quickly and leave a hard, tough

surface that can be sand papered, filed or polished, according to the nature of the surface desired.

OILING FORMS AND MOLDS

After the lining materials have been installed in the form work, they must be oiled to simplify stripping. Wood

FIG. 5—FORMS PARTIALLY LINED WITH FIBRE BOARD

molds that are not painted are given a coat of standard liquid form oil which soaks into the wood and requires no further attention. All lining throughout is next greased with a form oil that has a consistency of cup grease and finally wiped as clean as possible with rags, for any excess oil will cause unsightly stains on the finished surface.

Numerous methods are used with uniform success in greasing waste molds and which employ all kinds of lubricants from cylinder oil to cup grease. In one case cup grease is thinned to the point where it can be applied with a brush, by the addition of a mixture of crystallized stearic acid and a small quantity of kerosene.

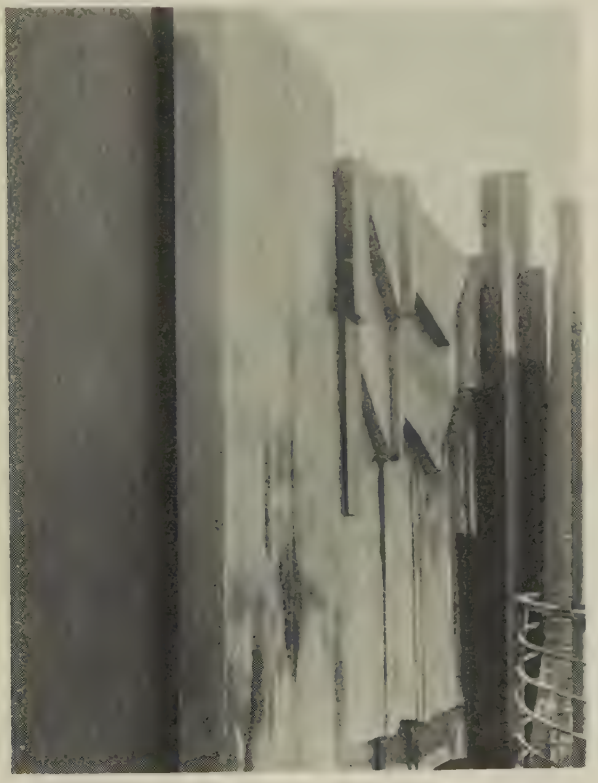

FIG. 6—WASTE MOLDS AND FIBRE BOARD IN PLACE

For anchoring the two sides of the form work, pencil wire ties equipped with collars and set screws are preferred to bolts, because they can be removed with less damage to the concrete. The tendency of such wire to stretch under pressure can be overcome by proper spacing of the ties according to conditions.

CONCRETE MIXTURES

The study of the various concrete ingredients and their proportions in the mixture is the most important step in developing satisfactory exposed concrete surfaces, because it controls the workability and the limits of adaptability of the concrete to

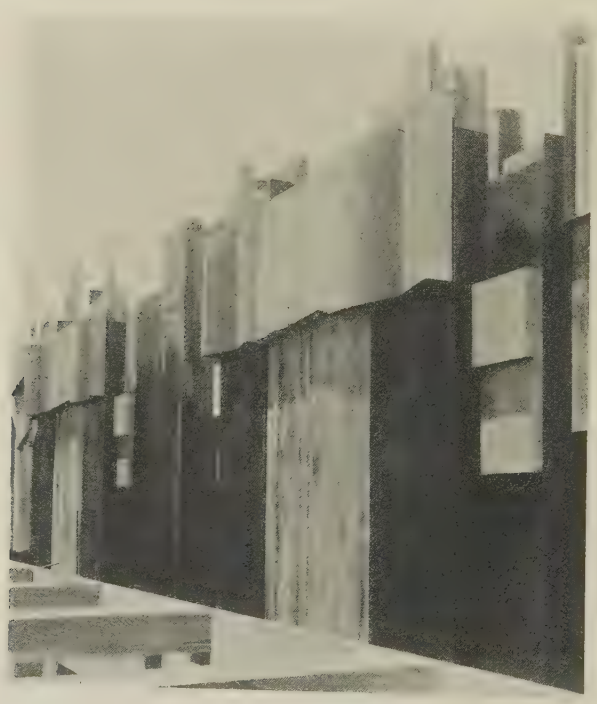

FIG. 7—WASTE MOLDS, FIBRE BOARD AND WOOD MOLDS IN PLACE

conditions of forms and ornament. Concrete control embraces the selection of aggregates, cement, sand, admixtures and water, and the testing of these materials in combination and for impurities.

The proportions of ingredients in the concrete mixture will be established by local building ordinances and by the water-cement ratio established for the developed strength required in the concrete. It seems a universal tendency to place concrete too wet and since excessive water is ruinous to concrete surfaces,

FIG. 8—WASTE MOLD IN PLACE

great care must be taken to prevent a surplus of water. The success of the concrete finish is dependent upon the proper suspension of the materials. A minimum of water helps to prevent the weakening of concrete and the formation of rock pockets and voids. There are conditions of difficult placing such as undercutting in waste molds or projections beyond the normal wall faces that demand a mixture of greater water content for proper workability, but this extra water is offset by a corresponding increase in cement. In all such cases of enriched mixtures, slump tests will determine the limits of richness. For plain surfaces proper workability requires a slump of approximately 4¾ in. in a specimen cone of a 6-in. diameter and 12-in. high. For varying conditions a mixture with as much as a 7-in. to 8-in. slump is often necessary. Similarly the concrete may vary from a mixture of 1 cement to 2½ sand, to 3½ rock or gravel, to a mixture of 1:3:3 or richer. For acceptance the concrete must develop a compressive strength of not less than 2000 lbs. per sq. in. in 28 days. Conditional acceptance at a seven day period

requires not less than 900 lbs. per sq. in. A survey of a series of tests shows that for a slump of 7-in. to 8-in. the concrete has developed compressive strengths that vary from 1000 to 1800 lb. per sq. in. after 7 days.

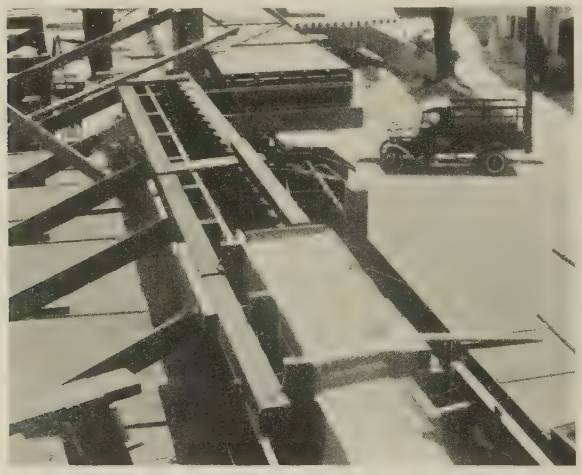

FIG. 9—CONCRETE PLACED AGAINST WOOD MOLDS

ADMIXTURES

Numerous properties are claimed for various concrete admixtures, among which are the tendencies to increase the workability of the mixture and to prevent efflorescence. From the standpoint of workability and finish alone, we have recently obtained more satisfactory surfaces by substituting an equivalent amount of extra cement for the admixture previously used. However, we do not necessarily subscribe to the idea that the use of admixtures should be abandoned for there is no doubt that they tend to increase the strength and durability of concrete, and admixtures which change the structure of hydrated lime are effective preventives of efflorescence. Other steps to prevent efflorescence are the usual rigid specifications governing the properties of the cement, sand, aggregate and water.

FIG. 10—TYPICAL ARCHITECTURAL CONCRETE SURFACE SHOWING WIRE AND MINUTE AIR HOLES AND DEPRESSION FROM A FIBRE BOARD JOINT

PLACING CONCRETE

Before concrete is deposited all debris and drippings should be removed and the forms should be thoroughly wetted. To insure a uniformity of surface texture, the concrete should be transported as rapidly as practicable and as near as possible to its final position to avoid rehandling and so placed in the forms that no separation will occur. It should be deposited in continuous horizontal layers with a difference in levels not greater than 18 in., in order that there be a minimum flow of the concrete. Throughout the placing operations the concrete should be assisted into place by constant puddling to insure a uniform filling of all voids and an elimination of rock and air pockets by forcing air and excess water to rise to the top of the pour. By tapping the form boards the sand and cement are drawn to the

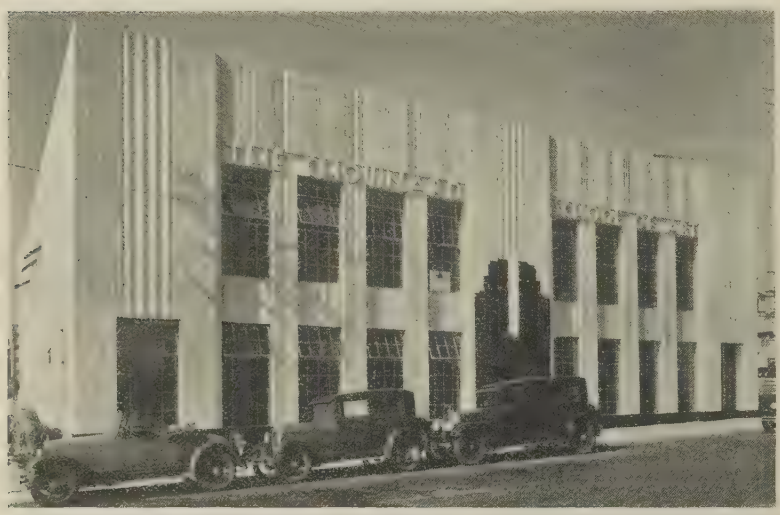

FIG. 11—CHOUINARD SCHOOL OF ART, LOS ANGELES—MORGAN, WALLS AND CLEMENTS, ARCHITECTS

outside of the wall and produce a smooth surface free from exposed aggregate. For agitating the concrete during the pour, puddling with wood strips is a safer operation than spading, because there is less opportunity to cut wire ties or to mar the surface of the form lining.

When it has been determined where the pour is to stop a wood strip is tacked to the forms at the outside surface of the concrete wall. The pour is carried about ½ in. above the underside of the strip and sloped to the inside face so that laitance and excess water will drain to the inside face of the concrete which will be cleaned and plastered. About an hour later the strip should be removed and the concrete leveled off with a steel trowel so that any demarcation between the subsequent pour will be a straight line and therefore least noticeable.

STRIPPING FORMS

Forms should ordinarily remain five to seven days before stripping and during this time the form work for the next pour is constructed. Before the next higher pour is made, the bottom

FIG. 12—CONCRETE WAS PLACED AGAINST MILLED WOOD FORMS AND SURFACES THROUGHOUT BRUSHED WITH CEMENT WASH AS FINISHING MATERIAL

FIG. 13—DETAIL CHOUINARD SCHOOL OF ART

whaler of the new form work is pulled as tight as possible against the top of the concrete previously poured to prevent soiling this surface by leakage of water and cement. Whatever water or laitance leaks through the bottom of the forms must be washed from the lower surface immediately in order to prevent permanent damage.

The removal of forms is an operation that requires extraordinary care to prevent damage to the concrete surface, and it is in this operation that the limitations of design become apparent. Design should provide means of disguising the variations between pours either by actual or painted architectural joints or by applied surface treatments. A mixture of cement and water applied with a brush will conceal slight discolorations and retain the natural color of the concrete.

For ease of stripping there should be no exterior acute angles. To allow for the uneven expansion of forms all exterior angles should be slightly obtuse wherever practicable because of the difficulty of removing the forms without spalling. On wide pilasters where a number of exterior angles occur, a series of kerfs to within ½ in. of the inside face and about 3 in. apart is a very effective method of relieving the possibility of damage to corners by absorbing the expansion of wood molds.

PATCHING AND CURING

To prevent extreme variations in color, it is important that the proportions of the concrete remain constant for similar and contiguous conditions and that the same cement mortar mixture used in the concrete be employed in patching spalls, voids and wire holes. Patching should be done immediately after the surfaces have been inspected and cleaned of all laitance and projecting fins.

Satisfactory curing requires that the concrete be kept wet for at least seven days, but this period varies according to the structural conditions of the concrete. After proper curing the surfaces should be brushed clean of all excess cement that might roll up under a painter's brush or tend to defeat any efforts to apply a finishing material.

Readers are referred to the JOURNAL *for March, 1931, for discussion which may develop. Such discussion should reach the Secretary by February 1, 1931.*

Design and Construction of Bonnet Carre Spillway

*With Special Reference to Concrete**

BY HELMER SWENHOLT†

INTRODUCTION

The bonnet carre spillway now under construction on the left bank of the Mississippi river, about 30 miles above New Orleans, is a controlled spillway 7700 ft. long, emptying in time of unusual flood through a leveed floodway into Lake Pontchartrain, six miles away. Authorized under the Flood Control Act of May 15, 1928, according to the adopted plan it is to be capable of discharging 250,000 sec. ft., leaving 1,250,000 sec. ft. to go by New Orleans, preventing the stage at Carrollton from rising above 20 ft. on the gage. This plan is the outcome of 200 years of discussion and efforts to control the flood waters of the Mississippi river by levees only.

HISTORY

The history of the lower Mississippi River is one of floods. Early settlers along the stream began the protection of their holdings from river encroachment as soon as residence was established. These holdings, in general, were in large grants, and plantations became the center of social and business activity. Small levees were built along their fronts, joining with neighboring levees, or extending rearward towards the swamps for flank protection. A levee along the New Orleans front was completed as early as 1727. Levee building by State and local interests was stimulated by the swamp land act of 1850 following the damage of the floods of 1849 and 1850, and levees were extended and built higher and higher as the South Central States advanced

*Presented at the 26th Annual A. C. I. Convention, February, 1930.
†Captain, Corps of Engrs., U. S. Army.

industrially and agriculturally. Floods kept pace with levee heights, frequently defeating the builders, the river spreading its surplus waters over the adjacent countryside through crevasses and finding its way to the Gulf, or perhaps back to its own channel through bayous, adjoining rivers and lakes. The confinement policy of flood control terminated with the disastrous flood of 1927, and as a direct result of this flood the Flood Control Act of 1928 was passed and the Bonnet Carre Spillway, a subfeature of the adopted plan, was authorized.

This spillway was discussed as early as 1816 and much interesting and instructive data exist in studies made at various times, including the investigation of the Corps of Topographical Engineers in 1850, the Humphreys and Abbott report of 1861, and others. As the result of the flood of 1922, Congress in 1926 authorized a Spillway Board, and its recommendations in House Document No. 95, 70th Congress are the basis for the present design.

DESCRIPTION

The plan adopted by the Flood Control Act of May 15, 1928, provides for the safe discharge of 1,500,000 cu. ft. per sec. below Old River between the main river levees, in detail as follows:

114. At Bonnet Carre a controlled spillway emptying into a leveed floodway to Lake Pontchartrain is to be constructed capable of discharging 250,000 sec. ft. This leaves 1,250,000 sec. ft. to go by New Orleans, and should prevent the stage at Carrollton from rising above 20 on the gauge.

115. The Bonnet Carre spillway is so designed as to afford complete control of the discharge into Lake Pontchartrain. This discharge will be begun when the flood stage at New Orleans has reached 20 on the Carrollton gage; it will be regulated to prevent the stage rising above 20, and will cut off as soon as the stage has fallen below that figure. Past records indicate that its operation will be required about once in five years; and for a period of from one to three months during each flood. The discharge through the spillway, in a maximum flood, will be about 10 per cent of the total flow at that latitude. Some of the silt carried by the discharge will be deposited in the floodway itself, the bulk of it in the upper end of Lake Pontchartrain. With the infrequent and limited periods of operation, the silting would not exceed an average of ¼ in. of depth per annum, even if all the silt content were deposited in the lake within 10 miles of the floodway outlet. The average rate of silting for the entire lake would be $\frac{1}{32}$ in. per annum. Discolored water from the discharge may, in a high flood, extend well into Mississippi Sound, but there will be no appreciable silt content remaining in the water at such a distance. The spillway is especially heavily designed to prevent even the remote possi-

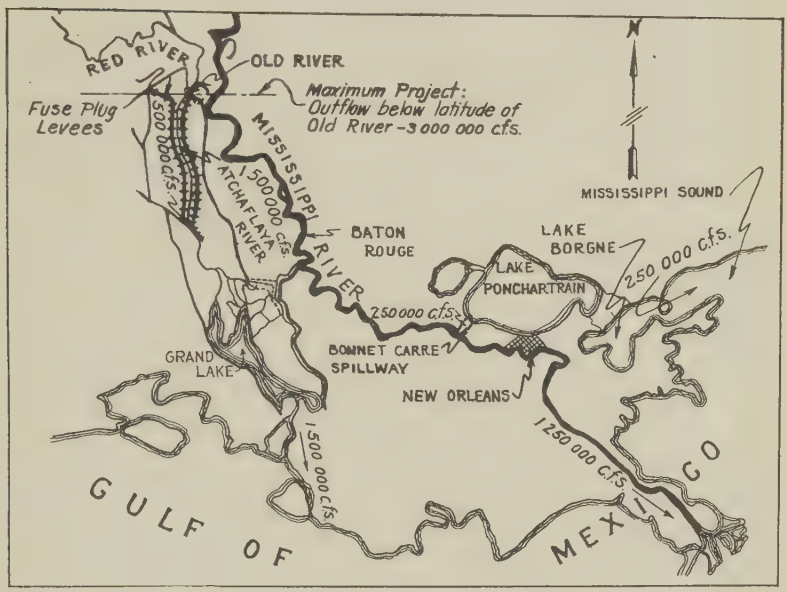

FIG. 1—MAP SHOWING ESTIMATED QUANTITIES OF DISCHARGE THROUGH VARIOUS CHANNELS

bility that the discharge will cut a channel from the river into Lake Pontchartrain.

116. The City of New Orleans has provided, with its own funds, levees on its river front of so wide a crown, and with such flat slopes, as to afford an abundant margin of safety against failure except by overtopping or by bank caving. After the Bonnet Carre Spillway has been constructed, there can be no fear that the flood stages will approach dangerously close to the levee top. The danger of bank caving is minimized by the revetment which has been placed on the under-water bank. The Bonnet Carre spillway will reduce the high current velocities now occurring in great floods. Further insurance can be provided by widening the levees to introduce any desired factor of safety.

In accordance with this plan a site was selected after detailed topographic surveys covering a large area in the vicinity of Bonnet Carre Point, 30 miles above the City of New Orleans. As in other parts of the Alluvial Valley, the river here flows between banks considerably higher than lands back from the river, the banks being about 14 ft. above mean Gulf level, sloping to Gulf level and even lower towards Lake Pontchartrain.

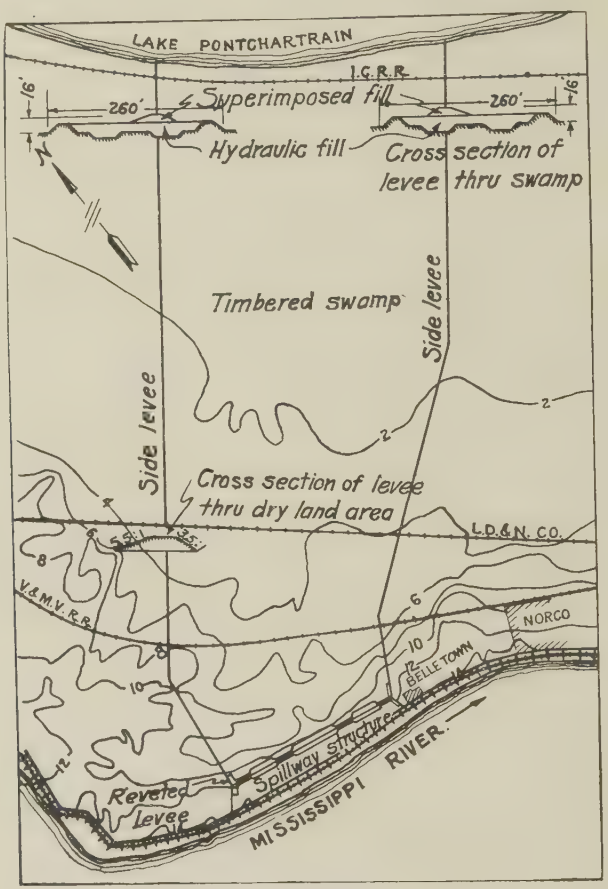

FIG. 2—LOCATION MAP BONNET CARRE SPILLWAY

Of the 7800 acres required, 30 per cent is cultivatable land from 4 to 14 ft. above mean Gulf level, while the remaining 70 per cent bordering on the lake is a low lying timbered swamp, much of the soil consisting of humus and muck. The floodway is crossed by three railroads, one highway, telephone, telegraph and power transmission lines, and a natural gas pipe line. The selected site is shown in Figs. 1 and 2.

DESIGN

In the design of the spillway the following principles governed:

(a) The discharge capacity of the weir must be at least equal to the required discharge under working conditions.

(b) The floodway capacity must be similarly ample.

(c) The structure must be safe, workable and subject to control.

Since the project involved the expenditure of many millions of dollars, it was felt that studies and experiments should be undertaken with great thoroughness. The economic desirability of the project having been previously determined these studies were largely technical, the economic feature entering only into details of design. These technical studies were unusual in that the structure is to rest on an alluvial soil and its operation is to cover all conditions of flow and backwater from no flow to full capacity.

A hydraulic laboratory was established on the site where various scale models were tested for performance. These tests were conducted to determine:

(a) The design which would most effectively dissipate the energy of falling water under any condition of flow.

(b) A design which would withstand such flow and energy as were not dissipated.

(c) A design which would cause the higher velocities of the water leaving the apron to be on the surface instead of at the bottom.

(d) The discharge capacity of weir types.

(e) The velocities at which scouring would occur.

(f) The velocities at which silting would occur.

(g) The rip-rap and toe protection required.

(h) Back water conditions and flow in the floodway.

Foundation tests were conducted also with a view to determining:

(a) The physical characteristics of the soil.

(b) The permeability of the soil.

(c) The bearing capacity of the soil.

(d) The type of foundation most suitable.

These tests and experiments were continued over several months, and influenced features of the design shown in Fig. 3.

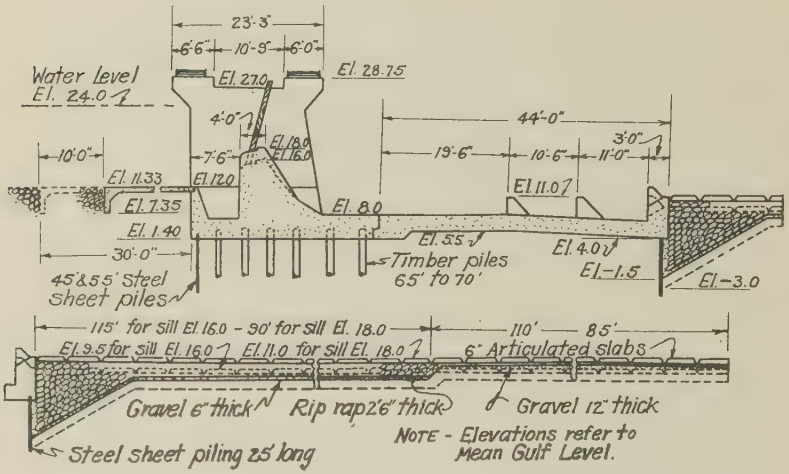

FIG. 3—FINAL DESIGN OF BONNET CARRE SPILLWAY STRUCTURE

The discharge capacity of the structure, which must be at least 250,000 cu. ft. of water per sec., is affected by several factors. It is reduced as backwater in the floodway is built up and the weir becomes submerged; it is increased by the head from a rising river surface above the weir. Computations gave the probable backwater height at the weir; gage relationships between Carrollton at 20 and Bonnet Carre gave a river surface elevation at Bonnet Carre of approximately 24. Discharge capacity was then determined. The concrete structure, 7700 ft. long with 350 20-ft. bays has the required capacity with an ample margin of safety.

FOUNDATIONS

The spillway structure proper rests on untreated wood piles 65 to 70 ft. long. Untreated piles were selected as most economical since their life when cut off below the ground water line is unlimited. The length of these piles conforms to New Orleans practice and the loads are transferred to a safe depth. No point bearing was secured during tests but loads of as much as 90 tons caused no failure of skin friction. The piles are spaced to meet conditions of eccentric loading, the average being 14 tons per

pile, which is standard locally. The fore apron 2.5 ft. thick is separated from the main structure by an expansion joint and rests upon the ground. Experiments indicated that the natural soil should carry this load without undue settlement.

CUT OFF WALLS

A cut off wall of interlocking steel sheet piling 45 to 55 ft. long, driven under the upstream edge of the structure, lengthens the line of percolation. The longer piling was driven to protect a stretch of softer material 1200 ft. along the site. Piling of an arch web section, with a flange and web thickness not less than $\frac{3}{8}$ in., an interlocking strength not less than 7000 lb. per lin. in. of pile, and a section modulus of 3.2 in. cubed was used. It has a copper bearing content of 0.2 per cent. A down-stream curtain wall of similar steel piling 25 ft. long was driven, at the foot of the stilling basin. This wall not only lengthens the percolation line but protects against scour which may occur below the structure. Cut off walls of 25 ft. steel piling are driven between up and down stream piling at intervals of 460 ft.

ABUTMENTS

The abutments at each end of the structure are gravity sections set on piles. A core wall resting on steel sheet piling extends fifty feet into each side levee, and wing walls, making an angle of 15 degrees with the central section, extend 100 ft. each way from these sections. These abutments were built first so that levees behind them would have ample time for settlement before being revetted. This revetment consists of a continuous concrete slab 4 in. thick, wire mesh reinforced, protected with a short cut off wall and rip-rapped.

WEIR

The weir is designed as a gravity section, sufficiently heavy to withstand lateral and uplift pressures. Its face is so shaped as to induce an abrupt drop of water, the eddy under the nappe tending to dissipate more effectively the energy of the falling water. A 4-in air vent through the piers will prevent the formation of a vacuum under this lower nappe. Sill castings to meet the operating needs of the needle type of dam are imbedded in the concrete at the crest of the weir. For maximum efficiency

FIG. 4—POURING FORE APRON

and convenience of operation these sills are arranged in alternating groups. Commencing at each abutment, 44 bays have sills at elevation 18, the next 44 consecutive bays having the sills at elevation 16, etc. This arrangement will be seen to provide for a center section consisting of 88 bays having sills 16 ft. above mean Gulf level. Expansion joints ½ in. wide and filled with an approved asphalt filler are provided at the center of every other weir section. These joints extend across the fore apron and stilling basin which lies below the structure proper, and are sealed on the upper side by a 12-in. copper strip extending from the steel sheet piling to the weir crest.

PIERS

The piers are 2 ft. thick, spaced 22 ft. center to center, reinforced with ½ in. bars set vertically. They are designed to withstand safely the pressure of water flowing through an opening on one side only. They are poured in monolith with a half section of weir on each side. The functions of the piers are three fold; they transmit a proportion of the water pressure received through the needles to the foundation; they divide the spillway into compartments whereby flow may be controlled; they carry service bridges from which the spillway is operated and escape bars which support the upper ends of the needles.

NEEDLES

After a study of various types of gates the needle method for control of flow over the spillway was adopted in the interests of economy, simplicity and certainty of operation. The needles are of 8 in. x 12 in. timbers resting on a sill at the weir crest, their tops supported by horizontal escape bars suspended between piers. Spaces between them may be closed by battens to prevent excessive leakage. A full bay may be released simultaneously by tripping the escape bar, but ordinary operation provides for lifting individual needles by means of hand cranes on the service bridges which surmount the piers. These needles when raised will be stored by hooking the lifted ends to one of the service bridges the other ends resting on the escape bar. The service bridges are standard gauge tracks, the stringers of each consisting of two 15 in. 33.9 lb. channels, to form rails for hand cars, the cross bracing forming the beams upon which the decking rests.

FORE APRON AND STILLING BASIN

The fore apron and stilling basin as shown in Fig. 3 consists of a concrete slab, 2.5 ft. in thickness, not reinforced. It is underslung in anticipation of possible settlement and as a better seal against upward pressure, as well as against currents flowing over the weir and apron. It is connected by re-inforcing bars to the main structure. The joint is treated as an expansion joint and has an asphalt filler. The design of this fore apron and stilling basin is regarded as one of the outstanding results of experiments made with the model spillway. The width of apron, location and shape of baffles, height of secondary weir and depth of stilling basin were all worked out in small scale tests which had two objectives: (a) to convert high spillway velocities to mean floodway velocities, and (b) to reduce the bottom velocity of water leaving the stilling basin to 50 per cent of the surface velocities.

A rear apron 9 in. thick, mesh reinforced, and 30 ft. wide lies above the weir. Its purpose is to prevent scour and it serves also to lengthen the percolation line under the dam. There is a shallow cut-off wall on the up-stream edge and a protection of rip rap.

TALUS

The talus of rather unusual design was worked out in model tests. Excavation of varying depth is carried about 200 ft. wide below the baffle wall and on this is laid a 6-in. surface of 3 to 6-in. spalls. Rip rap stone is next placed to a depth of 14 ft. at the wall and 2½ ft., 16 ft. beyond, this latter depth extending to 100 ft., the remaining distance being covered with gravel or spalls only. Over this entire area is poured a flexible concrete mat of considerable extensibility. The mat units are 3 ft. x 3 ft. x 6 in., fastened together, slackly, with copper bearing steel wire which is continued through the slabs as reinforcing. The slabs are beveled on the upper side, better to deflect the water upward, and the whole mat is fastened to the toe wall of the structure by means of reinforcing rods looped through Everdur bars, allowing 2 ft. of settlement at this point. Holes are left in each block for emergency ties.

FLOODWAY AND SIDE LEVEES

The discharge of the spillway will be carried to Lake Pontchartrain through a floodway of 7,800 acres, between levees 7,700 ft. apart at the structure increasing to 12,000 ft. at the lake. The upper levee has a length of 6.27 miles and the lower 5.52 miles. Approximately two miles of each levee back from the river is of the ordinary dry land type of construction; the balance extending to Lake Pontchartrain is being built by hydraulic methods to the section shown in Fig. 2.

As mentioned previously the floodway must be ample to pass the 250,000 sec. ft. discharged over the spillway. A thorough study was made, not only with model tests, but of experiments and records of other channels and floodways. Backwater curves were calculated using the formulas of Chezy and Kutter. Especial weight was given to the Department of Agriculture's determination of the roughness factor in the St. Francis Floodway. A final curve was worked out whereby an economic width is secured, levee heights are not excessive, velocities will not induce scour, and weir submergence will not exceed 60 per cent which is not objectionable. These conditions will be obtained when the floodway is cleared of undergrowth and small trees, leaving stubble and stumps not more than one foot high, and allowing trees of greater diameter than one foot to stand.

The levees are being built with ample freeboard to care for the maximum flow with an added factor of safety to provide for possible floodway deterioration from silting. The levees on the high alluvial land back from the river are of 17 ft. average height, with a crown width 12 ft. and slopes of 5.5 to 1 land side and 3.5 to 1 floodway side. The levees through the swamp section where the top soil is largely of muck and humus require a different construction. A base width of 260 ft. is cleared and two 40-ft. muck ditches dug, the material from which is used to build small confining levees. The space between these levees is then filled hydraulically to a height of about 10 ft. and after this base has dried out there will be built a superimposed levee of standard section to the required grade. About 8,000,000 cu. yd. of material will be placed in these levees. They are under contract and, except for the superimposed sections, it is expected that they will be completed early in 1931.

CONSTRUCTION OF SPILLWAY STRUCTURE

The contract for the spillway structure proper was let in August, 1929, and work started almost immediately. The quantities involved, the unit prices, and the status of the work on June 30, 1930, are shown in the following table:

Items	Estimated Quantities	Unit Price	Total Quantity to Date	Per cent Complete to Date
				June 30, 1930
Common excavation	420,000 cu. yd.	.40	332,296.	79.12
Back fill	8,100 cu. yd.	.37½	2,623.9	32.39
Levee fill	75,000 cu. yd.	.20	61,250	81.67
Steel sheet piling	600,000 sq. ft.	.80	583,104.69	100.00
Steel sheet piling, cut-off	———	———	91.	———
Wood piling	750,000 lin. ft.	.43	746,279.5	100.00
Wood piling, cut-off	———	———	11,076.	———
Class "A" concrete, structural	104,000 cu. yd.	9.50	78,581.4	75.56
Class "B" concrete, revetment	23,000 cu. yd.	10.00	693.	3.01
Rip rap	128,000 tons	———	22,612.95	17.67
Gravel (or spalls) except for concrete	70,000 tons	3.75	21,251.08	30.36
Castings	532,000 lb.	.06½	361,634.97	67.98
Bolts, etc.	75,000 lb.	.08¾	48,047.68	64.06
Reinforcing steel	280,000 lb.	.04½	253,359.19	90.48
Ladder rods	6,200 lb.	.44	3,627	58.50
Structural steel	500,000 lb.	.056	8,018.24	1.60
Reinforcing mesh	122,000 lb.	.07	1,263	1.04
Copper bearing steel reinforcement	537,000 lb.	.047	17,732.55	3.30

This contract awarded to one firm, involves $3,065,957; the service bridges and needles, let separately, will cost an additional $193,933. Completion is required in 530 days after notice to proceed and present progress indicates that the contractor will be well within the limit set.

Excavation, well ahead of pile driving, was done with a 1¼-yd. 50-ft. boom dragline, and the material hauled in dump cars to the side levees over standard gage work track with gasoline locomotives. Excavation was made to grade, but the driving of piles and some inflow of material made much hand work necessary.

Wood piling was driven with two drivers, and steel sheet piling with two smaller drivers and one caterpillar crane with swinging leads, this latter used on the short piling only. Driving was kept not less than 400 ft. in advance of concrete pouring to prevent vibration as well as other interference with that work. With the exception of one short stretch of the steel sheet piling, no particular difficulty was experienced in driving either wood or steel piling and this phase of the contract was finished ahead of schedule, and without interference or delay to the pouring of the weir structure, which began as soon as the abutments had taken a proper set.

CONCRETE

Concrete is the largest single item in the cost of the spillway structure and through sheer bulk and length of distribution is of considerable interest to engineers. One hundred thirty-three thousand cu. yd. is being poured over a stretch of 7,700 ft. and many problems have arisen in its proportioning and handling. Class "A", structural, 110,000 cu. yd., includes the weir and pier structure, aprons, abutment and core walls, and must have a water-cement ratio of .87 (6½ gal. of water per sack of cement) and a minimum compressive strength of 2,250 lb. per sq. in. at 28 days. Class "B," revetment, 23,000 cu. yd., is used in the flexible slab talus and the revetment for side levees, and must have a water-cement ratio of 1.07 (7½ gal. of water per sack of cement) and a minimum compressive strength of 1500 lb. per sq. in. at the same age. Durability and impermeability are the objects of the design; the high strength required is necessarily developed in the mixtures specified.

TESTING AND INSPECTION

A laboratory was established at the spillway site before construction was started, and complete preliminary investigations were made to determine the mix to be used. Studies were made of the fitness of available materials, the cement factor, the most desirable quality of concrete and the approximate cost.

Concrete aggregates, secured from three pits on the Tangipahoa river in Southeastern Louisiana were clean and hard, with negative colorimetric tests, containing about 0.2 per cent clay and silt, and having the following sieve analyses:

FIG. 5 DRIVING STEEL SHEET PILING — UPPER CURTAIN

GRAVEL

Size	Pit No. 1	Pit No. 2	Pit No. 3
1½ in.	0	0	0
¾ in.	28.2	26.6	25.9
⅜ in.	58.5	58.7	61.2
No. 4 sieve	6.7	8.1	8.0
No. 8 sieve	6.6	6.6	4.9
F. M.	7.08	7.05	7.07
Unit wt. lb.	101.	101.	100.
Spec. Gravity	2.64	2.65	2.64

SAND

Sieve No.	Pit No. 1	Pit No. 2	Pit No. 3
4	.4	.4	1.7
8	9.3	16.5	9.6
14	8.7	14.6	7.3
28	18.8	21.6	18.5
48	45.1	34.2	50.1
100	17.7	12.7	12.8
F. M.	2.48	2.89	2.56
Unit Wt. lb.	110.	113.	108.
Spec. Gravity	2.63	2.66	2.62

These tables would indicate that the aggregates were similar in gradation, but variation in shipment from any of the three pits is greater than the average difference between them. It was felt, therefore, that daily sieve analyses would be necessary to keep the mix workable and the concrete uniform, and to avoid too great fluctuation of the cement factor. The cement used comes from Alabama in bulk, is almost wholly free from lumps, and is shown by 7- and 28-day briquette tests to have a strength 25 per cent in excess of the A. S. T. M. standards. Ordinary Mississippi river water is used, and while it has a high silt content, no objectionable results have been obtained; in fact some of the high strength obtained in tests may be due to this presence of silt in the water. Preliminary investigations showed that materials were excellent, though poorly graded, and that good concrete could be made from them. As anticipated, however, actual field conditions and differences in the aggregate have made necessary constant revision in the mix as designed. The cement

factor has varied from 5.65 to 5.91 sacks of cement per cu. yd. of concrete, but the cost of raw materials has at no time exceeded $4.28 per yard.

The concrete inspection and field testing laboratory is under one head, thus unifying what are often two distinct departments, and making possible an immediate and constant check on all phases of the work and close co-ordination of action. An outside laboratory makes mill tests of all cement purchased, furnishing copies of results to the field laboratory. Cars are sampled and tested as received, and bin tests are made to prevent use of damaged or deteriorated cement. Aggregates are tested as received and before unloading, and samples sent to the laboratory for checking and recording. At least twice daily, cylinders are made from the concrete at the mixer and again after it has been placed in the forms. The mixer samples are given laboratory curing, those from the forms are cured under field conditions; careful records of both types are kept and parallel graphs of compressive strength at 7 days, 28 days, 3 months and 6 months, are plotted. Weight is given to precipitation, laboratory and ambient temperatures and relative humidity, and a composite chart of local weather conditions is plotted from observations taken three times daily.

MIXING

A mixing plant, central with reference to the longitudinal axis of the weir serves the purpose of the work. Here are installed two 1-yd. mixers equipped with inundators. Cement is lifted to the storage bins by compressed air and fed to the hoppers through a weighing device which closely checks the actual cement consumption and offers a practical gage for the theoretical cement factor. A 3-in. slump is desirable from the standpoint of workability, but is maintained with difficulty, due apparently to variation in the size of aggregates. It is necessary also to keep a constant check on the moisture content of the aggregate, particularly after a rain, and compensate for extra moisture with additional cement to maintain the proper ratio. Mixing is continued at least 1½ min., with 12 revolutions of the drum traveling at a rate of 200 ft. per min. The finished concrete is then dropped into buckets, which are conveyed by truck to the forms for pouring.

Transportation during the winter months and prior to construction of the fore apron, was hindered by soft roads, necessitating the use of mats. This difficulty was overcome, however, and for several months it has been possible to operate at the full capacity of 56 yd. per hr., a fleet of 4½ ton trucks, each carrying two 1-yd. buckets, hauling the concrete to the site of the work where it is lifted and poured by a caterpillar crane.

CHARACTER AND ORDER OF CONCRETE CONSTRUCTION

The specifications for concrete work require puddling along the face of all forms, the surface to be free from voids, and no plastering permitted. Defective concrete must be removed and new concrete keyed, dovetailed or anchored in its place. All top surfaces have a float finish without mortar, and all angles are rounded or beveled unless definitely specified otherwise. A curing period of 12 days is required for all horizontal surfaces, and 10 days for vertical surfaces. Water curing is used though wide latitude is allowed.

The two abutments were constructed first to give ample time for placement and settlement of adjoining levee before revetting with concrete. Forms of surfaced lumber, sealed with paraffin oil, were used; the sub-foundation was roughly surfaced and spread with a coating of sand, and the wood and steel sheet piling were scrubbed clean. Particular care was used in the puddling and placing of concrete, the result being walls entirely free from honeycombing. Some difficulty was experienced on the first abutment in holding the forms true to line, caused by the high lifts attempted, 13 to 15 ft. This height was reduced by half on the second abutment and no such trouble occurred.

Construction of the fore apron and baffle seats was started as soon as the abutments were finished. Beginning at the west end, alternate sections 22 ft. long, were poured. The two side bulkheads and rear face forms were of wood and the forestepped bulkhead was of steel. Side bulkheads were omitted when the intermediate slabs were poured. Perfect alignment of the baffle seat insets proved difficult until a special bridge was constructed and the sections lined separately with a transit.

FIG. 6—PLACING FORMS FOR WEIR SECTION

FIG. 7—CUT-OFF DITCHES—SWAMP SECTION LEVEE BASE

Pouring of the weir and pier base was started in December, 1929. This is a heavy slab, 4 ft. deep, built in 22 ft. sections with expansion joints at 44 ft. intervals. Upon this base rests the pier weir section started in January, 1930. Steel forms are used. They are fitted together to form a mold for a pier and half section of weir on each side. Pouring is continuous to the weir crest where a construction joint is prepared and the upper part is continuous to the weir crest where a construction joint is prepared and the upper part of the pier poured separately.

CONTRACTS

The contract for the entire spillway structure except for service bridges and needles is being undertaken by Stevens Brothers, St. Paul, Minn., and The Miller Hutchinson Co., Ocean Springs, Miss., combined. Doullut and Ewin, Inc., New Orleans, who will erect the service bridges and needles, also drove all piling under sub-contract. The dry land levees are being built by Boone and Wester, Sellers, La., the lower hydraulic section by the McWilliams Dredging Co., New Orleans, and the upper hydraulic section by Jahncke Service, Inc., New Orleans.

CONVENTION DISCUSSION

B. Moreell (Washington, D. C.): I would like to ask Captain Swenholt about the reinforcement for the flexible mat. I understood that copper bearing steel wire was to be used. Is that right, or is it copper covered?

Captain Swenholt: Copper bearing steel wire was decided on. There was a great deal of difference in the first cost. The copper bearing steel was believed amply good, and in case of deterioration, we could fasten the slabs together again, so rather than go to that additional expense, we selected the copper bearing wire. As a matter of fact, the real reason was the difference in first cost.

B. Moreell: How was the bearing power of the wood piles determined? Were they driven by formula?

Captain Swenholt: The bearing power of the wood piles was determined as the result of several things. In the first place, we conducted tests at the spillway to get the bearing power. We then employed J. F. Coleman, New Orleans, as a consulting engineer, and he, in conjunction with others, studied the results of these tests. The recommendation of Mr. Coleman was fourteen tons for each pile, and that was adopted.

B. Moreell: I think you do not understand my question. I want to know if you pre-determined the length of the pile and then drove that length, or determined the bearing power of the pile as you drove it, from the *Engineering News* formula?

Captain Swenholt: We tested the piles after they were driven. We computed the bearing capacity of piles from the *Engineering News* formula, but it did not seem to check with the actual results we got on our tests at the structure.

B. Moreell: In other words, you made a load test and then determined the number of piles required from your load test?

Captain Swenholt: Yes, sir.

Readers are referred to the JOURNAL *for March 1931, for discussion which may develop. Such discussion should reach the Secretary by February, 1, 1931.*

Composite Columns

BY L. J. MENSCH*

The composite column here considered is of hooped concrete with standard spiral and vertical reinforcement and with an additional heavy strengthening member or members of cast iron or steel inside the hooping. The spiral reinforcing is generally 1 to 1½ per cent, the vertical steel bars 1 to 4 per cent and the heavy metal core from 2 to 50 per cent of the area inside the hooping. Standard hooped concrete columns are considerably larger than fireproofed steel columns for loads greater than about 200,000 lb.

In high buildings, loads from one to two million pounds are common, requiring concrete columns from 3 ft. 0 in. to 4 ft. 6 in. square. No wonder architects and owners decide to use steel skeletons, although their cost is at least 6¢ per cubic foot higher than for concrete. In some instances engineers have used steel columns, or even steel skeletons for the lower part of a high building and reinforced concrete for the upper part, but results were not quite satisfactory, in having two different contractors working on the frame, which delayed progress and wasted money. As will be shown, composite columns can be designed to fail at a unit stress of 30,000 lb. per sq. in. of the spiral area, which is a considerably greater load than a fireproofed steel column can carry.

Composite columns were first investigated by the well known concrete pioneer Dr. F. Emperger, remembered in this country as the builder of the first Melan type of arch bridge, 36 years ago. He first tested structural steel columns embedded in plain concrete and found the strength of the combination to be considerably less than the sum of the strengths of the structural steel and

*Designer and Builder, 160 N. La Salle St., Chicago

of the concrete. Cast iron columns embedded in plain concrete gave still more unsatisfactory results. He found that the plain concrete failed first and that the shock of the failure of the concrete made the cast iron fail at a lower load than when tested alone.

The combination of cast iron core with hooped concrete was the next step and Dr. Emperger obtained results which showed that the strength of this combination is greater than the sum of the strength of hooped concrete alone and of the cast iron alone.

The difference in behaviour of plain and hooped concrete columns may be explained by the different compressibility of plain and hooped concrete. Plain concrete fails at a shortening of 0.001 of its length, while hooped concrete fails at a unit deformation of 0.01. At a unit deformation of 0.001, steel is stressed to about 30,000 lb. per sq. in., and cast iron to about 15,000 lb.; At a unit deformation of 0.01, steel is stressed to about 35,000 lb. per sq. in. and cast iron to from 50,000 to 100,000 lb. per sq. in., depending on the grade and provided that the strength is not reduced by deflection, or increased by lateral restraint. Hooped concrete forms such a lateral restraint and the object of all tests made up to this time, has been to find the law governing it. To recognize this restraint we have to know the strength of the metal core without its shell of hooped concrete.

We are still in the dark about the strength of structural steel, as the final report of the special committee of the A. S. C. E. on steel columns and struts clearly showed, and we are still less informed about the strength of cast iron members. For structural steel of heavy sections, and only those are of interest in composite columns, we can assume the ultimate strength for $l/r = 50$, 85, and 150 as 35,000, 32,000 and 23,000 lb. per sq. in., respectively. For cast iron without any defects a formula similar to Tetmayer's formula seems to give the nearest results. The ultimate strength per sq. in. $= 100{,}000 - 1500\ l/r + 7\ (l/r)$.[2]

This formula gives the following values:

l/r	20	30	40	50	60	70	80
Ultimate strength, lb. per sq. in.	72,800	61,300	51,200	42,500	35,200	29,300	22,800

The tests made by Dr. Emperger were under the auspices of the Austrian Committee for Reinforced Concrete and are described in No. 3 and No. 11 (1912 and 1927) of the publications

of that Committee and in No. 11 of the Oester. Wochenschrift fur den Offentlichen Baudienst of 1915.[1] The most important results are summarized in Table 1, while Table 3 shows all the particulars of the highly interesting group of 1926. These latter tests were comprehensive and included six standard hooped concrete columns, with 12 in. spiral of 0.64 to 1.65 per cent, with 1.1 per cent of vertical bars, and of a concrete mixture which varied from 1:8 to 1:4½.

FIG. 1—SECTION OF COMPOSITE COLUMN WITH FOUR VERTICAL STEEL BARS AND FOUR CAST IRON ANGLES. SEE TABLE 3

These columns were tested at ages from 14 to 69 days and gave ultimate strengths of the hooped concrete from 1942 to 5420 lb. per sq. in. Then 14 composite columns were made, having the same dimensions and properties as some of the standard hooped concrete columns, but reinforced in addition by 4 cast iron angles 3.14 x 3.14 in. x .39 in., tied together every 10 in. as shown in Fig. 1. They were tested at the same age as the corresponding standard columns. The difference in strength was ascribed to the cast iron core, and the stresses varied from 60,000 to more than 100,000 lb. per sq. in.

Concrete 14 days old seemed to show as good a stiffening effect as concrete 69 days old and the only positive conclusion we can draw from these tests is that 1 per cent and 1½ per cent spiral reinforcement gave more uniform and slightly higher stiffening effect than smaller spirals. It is true, however, that the l/r of the cast iron core was already very small, namely,

26.5, and the percentage of metal was only 9. Very interesting is the comparison between Columns II and IIIm, which were only 59 in. high. Column II had four structural steel angles and column IIIm four cast iron angles of the same size. Their l/r was only 17.5 and the cores ought to have been stressed nearly to their ultimate strength. Indeed it was found that the structural steel angles contributed 47,300 lb. per sq. in., and the cast iron angles 100,000 lb. per sq. in. to the ultimate load of the composite columns.

In order to verify Dr. Emperger's tests under American conditions the writer had 18 composite columns made, 12 in. in dia. and from 6 ft. to 14 ft. long, with 0.6 per cent each of spiral and vertical reinforcement and with a center cast iron core of pipe 6 in. in dia. and ¾ in. thick. These columns were tested by the U. S. Bureau of Standards in 1916 and a full description of the tests may be found in the 1917 Proceedings of the American Concrete Institute.[2] A summary is shown in Table 2. The stresses on the metal core were found considerably smaller than Dr. Emperger's tests and were ascribed to the poor quality of the hollow cast iron cores which showed great unevenness in thickness.

In 1918 the writer had a new set of tests made of composite columns at the Armour Institute of Technology. These columns consisted of: two standard hooped concrete columns 7 in. in dia. and 6 ft. long with 1 per cent each of spiral and vertical reinforcement; two columns, as above, with a solid shaft of cast iron 2 in. in dia. in the center; two columns as above with a solid shaft of mild steel 2 in. in dia. in the center; two cast iron bars 2 in. in dia. and 6 ft. long; and two mild steel bars 2 in. in dia. and 6 ft. long.

The hooped concrete columns failed at 5010 lb. per sq. in., the cast iron bars tested alone failed at 18,775 lb. per sq. in., the steel bars at 20,375 lb. per sq. in., while the metal cores in the composite columns contributed 53,500 and 56,300 lb. per sq. in., showing a very large stiffening effect, which must be ascribed to the comparatively small percentage of metal reinforcing.

To enable the engineers of the new building Code Committee of the City of Chicago to make a comprehensive ruling on composite columns, and especially to find the carrying capacity of metal cores having a large section in comparison with the hooped concrete area, the writer had a new set of columns made on July 13, 1930. These were tested by Prof. W. J. Putnam in the Laboratory of the University of Illinois, in the presence of members of the staff of the University and the Chicago committee. Fourteen columns were tested, having an outside diameter of spiral of 6½ in., the spiral being made of No. 12 high carbon wire at ½ in. pitch. The vertical reinforcement consisted of four ½-in. high carbon bars. The spiral amounted to 1.075 per cent and the vertical bars to 2.35 per cent of the core area. In addition, six columns had 4-in. cast iron cores, representing 38 per cent of the spiral area; two columns had 5-in. cast iron cores, representing 59 per cent of the spiral area; and four columns had 4-in. mild steel cores, representing 38 per cent of the spiral area.

The columns were 5 ft. and 7 ft. long, and two of the cast iron cores were spliced in the center of the height by means of thin wrought iron pipes 5 in. in dia. and 10 in. long. The concreting of the columns was done by foundry workers and the workmanship was not better than that found on the average job. The metal cores were squared at the ends, but were not placed quite square or quite plumb in the forms and it was the intention to have the column ends squared after the concrete was 2 weeks old. This was found impracticable with the tools at hand and the columns were tested with ends in which the concrete was not always even with the metal cores. The thickness of the concrete between metal core and the spiral was only ¾ in. to 1¼ in., which made tamping difficult and voids in the concrete could not be altogether eliminated. Therefore in estimating the load considered to be carried by the metal core, the load carried by the hooped concrete was taken as 5000 instead of the 5750 lb. per sq. in., which was the average strength of the two standard hooped concrete columns tested.

The tests of the spliced cores gave higher results than those of unspliced cores, hence we can say that splices as used do not diminish the strength of composite columns. The same result

was found with spliced cores in some of Emperger's tests and in those of the U. S. Bureau of Standards. None of the cast iron cores failed by breaking. The columns failed by deflection and at the ultimate load some spiral wires were broken. Again the ultimate stresses on the cast iron cores were lower than in the European tests and it is now clear that the hard grade of cast iron used there is more suitable than the soft machinery cast iron obtainable here. The results of the tests are given in Table 4 and are summarized in Table 2. All the tests mentioned show a considerable range of results and it is very difficult to formulate a rule which fits all conditions. It can be positively stated, however, that Dr. Emperger's claim of the strength of the composite columns being greater than the sum of its components has been verified by every test. It can also be affirmed that for columns of $l/d < 6$ and percentages of metal cores < 12 per cent, the stresses on cast iron cores are always greater than 50,000 lb. per sq. in. on common grade of cast iron, and greater than 40,000 lb. per sq. in. on structural steel. For columns having an $l/d = 8$ to 12 and metal cores less than 12 per cent, the ultimate stresses on cast iron equals 40,000 to 53,000 lb. on common grade, and 50,000 to 100,000 lb. per sq. in. on hard grade material. For columns having an $l/d = 14$, the ultimate stresses on the cast iron cores were found to be 36,600 lb. per sq. in. The tests further clearly show that the l/r of the metal core has a large but not preponderant influence on the result. Where l/r was smaller than 30 we always find stresses near the cubical strength of the material, and for l/r smaller than 50 the ultimate stresses on the cores are still very high. On the other hand for percentages of the metal core smaller than 9 (not very important in composite columns) the concrete exerted such a large stiffening effect, especially where l/d was smaller than 9, that the stresses in the metal cores were still found very high for very large values of l/r. The stiffening effect of the concrete is still clearly seen in composite columns with 38 per cent of metal core. While Tetmayer's formula would lead us to expect an ultimate strength of the cast iron of 35,200 lb. per sq. in. for a l/r of 60, the tests showed 38,500 lbs., and for an l/r of 48 we obtained 44,900 lb. per sq. in. against 44,200 according to Tetmayer.

The 4-in. mild steel cores showed stresses of 36,800 and 34,400 lb. per sq. in. as compared with 34,500 and 32,000 lb. per sq. in. by the formula. In nearly all cases common grade of cast iron proved more efficient than structural steel. Where stresses in the cores were less than 50,000 lb. per sq. in., the first cracks always occurred at 70 to 80 per cent of the ultimate loads. At the U. S. Bureau of Standards laboratory, elaborate extensometer tests were made and it was found that the vertical steel bars were stressed to the elastic limit long before the ultimate load was reached, and that the unit deformation of steel and concrete at ¼ load was 0.00035.

The present rulings on composite columns were not based on the tests above mentioned. The Chicago ruling under which quite a number of large buildings have been constructed with composite columns allow the following design stresses:

Stress on hooped concrete of 1:1:2 mix with 1 per cent of spiral ..... 800 lb. per sq. in.
Stress on vertical bars ..... 14,000 lb. per sq. in.
Stress on cast iron cores ..... 10,000 lb. per sq. in.

Detroit Ruling:

Stress on hooped concrete, 1:1:2 mix, with 1 per cent each of spiral and vertical reinforcing ..... 1,120 lb. per sq. in.
Stress on cast iron cores ..... 11,200 lb. per sq. in.

Joint Committee:

Stress on 1:1:2 concrete with one per cent spiral ..... 1,250 lb. per sq. in.
Stress on vertical bars ..... 7,500 lb. per sq. in.
Stress on steel cores not to exceed ..... 15,000 lb. per sq. in.
Stress on cast iron cores not to exceed ..... 9,000 lb. per sq. in.

The cast iron cores are limited to 12 per cent.

From the tests made at the Armour Institute and at the University of Illinois it is clear that the Joint Committee ruling favors structural steel and underestimates the value of cast iron, and on the other hand allows too low stresses on the vertical bars. The limitation of the cast iron cores to 12 per cent is wrong. The writer would propose stresses on the concrete as per ruling of the Joint Committee, stresses of 10,000 lb. per sq. in. on vertical bars, stresses on the metal cores, depending on the ratio of length to diameter as follows:

For l/d —	6	8	10	12	14	16
Permissible unit stress on metal core	13,000	12,000	11,000	10,000	9,000	8,000

All spirals consisted of No. 12 with ½ in. pitch. Area of spiral core, 33.2. Equiv. area of spiral, 1.075 per cent of spiral core. Area of four ½-in. Ø = .784 sq. in. = 2.35 per cent of spiral core.

Concrete mixture 1:1:2. Columns were 40 days old when tested.

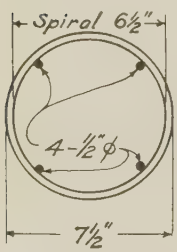

FIG. 2

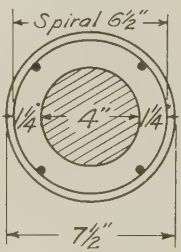

FIG. 3

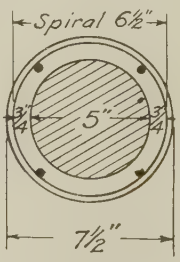

FIG. 4

which would result in factors of safety of 3.5 to 5 depending on the percentage of metal reinforcement used and on the l/r of the core. Composite columns have shown great uniformity of results where duplicate tests have been made, and they are just as reliable as steel columns. Hence the proposed factor of safety is very conservative in comparison with that of steel columns which is generally only 2½ and sometimes less.

As a result of these tests there are these observations:

High carbon wire for spirals was found much superior to ordinary steel wire, and the increase in strength of the hooped concrete was found proportional to the elastic limit of the hooping wire, or the ultimate strength in case of hard wire. A close pitch of the spiral wire produced more uniform results than a large spacing, and is very important in composite columns because the thickness of the concrete between core and spiral often is only a few inches. The practice of using a great number of vertical bars, 8 or more, to prevent a flow of the highly stressed hooped concrete is not warranted by these tests, and the flow is more positively prevented by a small pitch.

Dr. Emperger has used composite concrete sections of rectangular shape for ribs in a number of important arch bridges, and had tests made on rectangular columns with rectangular spirals of close pitch, containing about 10 per cent of cast iron core. He tested a number of sections of 9-in. x 19-in., having a kind of I-section of cast iron with large openings in the web, the cast iron representing 11 per cent of the section. The l/d was 14.4, the l/r was 84 and the ultimate load per sq. in. which the cast iron core supported was figured at 42,000 lb. The same sections loaded with an eccentricity of ⅓ the depth supported a load of ⅔ the concentrical load. Such composite compression members are of great advantage in arched bridges of great spans. Instead of plain reinforced concrete ribs of an ultimate strength of about 3000 lb. per sq. in., composite ribs can be designed for 18,000 lb. per sq. in. and more. The lighter section of the ribs not only reduces the cost of the abutments and that of the form work, but very materially decreases the stresses due to shrinkage or a drop in temperature. Deflections and settlements of the abutments cause very much smaller stresses in small crown sec-

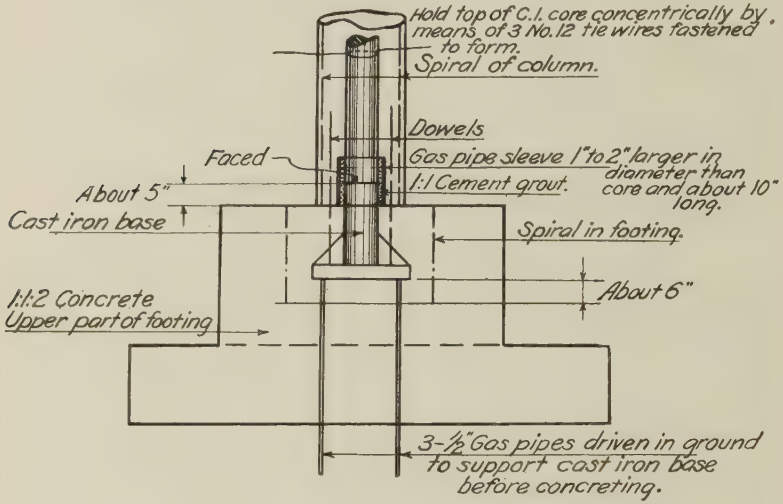

FIG. 5—TYPICAL FOOTING FOR COMPOSITE COLUMN

tions than in large ribs and make the introduction of hinges almost superfluous. Engineers are enabled to use arch bridges in localities where rock foundations hitherto considered necessary for every arch bridge, are not available for the abutments. It is also an easy matter to design the metal core for the support of the suspended formwork, thereby reducing the cost of this most important item to perhaps one third. Dr. Emperger has built a number of bridges from 200 to 300 ft. span in competition with wooden bridges and nearly all his bridges had abutments supported by piles. He obtained patents for his system of composite sections in nearly all civilized countries. The author has made designs for heavy bridges up to 1000 ft. span and found their cost considerably lower than steel or common concrete bridges of the same total length and divided into two or three spans.

In the practical design of composite columns the load from the metal core is transmitted to the footing by means of a cast iron base, as shown in Fig. 5. The upper part of the footing is made of 1:1:2 concrete and is strengthened by a spiral of about 4½ times larger than the core. The load from the core is transmitted

Basement 1420	25″	1½%	10—1¼″ sq.	11⅜″	38″	1½%	43—1¼″ sq.

From above data it is found that, assuming all columns to be 11 ft. high in each story,

Emperger columns contain:
1,100 cu. ft. of 1:1:2 concrete,
3,114 lb. of spirals
13,750 lb. of vertical steel
2,112 sq. ft. of forms, and
29,293 lb. of cast iron

Standard columns contain:
1,574 cu. ft. concrete
7,255 lb. of spirals
29,535 lb. of vertical steel
2,460 sq. ft. of variable forms.

by bond on the shaft of the base and by direct compression of about 1000 lb. per sq. in. on the plate. The direct stresses from the hooped concrete of the basement column can be assumed to spread out in the shape of a cone between the base plate and the footing spiral. Before the cast iron base is set, three ½-in. gas pipes are driven into the ground to the correct elevation of

the under side of the plate and the base is lowered to the proper level. The shaft of the base is made long enough to project 5 in. above the finished footing, and after the footing is concreted a gas pipe sleeve, one or two inches larger in diameter than the core, is placed concentrically over the protruding shaft and filled with cement grout of 1:1 mix to about ¼ in. below the top of the shaft. After the basement column form and the spiral and vertical rods are in place, the gas pipe sleeve is partly filled with grout by pouring from the top of the form and the metal core is lowered into the sleeve by means of a gin pole, the grout acting like a mirror, thus enabling the setter to center the core. Sometimes ¼ in. rods are placed in the space between the core and the sleeve to facilitate centering. The grout fills the space between sleeve and core, and to assure that no gravel has lodged between the faces of the cores, the upper core is turned a few times to the right and left to crush it. The top of this core projects 5 in. above the first floor and the connections on each floor are made with sleeves as described for the basement story. The top of the core is held in place by 3 wires connected either to the columns or floor forms.

It is important for engineers to know what size column to adopt to obtain an economical and practical design. They have to be guided by the fact that a great saving in the cost of the entire skeleton can be effected by making all columns of each column stack of the same size, and if possible use only one or at the utmost two or three column sizes in the entire structure. It is very much easier for the contractor to build all his column forms on only one or two benches without change of templates; he will not need special foremen to superintend the rebuilding of forms story by story. Neither will he have to rebuild the girder and lintel forms. He will need only two sets of column forms and not more than two sets of lintel forms even if his progress is at the rate of three stories per week, because he does not lose any time for rebuilding. Hence less talent has to be spent on the form work and more time is left for the leaders to see that good work is done on the concreting, and competent contractors will soon learn that they can do the form work for columns, girders and lintels for at least 5¢ per square foot less than in the old system with its repeated changes of form.

Experience has shown that a composite column stack with the same size of columns from top to bottom, costs less than a column stack with standard hooped concrete columns of varying sizes, when the basement columns are designed for about 4000 to 5000 lb. per sq. in. on the area within the spiral hooping. Table 5 shows such a comparative design for a 22-story building which has been constructed in the City of Chicago.

When the composite columns are made larger the cost is less, and when they are made smaller than shown in Table 5 their cost may become slightly higher than that of standard hooped concrete columns.

In order to solve the question of bond of the cast iron core with the hooped concrete, the writer had tests made by Prof. D. A. Abrams on smooth 2 in. bars 12 and 24 in. long, embedded in a 7-in. diameter hooped concrete block. The results of the tests were not published. The bond stress at failure was found to be from 900 to 1200 lb. per sq. in., and confirmed similar results found by Considere on gas pipes embedded in hooped concrete.[3] The bond stress is so much higher than in plain concrete because the hoopings prevent the concrete from splitting up. This high bonding value enables the metal core to take up in the depth of a girder the heaviest loads any girder or number of girders ordinarily transmit to a column in any one story; hence brackets or rings on the core beneath the girders are unnecessary. Engineers often inquire how the reinforced girders are connected to the columns. There is hardly any difference between this type of column and the ordinary concrete column, especially as the modern tendency is to make girders not much deeper than the joists framing into them. This requires that the girders be made wide, preferably as wide as the columns for economy in form work, which enables most of the straight and bent bars to pass by the cores, as there is nearly always at least 5 in. of concrete outside the cores. In special cases it may be necessary to use two or more extra bars for the negative moments at the columns. In a number of cases steel girders have been connected to brackets on the cores and

[3]Commission du Ciment Armé. Rapport etc. 1907.

in one case trusses, carrying over a million pounds, have been set on top of the cores.

It is the writer's practice to use as longitudinal reinforcement from 2 to 4 per cent of high carbon bars to take care of any bending moment which may be exerted on the columns. Because the loads are very large on composite columns, the eccentrity produced by connecting girders is not as a rule of great amount. It is different, however, with columns forming part of a wind

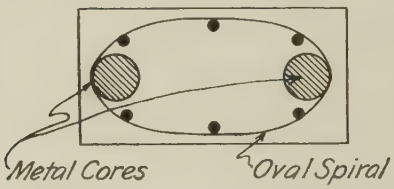

FIG. 6—SECTION OF COMPOSITE COLUMN FORMING PART OF WIND BRACING SYSTEM

bracing system. There the eccentricity of loading may be as large as 6 to 9 in., and such columns act similarly to the ribs in an arch bridge, and a design as shown in Fig. 6 will be more economical in buildings higher than 20 stories. Nearly all columns tested by the writer showed eccentricities of loading which varied from 1/20 to 1/10th of the diameter of the spiral; hence, engineers need not be too anxious about small eccentricities.

A comparison between composite columns with cast iron cores and structural steel cores might be of interest to the profession. Let us assume a column 15 ft. high has to support a load of 2,000,000 lb. Adopting the rule proposed by the writer we shall allow for 1:1:2 concrete with 1 per cent spiral, a stress of 1250 lb. per sq. in., and 10,000 lb. minus 1250 lb. or 8750 lb. per sq. in. on the vertical steel. Adopting a spiral of 22 in. we find the l/d equals about 8, hence the permissible stress on the core is 12,000 lb.—1250 lb. or 10,750 lb. per sq. in. The area of the 22-in. concrete core is 380 sq. in. and the area of eight 1¼-in. square bars, representing about 3 per cent of the area inside the spiral is

12.5 sq. in., hence the load carried by the hooped concrete is 380 x 1250 lb. = 475,000 lb.; by the vertical steel 12.5 x 8750 lb. = 109,000 lb., giving a total of 574,000 lb. Hence the metal core has to carry a load of 2,000,000 lb. — 574,000 lb. = 1,426,000 lb., requiring a sectional area of 1,426,000 divided by 10,750, or

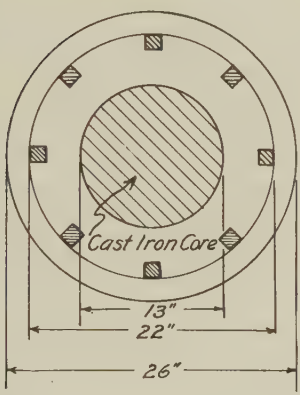

FIG. 7—SECTION OF COMPOSITE COLUMN WITH CAST IRON CORE

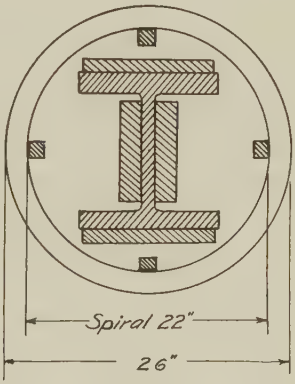

FIG. 8—COMPOSITE COLUMN WITH STEEL CORE OF BETHLEHEM H-COLUMN WITH COVER AND WEB PLATES

132.5 sq. in., equivalent to a cast iron core exactly 13 in. in diameter. The l/r will be about 55, and we may expect this core to fail at a stress of about 50,000 lb. per sq. in., if made of common grade of cast iron. This cast iron core will weigh about 425.0 lb. per lin. ft. A Bethlehem 16-in. H-column section would have about 126 sq. in. but cannot be used in any spiral less than 28 in. in dia., hence we have to use a 12 in. H-section weighing 190 lb. per lin. ft. and reinforce it with two cover plates 12 in. x 1¼ in. and two web plates 9 in. x 2 in., giving a total area of 121 sq. in. and weighing about 435 lb. per lin. ft. This section has about 9 per cent less area than the cast iron core, but is heavier, and costs, of course, a great deal more. Both sections are shown in Figs. 7 and 8. While cast iron cores can be shipped within 3 days, deliveries of structural steel cores would require

a great deal more time. If composite columns come into vogue it will, of course, be possible to get round sections rolled on short order.

An inspection of Fig. 7 will show that composite columns are more nearly fireproof than fireproofed steel columns because there is as a rule at least 5 in. of concrete outside of the metal core, and the core alone can support the load with a good factor of safety, even if the concrete is entirely destroyed. Composite columns have also been used in low buildings where small sizes of columns are of importance, such as garages and certain manufacturing buildings, or where the contractor appreciates the saving of form work in having all columns in the building of the same size. Engineers, also, ought to appreciate the savings in their own time of preparing column schedules. When all columns are the same size, and spirals and vertical steel are alike, the schedule will have to show only the size of the core for each story, and a simple note will take care of the spiral and vertical rods for most of the columns.

Readers are referred to the JOURNAL *for March 1931 for discussion which may develop. Such discussion should reach the Secretary by February 1, 1931.*

Specifications For Ready-Mixed Concrete

Proposed American Concrete Institute Specification No. 504

MILES N. CLAIR,* AUTHOR-CHAIRMAN

Committee 504, Specifications for Ready Mixed Concrete

1. General

(A) These specifications cover the special conditions affecting the use of Ready-Mixed Concrete and supplement the requirements of the General Specifications for Plain and Reinforced Concrete for this Contract.

(B) The term "Ready-Mixed Concrete" is used in these specifications as meaning[1] Central Plant-Mixed concrete and Central Plant-Proportioned Truck-Mixed concrete.

(C) The place where the materials are proportioned is referred to in these specifications as "the plant."

(D) The operation of the plant shall be under the direct supervision of a competent engineer.

2. Materials

(A) All aggregates, cement and water shall be of the quality required by the General Specifications for Plain and Reinforced Concrete. All conveyors, bins and hoppers shall be cleaned of unapproved materials before starting to manufacture concrete for this contract.

(B) No change shall be made in the materials used, during the course of this contract, except with the permission of the Architect or Engineer.[2]

3. Concrete quality and proportioning

(A) The concrete quality and proportions shall be in accordance with the requirements of the General Specifications for

*Vice-President, The Thompson & Lichtner Co., Inc., Boston.

[1]The Architect or Engineer must indicate which systems are allowed. It is recommended that in general both be included.

[2]In the use of this specification for a particular project one of these must be stricken out throughout the text to avoid conflict.

Plain and Reinforced Concrete. Proportions, however, shall be subject to change under the direction of the Architect or Engineer when necessary to produce proper workability or satisfactory strength.

(B) The measurement of the concrete aggregates and the cement[3] shall be by weight so that the proportions can be readily adjusted to assure a definite volume of concrete of the quality specified. The measurement of the water may be by weight or volume. The volume of concrete produced per batch shall be taken as the sum of the absolute volumes of the ingredients.

(C) A statement of the control quantities[4] used and the time at which the vehicle was loaded shall accompany each load of concrete. The organization supplying the ready-mixed concrete shall have available sufficient test data, certified by a competent concrete testing engineer, to enable the Architect or Engineer to determine whether the quantities used will give concrete of the desired quality and the stated quantity per batch.

(D) Facilities shall be provided at the plant to enable the Architect or Engineer to check easily at any time the quality of the materials and the accuracy of the measurements.

(E) Tests of the concrete as delivered to the forms shall be made during the progress of the work as required by the General Specifications for Plain and Reinforced Concrete.

4. MIXING AND TRANSPORTING CONCRETE

(A) *General*

(1) Transporting vehicles shall be so constructed as to insure rapid delivery without loss of ingredients.

(2) All concrete shall be mixed in a revolving drum type of mixer, whether stationary or movable. The mixing time or number of revolutions shall be as recommended by the manufacturer; but shall not be less than required by the General Specifications for Plain and Reinforced Concrete. The mixer shall not be loaded beyond the capacity recommended by the manufacturer.

[3]Bag measurement may be used provided the batches do not involve fractions of bags.
[4]"Control quantities" refers to the requirements of the specifications such as water-cement ratio, cement content, or proportions.

(3) A maximum period of 00 hours[5] may elapse between the addition of the cement to the aggregate and the placement of the concrete in the forms; but the concrete as placed shall be of the consistency and workability required by the General Specifications for Plain and Reinforced Concrete.

(4) Under no circumstances shall partially hardened or retempered concrete be placed in the structure.

(5) Special precautions shall be taken to protect the materials from damage during transportation under extreme weather conditions.

(B) *Central Plant-Mixed Concrete*

(1) The concrete shall be properly mixed in accordance with the requirements of the General Specifications for Plain and Reinforced concrete before being loaded into the transporting vehicle.

(2) Non-agitating type transporting vehicles shall not be used to transport Central Plant-Mixed concrete when the consistency of the concrete is wetter than a —-inch slump.[6]

(3) Remixing type transporting vehicles[7] shall not be used to transport Central Plant-Mixed concrete when the consistency of the concrete is wetter than a —-inch slump.[6]

(4) Agitating type transporting vehicles may be used without restriction as to consistency.

(C) *Central Plant-Proportioned Truck-Mixed Concrete*

(1) The procedure in loading the truck mixer[8] shall be such that the cement and aggregates are uniformly distributed throughout the batch when the loading is completed.

(2) Where the concrete is mixed during transportation of the batch to the job, means shall be provided so that the mixing time

---

[5]The Architect or Engineer must indicate the limiting period. A maximum period of one hour is recommended. (The committee is not unanimous. One group approves of the limit of one hour, as given. The remainder of the committee approves a statement in the footnote referring to this item as follows: "Present knowledge of the art indicates that the time may be as long as three hours under favorable conditions. It should be limited by the engineer or architect after a study of job conditions, kind of aggregates, and the prevailing temperature and weather conditions at the time the structure is being erected.")

[6]The Architect or Engineer must indicate the limiting slump. A maximum allowable slump of 2½ ins. for non-agitating type trucks and 6 in. for remixing type trucks is recommended.

[7]Re-mixing vehicles are those provided with special means of remixing or agitating the concrete to some degree during discharge but not during transportation.

[8]It is suggested that the cement and aggregates be fed simultaneously into the end loading type of truck mixer. For the top loading type of mixer this method of charging is not so essential; but is also recommended.

and the quantity of water added can be readily verified by the Architect or Engineer.

5. DELIVERY

(A) The organization supplying concrete shall have sufficient plant capacity and transporting apparatus to insure continuous delivery at the rate required.

(B) The interval between loads shall not exceed — minutes,[9] or in any case be so great as to allow the concrete in place to become partially hardened.

(C) The methods of delivering the concrete shall be such as will facilitate placing with the minimum of re-handling and without damage to the structure or concrete.

DISCUSSION

BY THE AUTHOR-CHAIRMAN

The specifications for Ready-Mixed concrete presented herewith to the Institute for tentative adoption have been developed after considerable discussion, among the members of the committee and others of the proposed specification published in the JOURNAL for February, 1930.* The questions about which the discussion centered are:

(1) Should the specification be considered as a complete specification in itself or as a supplement to a general specification for plain and reinforced concrete?

(2) Should separate specifications be developed for Central Plant-Mixed Concrete and for Central Plant-Proportioned Truck-Mixed Concrete?

(3) Should special limitations be placed on the methods of measuring materials?

(4) What limitations should be set up for the use of the various types of transporting vehicles and mixers?

The decision of the majority of the committee is apparent from the specifications here proposed; but some discussion and explanation may be of value in connection with its proper use.

*A. C. I. *Proceedings*, Vol. 26, p. 467.

[9]The Architect or Engineer must indicate the interval allowed. A maximum of thirty minutes is recommended.
(The committee is not agreed as to the consistency or slump limitation. The group in opposition to the form proposed desires something as follows in the footnote. "The Architect or Engineer must indicate the limiting slump. Practice indicates that while there are definite limitations to this type of transportation, the limiting slump will be determined by the particular type of equipment used, the nature of the mix, the length of haul, and the character of the road over which it is to be hauled."

Most Architects or Engineers use a standard general specification for plain and reinforced concrete based on the Joint Committee Report. That specification is relatively complete in regard to requirements for materials, proportions, mixing, quality of concrete, placing of concrete, and other items. The requirements necessary under most of these items for Ready-Mixed concrete are no different to secure good concrete than for job-mixed concrete. The Architect or Engineer is still conservatively inclined to use job-mixed concrete rather than the recently developed ready-mixed concrete; and, therefore, a specification that supplements his present general specification with additional safeguards has special appeal. The additional complication of separate specifications for central-plant-mixed concrete and central-plant-proportioned-truck-mixed concrete seems at this time unnecessary. Possibly abuses or future developments may later warrant such a separation.

The specification proposed is, as stated in its first paragraph, intended for use as a supplement to the General Specifications for Plain and Reinforced Concrete for a particular contract; and, therefore, only such special requirements are given as appear necessary to insure concrete of the quality desired. The conception of a specification as a statement of the results desired rather than of the methods or equipment to be used is adhered to as far as possible. It is considered the function of another department of the Institute to set up requirements for equipment and procedure to meet these specifications. The specifying of the supervision of the plant operation by a competent concrete engineer is considered necessary because the plant must be ready to produce on almost instant demand concrete to meet any one of many specifications. A technical education combined with considerable field experience with concrete construction and the control of concrete quality are essential requirements for such a supervising engineer.

Two special requirements are set up in regard to materials. The ready-mixed concrete plant in general has a tie-up with definite material sources which will satisfy the usual specifications. Special materials are required for some work, however, and contamination by usual materials must be prevented. Like-

wise, change of source of materials during the course of the work must be subject to approval by the Architect or Engineer so that not only the quality but also the appearance will not vary.

Although most general specifications for plain and reinforced concrete at present set up requirements in terms of strength, cement content, water-cement ratio, and workability, and do not closely limit proportions, the concrete as produced by the ready-mixed concrete operation may call for changes which the Architect or Engineer should be free to make. The requests for such changes will, however, most frequently come from the plant operator who knows from experience the best combinations, for his equipment and conditions, to meet certain requirements. Changes as requested by the concrete foreman on the job should never be made without the approval of the Architect or Engineer.

A ready-mixed concrete plant cannot accurately meet the demands of numerous specifications and pre-determined quantities unless the aggregates are weighed. The entire operation becomes simplified if all the materials including cement and water are weighed. One of the principal causes of controversy in regard to ready-mixed concrete is the basis on which the volume of concrete delivered shall be measured. Direct measurement in most cases is not possible; but if weight proportioning is used, the yield as computed from the absolute volumes of all the materials is sufficiently accurate and will closely agree with direct measurements.

The Architect or Engineer on the usual construction project can at any time readily go to the mixer and check up on the mix. He also generally has some check on the amounts of materials used, and so will know whether the concrete is nearly of the mix required. The ready-mixed concrete plant is almost always at an appreciable distance from the job; and, therefore, a statement of the basic control quantities used for each load is desirable. These quantities can be used not only as a check on proper quality and quantity, but also to enable the Architect or Engineer to estimate, from the test data and records of batch quantities available at the plant, the probable strength at any given period.

The ready-mixed concrete operation differs from the usual job concrete procedure mainly in the mixing and transporting of the

concrete. The central-plant-mixed concrete system mixes in a regular mixer of a large size, and transports the concrete to the job in ordinary trucks or special trucks. No comments are necessary in regard to the mixers except that they are usually of larger sizes than is common for job set-ups; and, therefore, the mixing time required is generally greater. Minimum mixing times of one minute for a one-yard mixer, 1½ minutes for a two-yard mixer, and two minutes for a three-yard mixer, are recommended. The conveying vehicles should be water-tight so that no ingredients of the mix are lost. Agitator trucks should be designed so that they really do keep the concrete mixed throughout the truck. Overloading of agitator trucks results in decided decrease of efficiency of the mixing action.

Central plant-proportioned-truck-mixed concrete requires special mixing and conveying equipment. Some of the truck mixers are essentially the same as the standard mixers of low length-diameter ratio; but the more common type is of high length-diameter ratio. These truck mixers also range to sizes as large as five cubic yards. Experience has indicated that a mixing time of five minutes, or better 40 revolutions, is necessary for such mixers. There is plenty of time for such mixing during the trip to the job. Some end-loading types of mixer trucks also require special care in loading to assure uniform distribution of the materials, unless excessively long mixing time is used. The truck mixer type of operation puts the mixing and water measuring operations in the hands of the truck driver, if done on the way to the job; and, therefore, some means of readily checking up on these operations should be provided.

The Architect or Engineer is most concerned when using ready-mixed concrete that the concrete comes to him in a homogeneous mix and without damage due to the time elapsing in transportation. Transportation of the concrete in an ordinary truck that may be used at other times for sand and gravel appeals to the ready-mixed concrete plant operator because of its low cost. Experience, however, has shown that concrete wetter than a 2½-in. slump cannot be transported in such trucks without segregation and consequent difficulty in unloading and detriment to the quality of the concrete. Under special conditions of mix, ma-

terials, or very short hauls, wetter concrete has been successfully handled; but such cases are not usual.

Agitator type trucks are satisfactory for concrete of any slump likely to be used. Most agitators keep the concrete well-mixed despite the surprisingly small amount of movement given the mass. Improvement in the design of some agitator trucks is desirable, however, to insure a more uniform mixing action, particularly where several batches are used to fill one truck.

Most architects and engineers agree that concrete that has partly hardened should not be used. What is meant by "partly hardened" is difficult to define; but it is more readily determined in practice, as such concrete has a peculiar crumbly appearance when mixed which is different from concrete that is just dry. The limit to be set on the time elapsing between the addition of the cement to the batch and the placing of the concrete in the work will depend on many factors; and cases have been cited to favor a shorter or longer period. Without tests for a particular set of conditions, it is recommended that a maximum elapsed period of one hour be allowed. This is considered as properly applying to truck mixing operations as well as to central plant mixing, because the water in the aggregates in the former operation is available for action with the cement.

The section of the specification on Delivery is intended to safeguard the work from delay due to failure of the ready-mixed concrete supply. It might in many cases well include a requirement of a bond to insure proper service and to cover damages.

The writer is considerably indebted to the critic members of this committee for their suggestions, criticisms and interest. Unanimous agreement in regard to all items was not possible or expected as the use of Ready-Mixed Concrete is comparatively new. Changes in any specification will be made as experience in the field concerned gives more facts on which to base conclusions. It is hoped that this specification will be considered of sufficient merit to be given a working trial as a Tentative Standard Specification.

Readers are referred to the JOURNAL *for March, 1931, for discussion which may develop. Such discussion should reach the Secretary by February 1, 1931.*

Discussion of Report of Committee 604

"Winter Concreting Methods"*

BY I. E. BURKS AND G. D. DURHAM†

It was not so very many years ago that constructors faced with the necessity of placing concrete in freezing weather, attacked the problem with apprehension and doubt. There seemed to be a feeling that a structure erected under such conditions *might* be satisfactory and a fair chance that it might *not* be. Today, thanks to the information made available through the publications of various technical societies, and through the experiences of individual engineers and constructors, we are able to attack a concrete job at 30 or 40 degrees below zero with a feeling of absolute confidence in the results—*if certain rules of the game are carefully followed.*

It is certainly true that there are a few examples of partial failure, directly attributable to frozen concrete. There are also dozens of noteworthy examples of excellent concrete work done at extremely low temperatures. Committee 604 hopes to be successful in correlating the experience and observation of constructors responsible for the successful operations and also the failures. Mr. Johnson, in his preliminary report, has paved the way for writing recommended practice which may eventually be adopted as standard by the Institute, and which may be followed with confidence and safety by engineers and constructors.

In his report as author-chairman of the committee, Mr. Johnson limits its scope to concrete construction in ordinary buildings —but, he points out that the principles involved are equally appli-

*By Robert C. Johnson, as author-chairman of committee 604, Winter Concreting Methods, published in the Journal, Feb. 1930—A. C. I. *Proceedings*, Vol. 26, p. 397. See also discussion Journal, June 1930—*Proceedings*, Vol. 26, p. 904.

†Mr. Burks is concrete technician for the Aluminum Company of America, member of Committee 604 and wrote "Concreting Methods at the Chute a Caron Dam" (in the Journal for Feb. 1930—A. C. I. *Proceedings*, Vol. 26, p. 315) where concrete was placed at 40° below zero. Mr. Durham is his associate on that work.

cable to other types of construction less difficult to protect. For the purpose of this discussion, perhaps it would be helpful to divide all concrete work into two general classes, viz., Reinforced Frame Sections, and Heavy Mass Work. We agree that the principles of protection are the same for either of the classes named but suggest that the objective may be slightly different. To cure concrete for such a time as simply to protect it from damage by freezing is one objective; to cure it for an additional period in order that it may attain a specified strength at a designated time, is another objective. The first is usually the only requirement in heavy mass work. The second, is generally an important and necessary consideration in reinforced frame construction.

If concrete freezes before it solidifies, the uncombined water forms small ice crystals throughout the mass. If it is thawed and thoroughly cured at temperatures above 50° it will attain a strength equal to from 75 to 95 per cent of its potential strength. It has often been stated that *one* such freezing does little if any permanent damage to the concrete, nevertheless, as pointed out by R. B. Young,[1] it is difficult to conceive that the pores formed by the ice crystals are all entirely closed and the mass consolidated as it would have been had freezing not occurred. From this it is evident that the greatest damage done by freezing occurs after the concrete begins to solidify or harden.

The length of time that concrete should be cured to prevent its being damaged by freezing, depends mainly on four factors: (a) type of cement; (b) richness of mixture; (c) amount of heat supplied by the aggregates and mixing water; (d) temperature of the air within the protective enclosure.

In heavy mass construction, the safe protection rule is to provide means of maintaining the temperature of the green concrete near exposed surfaces, above 50° F. until it has attained sufficient strength to withstand frost action. In general it may be stated that concrete designed to have compressive strength of from 1500 to 2000-lbs. per sq. in. at 28-days should be kept at or above the temperature stated until 40 per cent of the designed strength is developed—2000 to 3000-lb. concrete should have 30 per cent, and 3000 to 4000-lb. concrete should have 20 per cent

[1]Discussion of Report of Committee 604—A. C. I. JOURNAL, June 1930—A. C. I. *Proceedings*, Vol. 26, p. 904.

of its designed strength before the temperature of sections near the surface is allowed to fall below 50° F. In gravity dams, high strength is desirable but it is not essential and curing is largely directed to obtain a surface that will withstand the weathering action of the elements. The surface area is small as compared to the mass and the heat loss by radiation is small —consequently the heat developed by the hardening concrete is retained for a longer period.

In thin reinforced frame work, the concrete may be protected until the danger by freezing is eliminated and still not attain its designed strength at the 28-day period. Consequently, there is a possibility of damage by premature loading unless proper protection is provided to meet the requirements of individual cases.

Small walls and structural members encountered in building construction offer a very definite structural hazard when subjected to freezing. The problem of protection and curing is to enable these members to obtain their designed strength before being loaded. In proportion to their mass the surface is great—hence the heat developed by the chemical reaction of the hydration of the cement plus the heat supplied at the mixer, is readily dissipated by the lower air temperatures. Therefore, in thin reinforced frame construction, the forms must be covered and the enclosure maintained at a temperature sufficiently high and for a period long enough to insure the development of the required strength.

On the work on which the authors are engaged,[2] a series of preliminary tests was made to determine the length of time it is necessary to cure concrete placed at temperatures considerably below the freezing point. The experiments were made by the field laboratory organization in the winter of 1929-30 when it was convenient to take advantage of the low atmospheric temperatures for freezing the specimens. The work had to be temporarily discontinued in the early Spring of 1930 because of temperature conditions, but it is to be resumed in the Winter of 1930-31. The series on which results are available at this time includes only one water-cement ratio—viz., 0.80. The second series is to be made using a water-cement ratio of 1.0.

[2]Chute a Caron Dam, Province of Quebec, Canada.

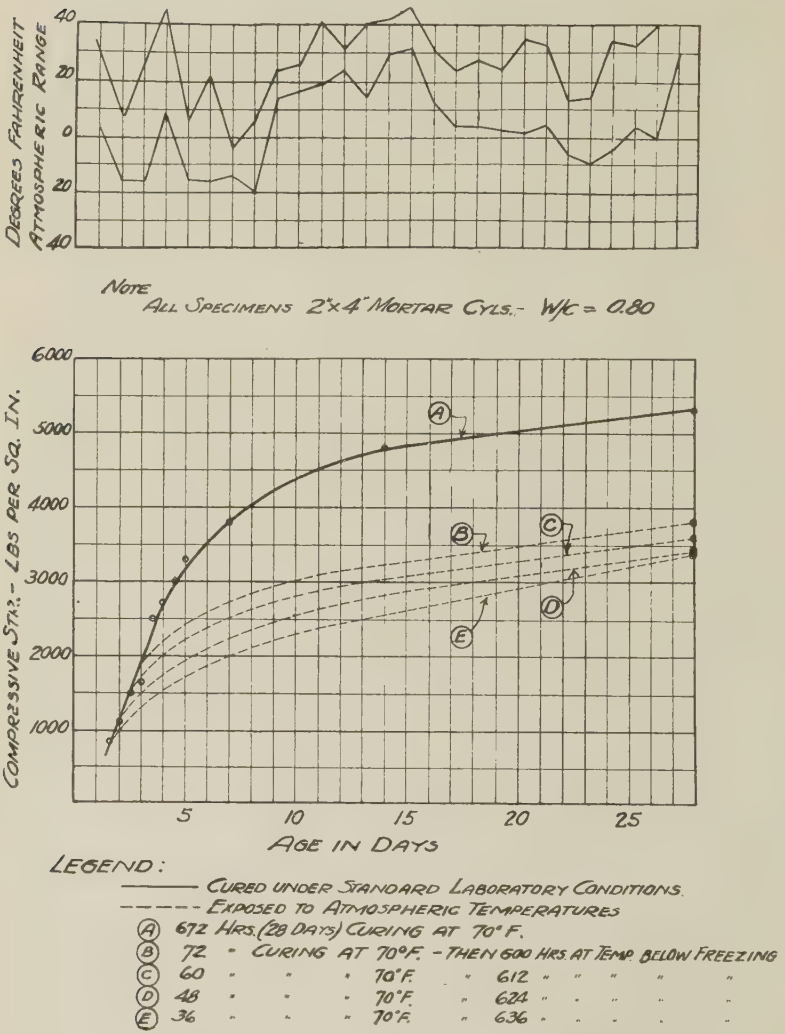

FIG. 1—EFFECT OF EARLY CURING AT LOW TEMPERATURES ON 28-DAY STRENGTH

For convenience, and since comparative results only were required, all specimens made were 2 by 4-in. mortar cylinders, formed in accordance with standard practice. The specimens were cured for varying periods under standard conditions and then exposed to the existing freezing weather. The earliest breaking period was 36-hours. Breaks earlier than this were so low as to be of questionable value and were probably beyond the range of accuracy of the testing machine. All specimens were capped and allowed to remain in laboratory air (70°) one-hour before testing. Figs. 1, 2 and 3 show the results obtained. It should be pointed out that in these experiments the effect of freezing is magnified somewhat because the surface area of the test specimens used is so great in proportion to the volume.

In Fig. 1, Curve A represents the potential strength of a mortar at various ages up to 28-days when cured under standard laboratory conditions. Curves B, C, D and E indicate the strength of the same mortar when cured under standard conditions for 72, 60, 48 and 36 hours and then allowed to freeze for the remainder of the 28-day period. It will be noted that the frozen specimens acquired from 63 to 70 per cent of the potential 28-day strength.

Fig. 2 shows the same general strength relation as Fig. 1, except that all frozen specimens in this group were broken at the age of 7-days. It will also be noted that slightly different temperature conditions prevailed. In this group the specimens were cured at 70° for 36, 48, 60 and 72 hours and then allowed to freeze for the remainder of the 7-day period, show 55, 66, 71 and 75 per cent of the potential 7-day strength.

In Fig. 3 the specimens received the same early curing treatment as those in Figs. 1 and 2—but at the age of 7-days were returned to the warm air of the laboratory where they remained until the 14-day period, at which time they were broken. The direction taken by Curves L, M, N and O seems to indicate that at some period beyond the age of 14-days these curves would join the potential strength curve. It is regretted that this series does not include definite data on Curves L, M, N and O at the later ages, however, this is one of the series which will be developed further in the coming winter.

FIG. 3—STRENGTH GAIN WHEN CURED IN WARM AIR AFTER INITIAL CURING AT LOW TEMPERATURES

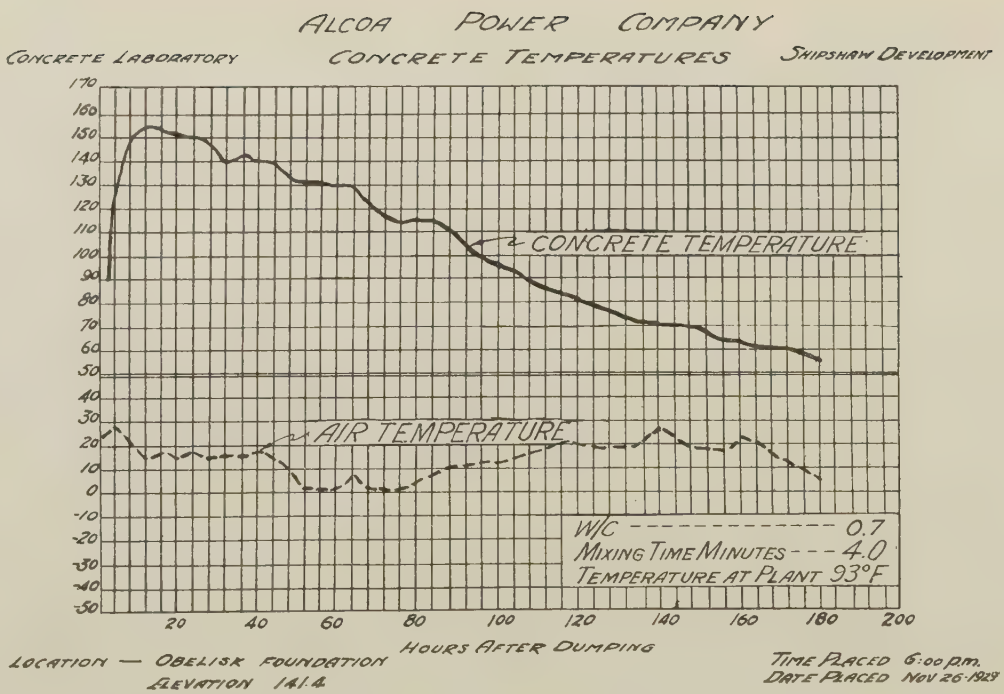

FIG. 4—TEMPERATURE RANGE OF MASS CONCRETE

During the time that the tests referred to above were being made, an arbitrary curing period of 72-hours was specified for concrete placed in all structures on the Chute a Caron project. By this is meant that adequate heat should be supplied, and proper covering provided to retain that heat, so that the temperature of the concrete 1-in. from the form faces would not fall below 60° for 72-hours after placing.

In general, this specification gave excellent results. In certain sections of the heavy mass work it was found that the form covering could be removed and the steam heat discontinued after 36-hours and the temperature of concrete near the exposed surfaces would still be 50 degrees or above at 72-hours after placing. On other smaller sections of the Power House work it was found necessary to keep the covering in place and the steam heat circulating for the full 72-hour period.

The chart, Fig. 4, gives a good idea of the temperature range on mass work. It will be noted that the concrete left the mixing plant at 93° F. The temperature began to rise immediately after placing and continued to do so until it had reached about 155° at 12-hours. It then decreased gradually until it reached 55° at 180-hours. In this instance the protective covering was kept in place for 60-hours.

It is not a difficult matter to work out a satisfactory type of form covering. Charles S. Hill, in his book "Winter Construction Methods" gives several excellent examples. The methods used at Chute a Caron Dam are shown in Figs. 5 and 6. It will be noted that practically the same type of covering is used on the small sections (Fig. 5) as on the heavy mass work (Fig. 6). The form sheeting is made of 2-in. lumber and this has considerable insulating value in itself. The covering for vertical faces consists of 4 by 10-ft. panels, burlap and tar-paper covered. These may be nailed to the main form walers, or placed about 18-in. back from the main form to provide a working space for pipefitters. A 1-in. steam line is run around the form at the bottom and at the center of each lift. The opening between the two forms is closed at the bottom to prevent upward draft. The top is covered by tarpaulins. Over large forms the tarpaulins are supported on

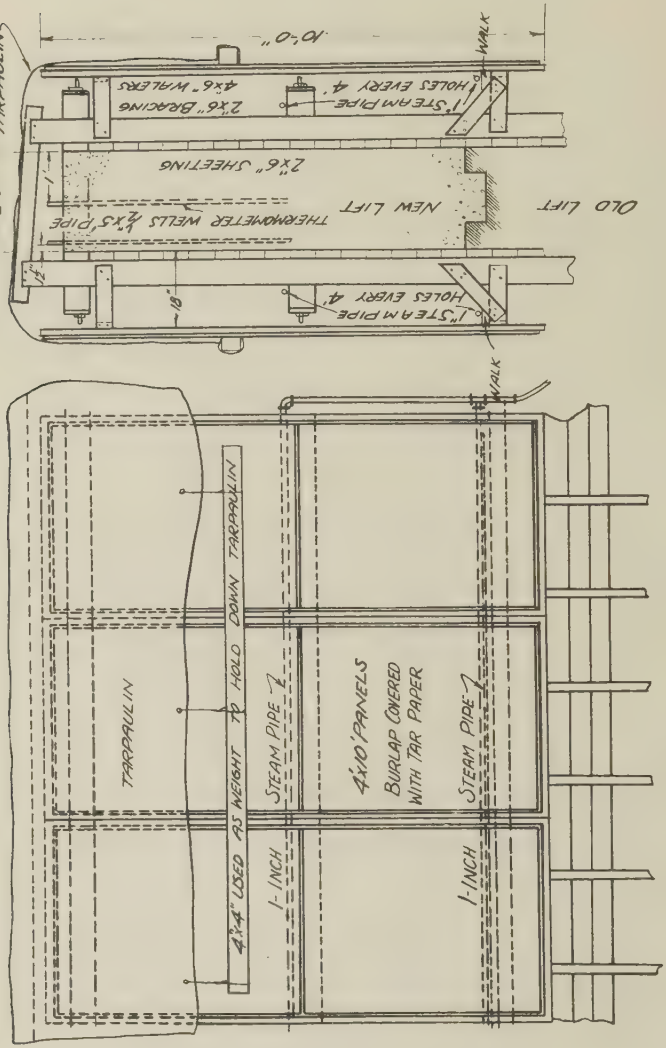

FIG. 5—METHOD OF PROTECTING SMALL SECTIONS OF CONCRETE

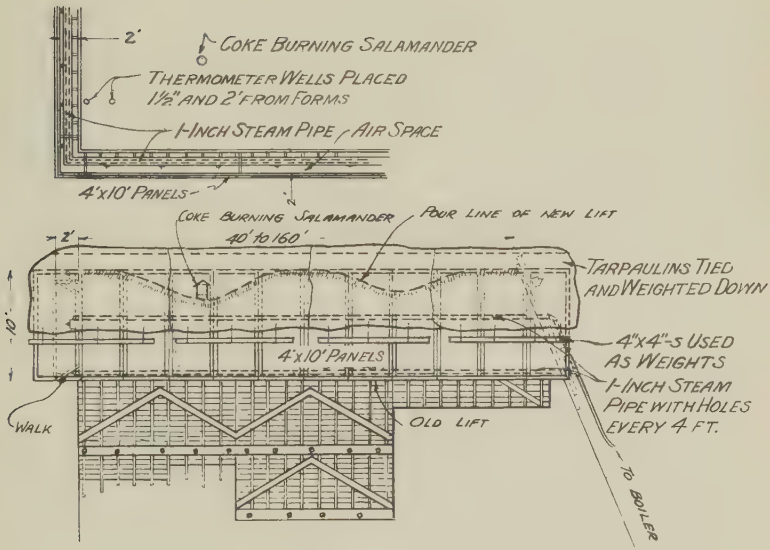

FIG. 6—METHOD OF PROTECTING HEAVY MASS WORK

light frame-work, and coke-burning salamanders are placed in the shear valleys, as shown in Fig. 6.

It is recognized that live steam, due to the moisture supplied, provides better curing protection than dry coils—however, it was found necessary to arrange the piping so that both types could be used on this work. If live steam is used while the placing is in progress, clouds of steam prevent the crews from seeing and the work becomes difficult and dangerous. Valves are placed at intervals in the coils so that dry heat may be supplied during the time the form is being filled, and then the valves are opened and live steam supplied when the form is finished and covered. Thermometer wells made of ½-in. water pipe, from 3 to 8-ft. long, are placed in the lift while the concrete is soft. These are normally located in three positions in the form; one at the up-stream face, one near the center and one at the down-stream face. Temperature readings are taken in these wells during the curing period.

When the air temperature is below the freezing point, necessary arrangements are made at the mixing plant to produce concrete having a temperature of from 70° F. to 100° F. It was found that concrete heated to above 100° was in danger of taking a flash-set. On two occasions when the mixture was discharged at 110° the concrete was set up in the buckets before it could be delivered to the forms (a matter of 25 or 30 minutes). This may have been caused by certain characteristics of the particular brand of cement used, or, it may have been caused by the manner in which the materials were introduced into the mixer drum. It has been suggested that if the cement came into immediate contact with mixing water at a temperature of from 180° to 200°, the chance of a flash-set would be much greater than when the mixing water had first been cooled to some extent by contact with the sand and stone. It is the opinion of the authors that there is no advantage in heating concrete higher than to 100°. This temperature offers ample protection for any ordinary transportation and placing system and has been found to be quite satisfactory where air temperatures are as low as 40° below zero.

Mr. Johnson has stated that concrete should be placed in the form at not less than 70° and not more than 140°. The lower limit would be quite satisfactory for reinforced frame-work, but it should be pointed out that temperatures from 10° to 15° lower than this can be used with safety on mass work where the air temperature is anywhere above zero. This is assuming that proper protection at the form is provided. His upper limit of 140° is open to question and there seems to be a great difference of opinion on the subject. The authors' views on this point have been stated in the preceding paragraph.

The matter of heating aggregates is not a serious problem where proper facilities are provided. It is probably a waste of time and money to try to heat the coarse aggregate at all. If enough stone or gravel is to be used to feed even a 3-bag mixer continuously the time and money required to heat this material is out of all proportion to the benefits obtained. Instances are very rare where more than a small portion of the stone particles are ice-coated and the heat of the mixing water alone is enough to thaw any such ice-coating before the concrete leaves the mixer.

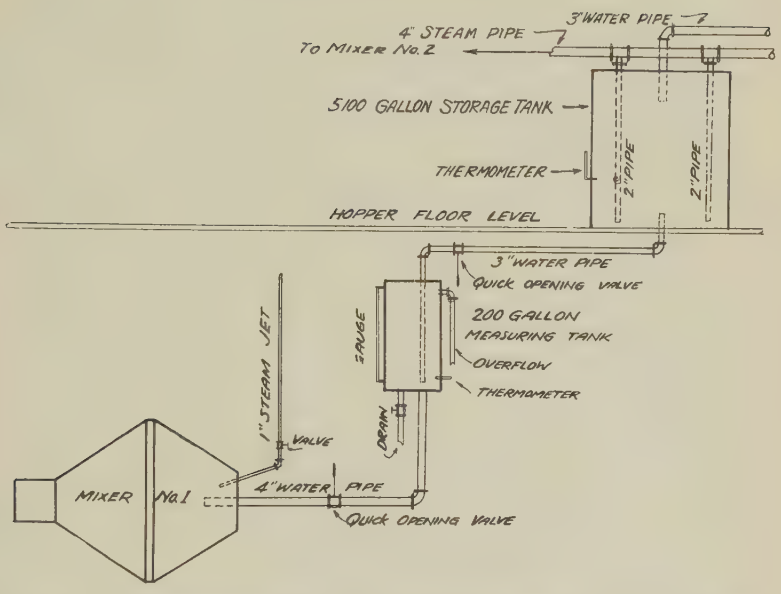

FIG. 7—ARRANGEMENT FOR SUPPLYING STEAM AND HOT WATER TO MIXERS

By using live steam it is a simple matter to heat sand to almost any temperature from 60° to 150°. On our work the sand temperature usually runs between 70° and 80°—with the mixing water at from 180° to 200°. This combination, together with a 1-in. steam jet in the mixer, will produce concrete at from 70° to 100°.

Mr. Johnson recommends that the sand and stone be heated when the air temperature is 35° F. and lower. This precaution would certainly provide a comfortable margin of safety. However, the authors are of the opinion that in some cases it would add an unnecessary item to the cost of winter construction. Where the efficiency of the form protection scheme is questionable it might be a worthwhile precaution to heat the aggregates as Mr. Johnson suggests. It has been the experience of the authors that heating the mixing water only, will provide ample protection until the air temperature gets down to about 15° above zero.

The method used at Chute a Caron for supplying hot water and steam to the mixing plant may be best understood by study-

ing the diagram, Fig. 7. The 4-in. pipe-line, which supplies the steam for heating water in the two 5100-gal. storage tanks, is taken from two 80-h. p. boilers. These boilers also furnish steam for the 1-in. jets in the mixer drums and for the various jets in the sand stock-pile.

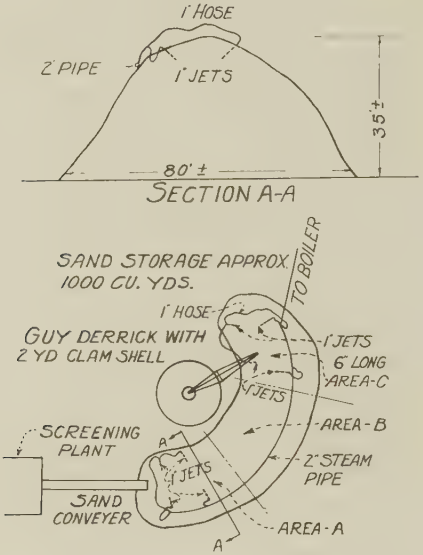

FIG. 8—METHOD OF HEATING SAND IN STORAGE PILE

The sand in the storage pile is heated by several 1-in. steam jets which are moved about as conditions require. The storage pile is divided roughly into three areas, two of which are being steamed while sand is being used from the third. A sketch showing the sand heating arrangement is shown in Fig. 8.

If conditions do not favor the storage pile arrangement, and it is found more convenient to deliver sand directly from the pit to mixing plant bins, a very satisfactory method of heating is to provide steam jets in the dump cars, as shown in Fig. 9. Eight 1-in. steam jets placed in a 30-yd. car will thaw all frozen lumps and heat the sand to about 100° F. in about 3-hours. If the sand

is to be screened before using, an added benefit of heating in the cars lies in the fact that the hot sand prevents the conveyor belts and screens from freezing. The maximum loss of heat caused by handling sand from cars, through the screening plant and into the mixer bins, was found to be about 20 degrees.

While the heating and protection arrangements outlined above have given very satisfactory results at Chute a Caron Dam, there

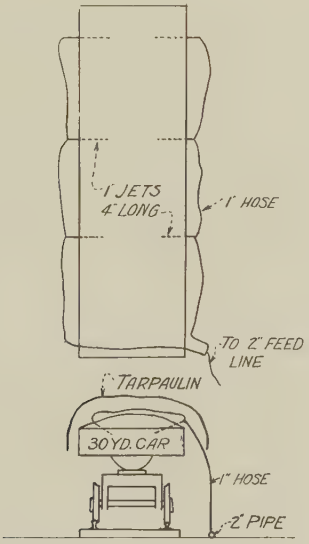

FIG. 9—METHOD OF HEATING SAND IN DUMP CARS

are doubtless many other methods in use which are just as good, or better. It would be a fortunate circumstance if Mr. Johnson's committee could be successful in getting all engineers who are familiar with cold weather concreting work to record their experience in order that the most efficient methods could be described in detail and published in his committee's final report. If "Recommended Practice for Winter Concreting" is to be written and sponsored by the Institute, the economic phase should be given very careful consideration. While the ultimate

aim of such a specification should of course be to produce concrete of the quality prescribed by the design, the requirements of the specification should be such as to avoid unnecessary expense. A constructor should not be required to keep a section of his concrete work covered and heated for 10 days if 3-days will suffice—neither should he be required to go to the expense of heating aggregates before conditions warrant such action.

Discussion of Report of Committee 403

"The Treatment of Monolithic Concrete Surfaces"*

BY H. M. HADLEY†

The report of Committee 403, Monolithic Concrete Surfaces, by N. C. Johnson, is good reading. Definite ideas are definitely expressed. There is nothing vague or nebulous about Mr. Johnson's statements, and whether in agreement or disagreement with them, one finds them refreshingly explicit and to the point.

Mr. Johnson looks for major developments in concrete as a surfacing material of artistic worth by removal of "the objectionable and harmful cement form skin" and exposure of the aggregate, either without further treatment or as a clean sound base for veneers. He properly enumerates the several defects and disadvantages which may singly, or severally, or—also be it said—may not at all occur with form-cast surfaces. "The constant and resistless and never-ending action and reaction of this surface excess of cement with atmospheric moisture" does indeed lead to "unfortunate volumetric and appearance changes" sometimes and under certain conditions, but such changes are not inevitable. In fact, the writer's observations, not wholly confined to "balmy climates of almost constant humidity," would lead him to think that concrete surfaces, untouched and direct from the form boards, withstood the attrition of weathering processes in a highly satisfactory manner wherever the concrete itself was of sound, good quality. Where the quality was not good, that fact also was revealed. It is impossible to run a bluff on nature. But

*By N. C. Johnson, author-chairman; Journal, May 1930—A. C. I. *Proceedings*, Vol. 26, p. 717.

†Regional Structural Engineer, Pacific Coast Region, Portland Cement Association, Seattle, Washington

FIG. 1—LIFE SCIENCE BUILDING, UNIVERSITY OF CALIFORNIA, BERKELEY. GEORGE W. KELHAM, ARCHITECT. ENTIRE STRUCTURE OF MONOLITHIC CONCRETE, INCLUDING ORNAMENT

the opinion is submitted that concrete of good structure and quality possesses a form-cast surface requiring no additional treatment to render it enduring and permanent, and, in this respect at least, entirely satisfactory.

It is because the great and truly impressive growth of architectural concrete on the Pacific Coast has proceeded almost wholly through the development of the form-cast surface that fuller mention of such treatments should be made. These form-cast surfaces have been wash-coated, acid-stained, or painted for color as the case may be, or may have been left in natural color, but they are all characterized by the distinct preservation of the form marks and form surfaces. Such architectural designs emphasize *concrete*, in contrast with designs in which veneers,

either of mortar or masonry, conceal it. They present construction problems, some of a general and some of a peculiar nature, but they also offer opportunities for the exercise of freedom in architectural design which is delightful and the beauties of whose results cannot but command admiration and respect.*

He was a brave man who ate the first oyster, it is said. Quite his peer is that nameless architect who first dared to leave concrete frankly exposed, with the form-marks showing and the grain of the wood revealed and imperfections of various minor kinds all plain to view. Here a board bulged slightly; there was a knot; over there a nail bent for some cause or other and a carpenter swore. But the nameless architect who knew that according to all the conventions it ought to be plastered or

*See "Architectural Concrete—Forms, Molds and Surfaces" by William C. Wagner, in the pages of this JOURNAL issue.—EDITOR.

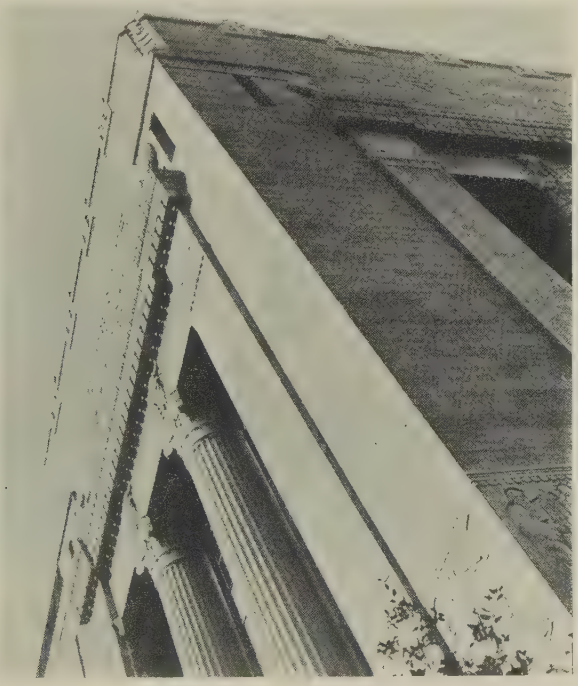

FIG. 2—DETAIL OF LIFE SCIENCE BUILDING, SHOWN IN FIG. 1

FIG. 3—ENTRANCE HAWTHORNE SCHOOL, BEVERLY HILLS, CALIFORNIA. R. C. FLEWELLING, ARCHITECT

veneered, also knew in his own mind that this surface with natural random variation of line and texture, just as it came from the forms, was rich in interest and was as good as any veneer could possibly make it. Why not, when the forms and molds are as characteristic of concrete, are as intimately and as essentially part of the construction, as is the concrete itself? It is basically good in everything, architecture included, to be honest. So since the cost of the veneer he had planned on could be used to take care of one or two troublesome "extras" that had developed on the job, and since he had pretty good concrete in the walls anyway, our nameless architect nerved himself and decided to leave it exposed with only a wash coat to give it color. And he got away with it, and later found that he liked it more and more, and found that after the first shock, other people did, too; and so on.

Probably such are the details of this first and unknown case. Be they what they may, the later uses are known and stand in evidence, and of their beauty and charm there can be no question. They are accomplished facts. See Figs. 1, 2 and 3. For buildings of more formal character to which the ordinary textures of wood are less well adapted, extremely true plane surfaces are obtainable by lining the wooden forms with sheets of pressed wood fiber. Jointing and rustication of such surfaces is obtained by nailing beveled strips over the fiber board lining. Again, various formal surfaces of large area may be obtained with wooden forms, milled to desired pattern, shellacked and oiled. For more elaborate decorative effects, waste molds of plaster, or wooden molds, are built in with the wooden forms and offer wide scope for variety in design. Accompanying views are representative of the results being obtained with treatments of this type.

Color effects may be produced in this type of construction where other than the natural tone of the cement is desired either by wash coats or by the integral admixture of color in the cement. The Wilshire Professional Building derives its white color from a paint coat. The exposed concrete of the Richfield Oil Building—approximately half of the entire exterior—was made to conform with the black terra-cotta of the main facades by covering it with a China wood-oil carrying a carbon pigment.

FIG. 4—BANK OF HOLLYWOOD BUILDING. TWO LOWER STORIES ON STREET FRONT ARE TERRA COTTA; ABOVE, ALL CONCRETE WITH SURFACES AS LEFT BY PRESSED FIBRE FORM LINING AND ACID STAINING BY LAEMMENS PROCESS

It cannot be too strongly emphasized that with designs contemplating exposed concrete exteriors, the concrete, just as the name indicates, is really and actually to be exposed in the finished structure and will be in the plain sight and view of everyone. This means that comfortable, easy-going, good-enough concrete, whose defects can so easily be concealed by veneers, is eliminated at the outset. It simply cannot be tolerated because it would be an

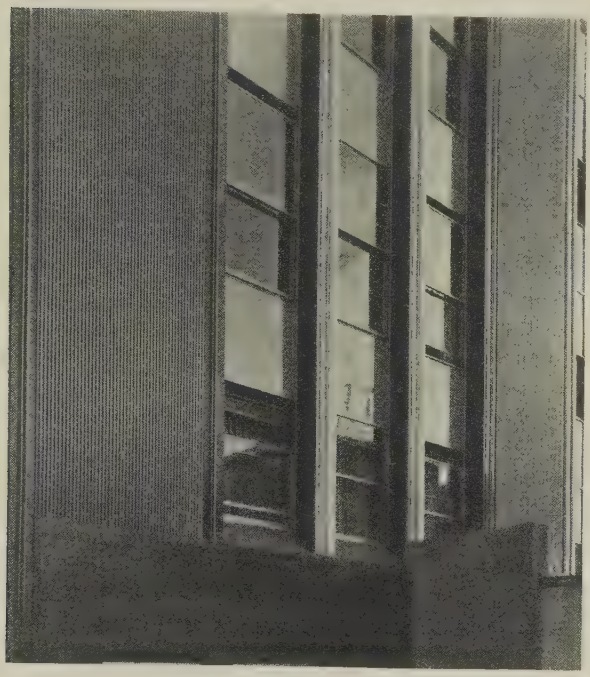

FIG. 5—DETAIL OF CONCRETE PORTION OF RICHFIELD OIL BUILDING, LOS ANGELES. TERRA COTTA ON STREET FRONTS; CONCRETE ON PROPERTY LINE SIDES; WOOD FORMS WERE MILLED AND FLUTED TO CONFORM WITH TERRA COTTA

eyesore to all beholders and a continued standing indictment of the contractor who built it and of the architect who permitted it to be built. It would be better not to attempt exposed concrete than to fail at it. Yet successful results can be obtained readily. What is required is a concrete surface of uniform quality, free from gravelly, honeycombed blotches, segregation of materials, ragged and irregular pour lines, laitance or sawdust in construction joints, badly sprung forms—in fact a concrete free from major and serious defects. There must be obtained as near to a full 100 per cent extent as possible that same excellent good quality of concrete surface which even a poor job will show over

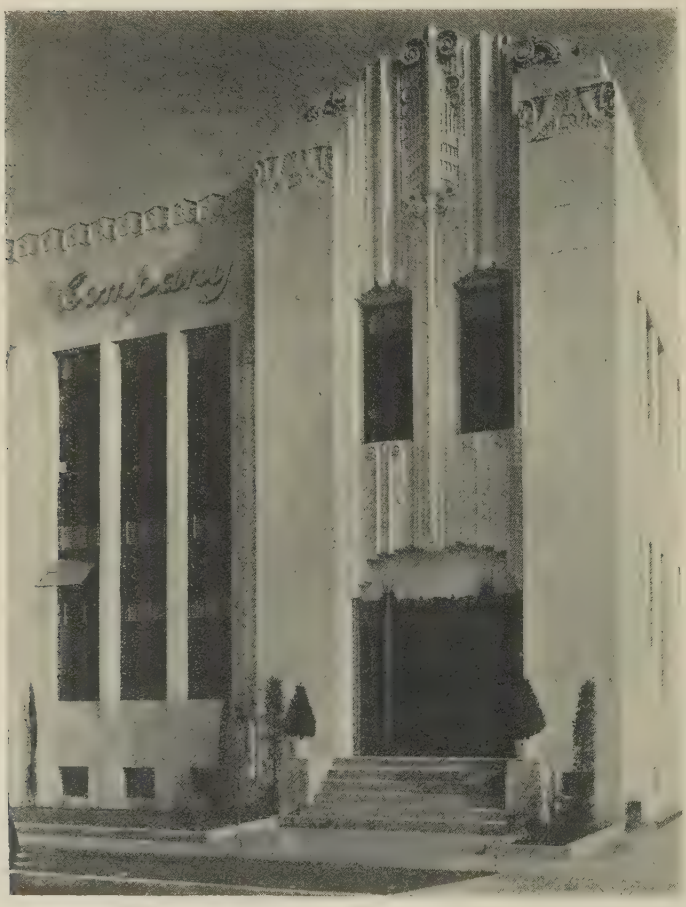

FIG. 6—HOFFMAN CANDY CO. BUILDING, LOS ANGELES. PLASTER WASTE MOLDS USED TO PRODUCE ORNAMENTATION

most of its area. A plastic workable mixture of minimum water content has to be placed to fill completely the forms which have been built to receive it and in such a manner as to result in a homogeneous, uniform concrete. Merely superficial blemishes—air pockets, water voids, exposure of fine honeycombing of no depth —are not at issue. They give variety and attractiveness and interest and prevent the monotony of uniform perfection. But

the question of uniform, good concrete is of issue and has to be met.

The architectural uses of concrete are to be welcomed by everyone concerned with improving the quality of concrete. To bring concrete into the focus of attention, to make it visible, subject to the critical examination of all eyes, will almost automatically eliminate careless slipshod work. When slipshod work can not be hidden but has to stand in plain view, nobody wants it and everybody disclaims it. It becomes inexcusable, intolerable. To subject concrete to such a searching scrutiny and inspection as it must of necessity receive when used architecturally will have a very wholesome effect upon its quality.

BY B. STUART MCKENZIE*

In my construction experience I became acquainted with two methods of finishing concrete surfaces which have not been mentioned. Both methods proved most satisfactory in service.

The first consisted in the application of a cement grout wash rubbed in by means of a canvas sack, usually an old cement bag, immediately after the removal of the forms. The result was much more satisfactory than that obtained by the use of a whitewash brush, which is the usual custom.

The other method consisted in the use of a hand block made of cement mortar. The surface to be treated was thoroughly wet with a whitewash brush and then rubbed with the cement block. This served to grind off the surface imperfections and also to fill voids and produced a surface which was practically perfect.

It may be objected that these methods, particularly the latter method, are too expensive from an operating standpoint but in my own experience the results obtained were well worth the cost.

AUTHOR'S CLOSURE BY NATHAN C. JOHNSON

Discussion of any subject is always most interesting. The discussion by Mr. McKenzie and Mr. Hadley are welcome sidelights on this subject of surfacing, which has too long been neglected.

The writer intended, in speaking of "Wash and Float Finishes," to include by inference the methods mentioned by Mr. McKenzie.

*Secretary, Canadian Engineering Standards Association.

Beyond this acknowledgment, there seems no need to amend the text of the report as it is.

The comment of Mr. Hadley is particularly forceful in one sentence.

This sentence is: "It is impossible to run a bluff on Nature."

This sentence, perforce, runs through all of Mr. Hadley's comment. Each paragraph of that comment should have, as an opening sentence, this deep truth, that: "It is impossible to run a bluff on Nature."

Mr. Hadley brings California to us once again, but all the concrete in the world is not in Los Angeles. For every photo he will show in illustration of his comment, any camera in any other clime or city could bring other photos, sometimes unbeautiful in the extreme, proving by concrete buildings elsewhere, that "It is impossible to run a bluff on Nature."

It is recognized that Mr. Hadley's comment is familiar propaganda. But is it helpful propaganda? Unless a statement of position tends to advance or improve an art, over what has been done before in that art, it may well prove to be harmful and delusive.

In Egypt, thousands and thousands of years ago, long before portland cement was thought of, the artisans of that country colored, stained, painted and otherwise over-treated mud surfaces (form surfaces, if the term is preferred) because they were unlovely as they were and because it was even then recognized that they had to be and should be covered up to make them "good enough," even for those days.

And they succeeded then, because the climate of Egypt is so ridiculously dry that even unbaked mud bricks of those past ages have endured to the present day.

In Los Angeles, where humidity is so constant, one can and may cover up unlovely form skins with stains, varnishes, china-wood paints and other means as mentioned. But to infer or to state that in other and unlike parts of the world these things may be successfully done, is no kindness to the art of using concrete, for "It is impossible to run a bluff on Nature."

In detail, one cannot but wonder if Mr. Hadley ever attempted to make or to cast an intricate form, or to line a form with pressed wood fiber and so on. Some of us have.

It is also a grave mistake to talk, except perhaps in California, of painting concrete with china-wood or linseed paints, without special pre-treatment.

Other comments on the factual and economic aspects of Mr. Hadley's views might properly be made and to the advantage of the industry, but if it be remembered in reading them, that it is, in very truth, "impossible to run a bluff on Nature," much time will be saved.

The Committee report as it stands, it is true, mentions things that our grandfathers did not know about, although they knew all about form-mark surfaces. But in no industry that we know of is enterprise and improvement considered a crime, except in the minds of the few and even with them, it is a crime for a brief time only.

As Dr. Aggasiz so aptly phrased it many years ago:

> Every advance passes through three stages: First, men say it is not true. Then, they declare it is hostile to accepted beliefs. Finally, they say that it is right and is true and that everyone had always known it.

The Committee report as it stands does not seem to need correction or modification.

Strength and Shrinkage of Mortars Made with Blends of Portland Cement and Pozzuolanic Materials

C. A. HUGHES* AND A. S. LEVENS†

A POZZUOLANIC material has been defined[1] as "a substance, while not necessarily cementitious by itself, possesses constituents which will combine with hydrated lime at ordinary temperatures in the presence of moisture to form stable insoluble compounds of cementitious value. When added to lime mortar in addition to or in partial substitution for the sand, it will impart hydraulic properties and greater strength. When added to concretes and mortars made with portland and similar cements by the consequent removal of the free lime, it will impart to the material an increased degree of resistance to various agencies which are normally liable to cause disintegration."

If it be accepted[2] that the compounds formed by a pozzuolana and the lime hydroxide liberated during the hydration of Portland cement are of cementitious value, then the use of pozzuolanas with Portland cement will affect the water-cement ratio strength relations.

It is claimed[3] also that pozzuolanic admixtures reduce defects caused by shrinkage, particularly crazing and checking.

[2] "Tufa Cement, as Manufactured and Used on the Los Angeles Aqueduct"—J. P. Lippincott, *Transactions of American Society of Civil Engineers*. Vol. 76, 1913, page 520. This paper and discussion containing much data from tests made during the construction of the Los Angeles Aqueduct and elsewhere is to the authors' knowledge, the most complete treatment of blended cements as used in America. Mr. Lippincott's conclusions are as follows:

[3] An American Pozzuolana and Its Effect on Portland cement Concrete. Dr. E. Lee Heidenreich, *Rock Products*. Sept. 29 and Oct. 27, 1928.

1st.—The tufa, when finely ground with cement and used in concrete, combines both chemically and mechanically. Blends of 50%, when mixed with sand, give greater tensile strength after 10 days than straight cement mixed with the same proportion of sand. The leaner the mixture, the greater the relative superiority of the tufa cement. In compression, the tufa cement concrete is less strong (20%) in rich mixtures (1:2:4), and as strong in leaner mixtures (1:3:6). (footnote cont'd p. 318)

The tests for which the data are presented herewith were undertaken to determine the effect of four pozzuolanic materials on the strength and shrinkage of mortars. Compression tests were made on 218-2x4 in. cylinders and shrinkage measurements taken on 27-2x2x10 in. beams.

MATERIALS

Cement. Two brands of portland cement were used. These are designated by the letters N and A. The N brand was used for the majority of the tests. Both cements complied with the requirements of the A. S. T. M. specifications.

Fine Aggregate. The fine aggregate was a local concrete sand graded from the No. 4 sieve down with a fineness modulus of 2.6. It was used in a bin-dry condition and had a net absorption of 0.6 per cent. Care was taken to maintain a uniform grading for all mixes.

Water. The mixing water was from the Minneapolis City supply and was at 70° F. when used.

Pozzuolanic Materials.

F—a volcanic ash obtained from a deposit near Fresno, Calif.

P—a volcanic ash sold commercially as a concrete admixture.

S—Blast furnace slag used as a raw material in the manufacture of portland cement.

H—Burnt shale sold commercially for concrete aggregate.

F and P were used as received. S and H were ground in a ball mill. No measure of the fineness of the pozzuolanas was obtained other than that all passed the No. 200 sieve, which is of little significance since pozzuolanic action results from the very fine particles.

The pozzuolanas were substituted for cement by weight so that the total weight of cement or cement plus pozzuolana was constant for all mixes. The cement and pozzuolana were blended to a uniform color before mixing the mortars.

2nd.—Tufa cements, in tension, of blends from 30 per cent to 80 per cent show a continued growth in strength with age, as far as tested, up to 5 years, and in this respect are superior to straight cements, which usually show declining strengths.

3rd.—The tufa concretes must be handled with greater care with reference to both cold and drying, and forms should be left in place about one-third longer. In massive work this feature is negligible.

4th.—From the fact that the tufa cement is more finely ground and, in part, combines mechanically with other aggregates, carrying the graduation of fineness one step farther, it makes a denser and more impervious concrete.

5th.—Where cements are high priced, a substantial economy may be effected if deposits of tufa are available. These conditions occur in portions of Western America. The milling cost of producing the extra barrel of tufa cement in small plants should not exceed 75 cents.

Pozzuolanic Activity

The relative activity of the four pozzuolanas was determined by a method used by the Building Research Board.[1] This consisted of adding 0.6 g. of pozzuolana to 0.4 g. of slaked lime in a test tube, covering with pure water and shaking every twelve hours.

The interaction between the solution of lime in water and the pozzuolana will give rise to hydrated calcium alumino-silicates of complex or indefinite chemical structure; these hydrates will be formed in a colloidal condition, and are much more bulky than the pozzuolana or lime, with the result that after seven days the tube will contain an increased volume of solid matter as measured by the height it extends up the tube, also the rate of settlement, owing to its flocculent nature will be slower; the activity of the pozzuolana can, therefore, be judged by inspecting the tubes at different times after shaking. In comparison, the volume of the solid matter immediately after mixing will be much smaller and it will settle immediately.[1]

The per cent increases in volume following a 30 minute settling period are shown in Table 1. Also see Fig. 1.

TABLE 1—PER CENT INCREASES IN VOLUME RESULTING FROM POZZUOLANIC ACTIVITY

Age Days	Pozzuolana			
	F	P	S	H
2	8	64	16	52
3	46	79	236	73
4	92	89	245	83
5	123	97	245	94
6	143	100	247	115
7	146	100	254	135

Mixing. From each batch consisting of 1500 grams of sand and 500 grams of cement, or cement plus pozzuolana, were made three 2x4 in. cylinders or one beam. The method of mixing the mortars was that specified by the Standard Specification for Portland cement. Four sets of cylinders and two sets of beams were made, each set being molded on separate days.

Consistency. All mixes were brought to a "just plastic" condition. The quantity of water required for each mix was determined from preliminary trial batches and checked on the mixes used in making the specimens. In the trial batches, water

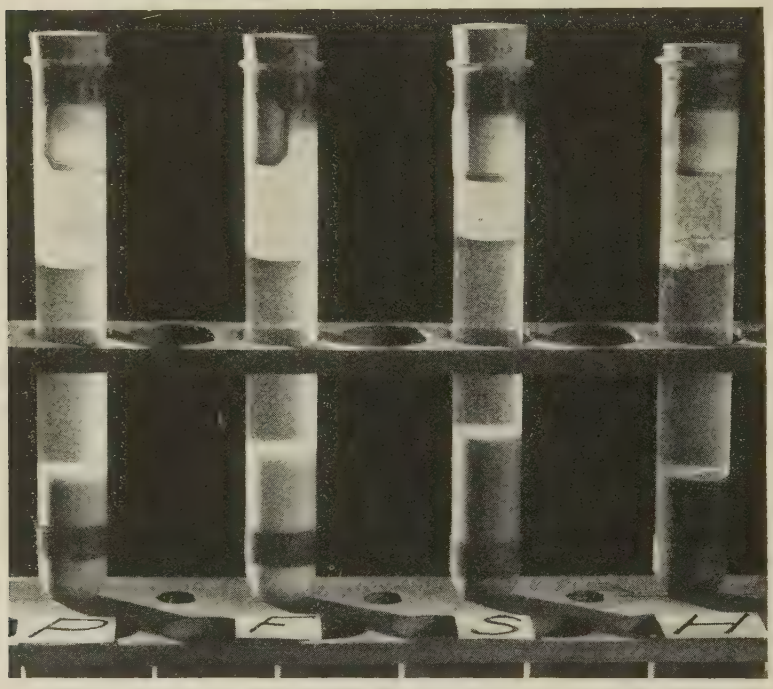

FIG. 1—TEST OF POZZUOLANIC ACTIVITY

The top edges of the black tapes at the bottoms of the test tubes are at the original levels of the mixtures of pozzuolanic materials and lime.

was added in increments until the mix changed from a more or less granular to a plastic, cohesive state. This change is well defined for most mortars. The quantities of water determined by independent trials checked closely. The mixes when "just plastic" were considered to be of equal consistency.

Curing. All specimens were placed in a moist closet immediately after molding and stripped at 20 to 22 hrs. All compression specimens were then placed in water storage at 70°. The subsequent curing is recorded in Table 2. The curing conditions for the shrinkage specimens following stripping is given in Table 4.

Testing. All specimens were tested in the moist condition, the air-cured specimens being submerged in water for 24 hours im-

TABLE 2—COMPRESSIVE TESTS.

Specimens—2 x 4 in. cylinders.
Mix—1:3 by weight.
Pozzuolanas substituted for cement and blended with it before mixing mortars.
Water used in calculating the ratios of water to cement and water to cement plus pozzuolana corrected for the absorption of the sand only. The absorption of the pozzuolana is not considered.
All strengths are an average of four specimens made on different days, except as noted.
All specimens submerged 24 hours prior to testing.

mediately prior to testing. One specimen from each batch was tested at each of the ages of 7, 28 and 90 days.

Shrinkage Measurements. The shrinkage measurements were taken with a Berry strain gauge on an 8-in. gauge length.

Initial readings were taken on the shrinkage specimens at 20 hr. for the first or "a" set and at 22 hr. on the second or "b" set. Drilled and countersunk brass plugs were used for gauge points. Three standards and all specimens of one set were read with one setting of the dial. Two such series of readings were taken each time, the dial being shifted between series. Third readings were taken when necessary. The relative movements were then calculated from the averages of those differences not varying by more than four "points" which corresponds to a movement of 0.001 per cent.

The per cent linear changes relative to the 1 day (20 and 22 hr.) lengths and the differences between the "a" and "b" specimens are given in Table 3 for 5 ages. The differences shown vary from a maximum of 0.0128 to a minimum of 0 and have an average value of 0.0033 per cent relative movement. This agreement is considered satisfactory, particularly in view of the fact that the "a" and "b" sets were made one week apart.

DISCUSSION OF RESULTS

In Table 2 the quantity of effective water is expressed both as a ratio of the quantity of portland cement by bulk volume, and as a ratio by weight of the blended cement. The quantity of effective water* used in each batch is easily obtained by multiplying the latter ratio by 500. With one exception (the mix containing 30 per cent substitution of H) more water was required for the blended mixes than for the plain mixes. Except for the mixes containing P, the additional quantities of water required were small, but since the quantities of portland cement were reduced, the differences in water-cement ratio are considerable.

Abram's "water factor"[4] defined as "the quantity of mixing water required by the addition of a unit weight of any constituent in order to maintain a given workability," is given for each

*The term effective water is used here to mean the quantity of added water corrected for the absorption of the aggregate, no allowance being made for absorption by the pozzuolanas.

[4]Duff A. Abrams, "Tests of Powdered Admixtures in Concrete." Proc. A. S. T. M., Vol. 29, 1929, Part II, p. 627.

material in the fourth column of Table 2. These were calculated on an assumed water-factor for cement of 10 per cent. Taking into account the fact that small changes in the total quantity of water result in very large changes in the water factor, the agreement between the values obtained for the blends of the two cements and the two percentages of each pozzuolana is good.

The authors believe that the accuracy of the method used in determining the quantity of water may be judged by comparison of the cement factors for the same pozzuolana obtained from different mixes. The ratios of water to cement plus pozzuolana are given to three decimal places for convenience in checking since the use of these figures when rounded to two places would give cement factors appreciably different from those shown.

Compressive Strength

The relative strengths, plotted from the data of Table 2 are shown in Fig. 2. All four blends show a considerable loss in strength at 7 days for both conditions of curing. In general, the compressive strengths of the blended mortars increase relative to those of the plain mortars with increase in age. Materials S and P, showing the greatest and least pozzuolanic activity respectively, also had the greatest and least relative strengths.

Moist cured specimens. With the N cement, the use of both 10 and 30 per cent substitutions of S and H gave relative strengths at 90 days greater than 100. With both N and A cements the 10 per cent substitution of F and S resulted in some retrogression at 90 days from the 28 day relative strengths. The average relative strength of the 10 per cent blended specimens made with N cement were about equal at 7 days and considerably higher at 28 days than that of those made with A cement.

In general, there is considerable difference in the data given by the two brands. Assuming that there is chemical action due to the pozzuolana, it is natural to expect different effects with different brands of portland cement, as has been found to be the case with other chemically active materials such as calcium chloride.[5]

Air cured specimens. These specimens were moist cured for the first seven days and then left in air. While the small specimens

undoubtedly dried out quickly, this curing was thought to be comparable to that obtained in ordinary construction. If the drying were more rapid, the initial curing was probably more efficient than that of the usual job. For this curing condition, the average strengths of the specimens made with the S and H materials substituted for 30 per cent of the cement by weight were 66, 87 and 97 per cent of the plain mortar strength at 7, 28 and 90 days respectively, whereas the corresponding figures for F and P were 40, 50 and 54.

Since the rate of the reaction between the silica and alumina of the pozzuolanas and the lime of the cement is low, it is to be expected that strength comparisons would be more favorable for the blended cements for long periods of moist curing. This is indicated by the slope of the graphs of Fig. 2, particularly by those for the 30 per cent blends. It is significant that pozzuolanic cements and blends of portland cement and pozzuolanic materials have been used almost exclusively for hydraulic structures

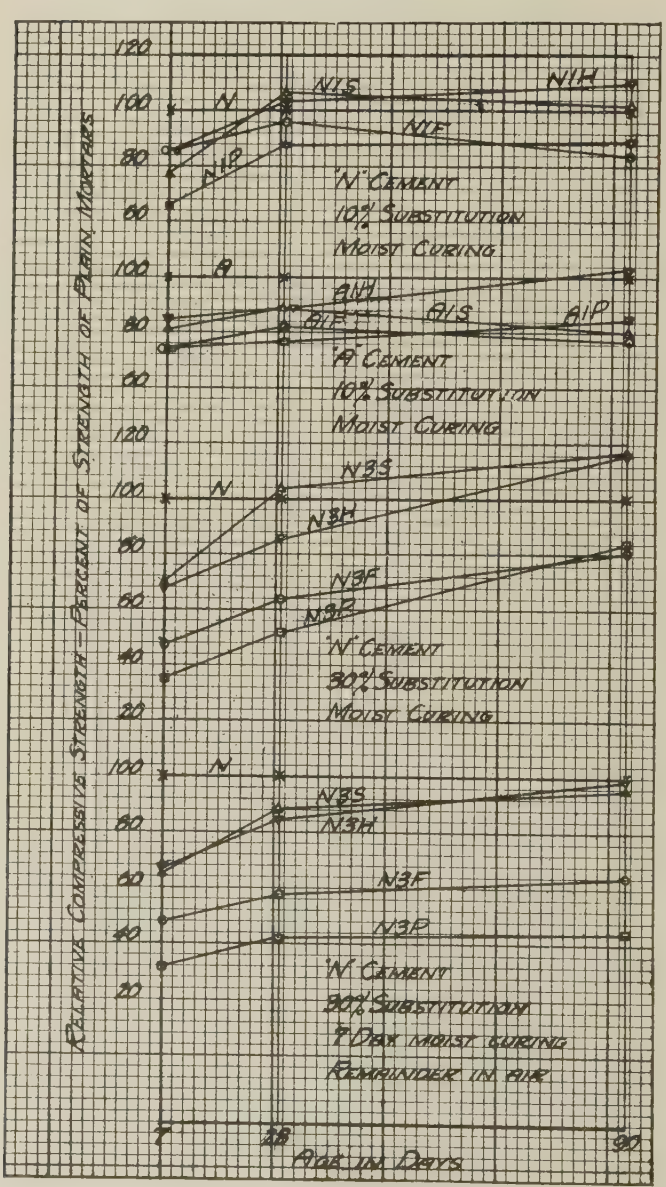

FIG. 2—COMPRESSIVE STRENGTHS OF 1:3 MORTARS MADE WITH BLENDED CEMENTS RELATIVE TO PLAIN MORTARS

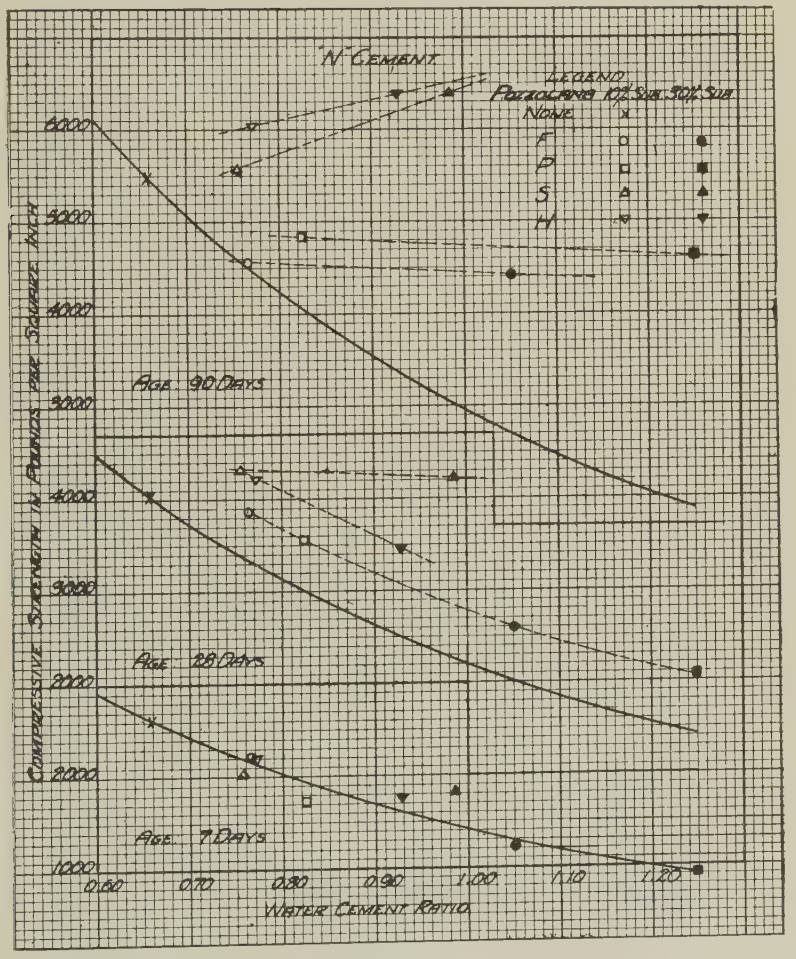

FIG. 3—WATER-CEMENT RATIO STRENGTH RELATIONS FOR BLENDS OF POZZUOLANAS WITH "N" CEMENT

(tunnel linings, aqueducts, sea-walls and the like) in which the conditions are favorable for continued moist curing.[2]

It is at once evident from Fig. 2 that admixtures S and H are more desirable than F and P, particularly for the shorter periods of moist curing and for air curing following a short period of moist curing. When used with N cement, the 30 per cent substitution resulted in greater reductions in strength at early ages, but for continuous moist curing gave strengths at 90 days equal to or greater than those for 10 per cent substitution. The fact that blends of 30 per cent of S and H gave strengths 17 per cent and 16 per cent greater respectively than plain cement is particularly notable.

Water-cement Ratio Relations

In Figs. 3 and 4 the water-cement ratio strength relations are shown for the moist cured specimens. The dotted lines of Fig. 3 joining the points for the 10 and 30 per cent blends have no special significance, but are shown only as an aid in reading the diagrams. The solid lines are believed to approximate the relations for plain mixes. The data for the solid lines were obtained in the following manner: The 7 day strengths were plotted on semi-log paper and a straight line drawn through them. The ordinates for the 28 day and 90 day curves were then obtained by multiplying the 7 day ordinates by the ratios of the 28 day and 90 day to 7 day strengths of the plain specimens. These ratios were 1.55 and 2.09 for N cement and 1.49 and 1.73 for the A cement. Corresponding ratios given by Gilkey[6] for the average portland cement are 1.52 and 1.94. This procedure assumes that the pozzuolanic materials have caused no increase in strength at 7 days over plain specimens made with equal water-cement ratios. If the blended specimens were stronger than corresponding plain specimens (equal water-cement ratios) at 7 days as is likely (see Fig. 5), then the solid lines should slope to the right at a greater angle and the pozzuolanic effect would be greater than that indicated in Figs. 3 and 4.

In general, the divergence from the solid lines increases with increase of age and per cent of substitution. The 10 per cent

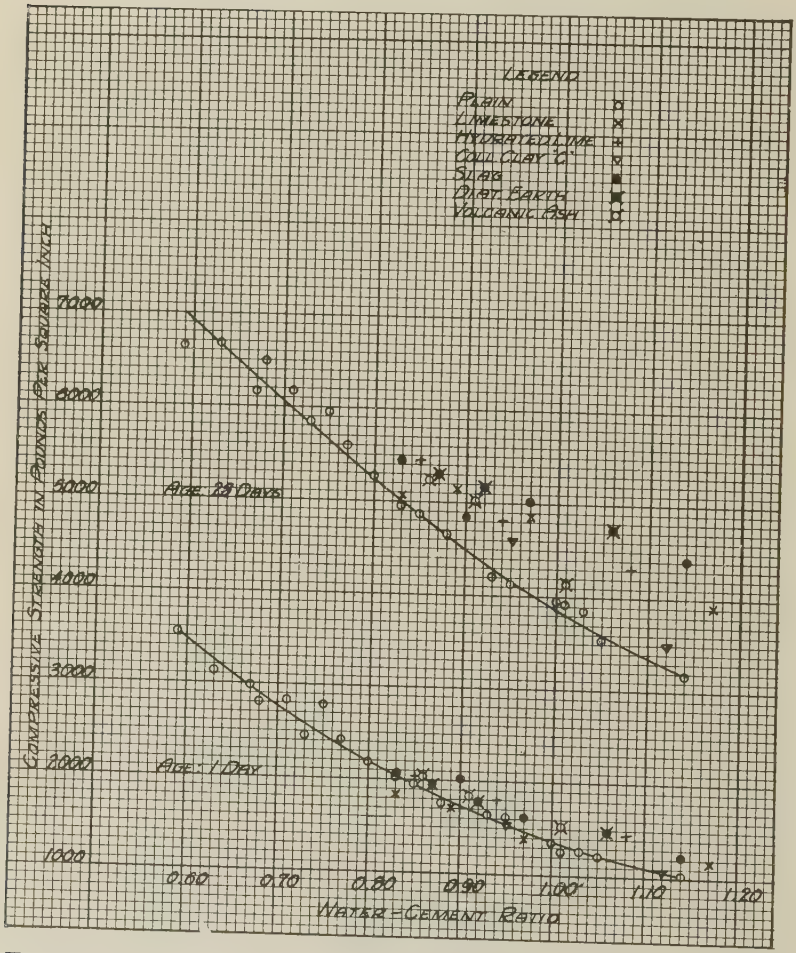

FIG. 5—WATER-CEMENT RATIO STRENGTH RELATIONS FOR CONCRETES CONTAINING VARIOUS ADMIXTURES. DATA FROM TABLES II AND III OF "TESTS OF POWDERED ADMIXTURES IN CONCRETE." BY DUFF A. ABRAMS, PROCEEDINGS A. S. T. M., VOL. 29, 1929

blends of F with N cement and F and S with A cement fall on the solid line at 90 days and yet are above it at 28 days. This does not appear to be in line with the data for the other blends. This may be due to the limited number of specimens tested or may be explained in the following manner:

Since the pozzuolanic materials are chemically active, they will affect the hydration of the cement and we have in effect a new cement having strength-age and water-cement ratio strength relations peculiar to itself just as is the case with different brands of portland cement. Regarding the blends in this way, it would not be unreasonable to expect different percentages of pozzuolana to give strength-age curves differing in shape as well as in position. Since the strength-age curves for different brands of portland cement have been shown to cross,[7] the positions of the points for the 10 per cent blends of F and N cement and F and S with A cement at 90 days might be explained analogously.

Fig. 5 was prepared from data in Tables 2 and 3 of "Tests of Powdered Admixtures in Concrete."[4] The general relations of the data are similar to those of Figs. 3 and 4, the majority of the points falling reasonably close to the curve for the plain specimens at 1 day whereas at 28 days the mixes containing admixtures fall well above the corresponding 28 day curve. These data seem to show that the strengths for equal water-cement ratios are affected by any finely divided material, not just those commonly regarded as pozzuolanic. The high positions of the points for mixes containing limestone certainly cannot be explained by pozzuolanic action.

Figs. 3, 4 and 5 might be misinterpreted to indicate that greatly increased strengths are obtained from the use of admixtures. Fig. 2 shows clearly that such is not the case when the comparison is made on the basis of the same consistency, particularly at early ages and for ordinary periods of curing.

SHRINKAGE AND WEIGHT TESTS

Data from these tests are given in Table 4. The linear change-age relations are shown in Figs. 6, 7 and 8. In the legends shown the numbers 1 and 3 signify 10 per cent and 30 per cent substitution of pozzuolana for cement. The significance of the various

letters has already been given. The curing conditions for these specimens are given at the head of Table 4 and indicated on the figures. Readings were taken frequently to 201 days. The final reading was taken at 339 days, there being no readings between 201 and 339 days. Weights were taken each time shrinkage measurements were made.

Shrinkage Tests

From Figs. 6, 7 and 8, it will be seen that the shrinkage of the mortars made with blends of H pozzuolana were less for 10 per cent substitution with A cement and 30 per cent substitution with N cement and more for 10 per cent substitution with N cement than that of the corresponding plain mixes. The differences were small, however, and the linear change of these blends may be considered equal to that of the plain mixes. All other blends showed increased shrinkage. The shrinkage curve for the plain mix of A cement is plotted on Fig. 6 to show the effect of the brand of cement. Comparison of Figs. 6 and 7 will show that the difference between the graphs for the two plain mixes is about the same as the maximum difference between the plain and the 10 per cent blended cements. In general, the shrinkage increased with increase in the ratio of effective water to cement plus pozzuolana, the mixes containing S being exceptions to this rule.

The movements of the various mixes relative to those of the corresponding plain mixes are given by the linear change ratios of Table 4. These ratios are less for the shrinkage from 156 to 201 days than from 7 to 142 days particularly for those having 30 per cent substitutions of pozzuolanas. This indicates that with age the volumetric changes may decrease for the blended cements. This is the only evidence given by these tests that shrinkage defects may be less for the blended cements.

Weight Tests

The data from these tests are also given in Table 4. The weight-age graphs (not shown) were similar in shape to the linear change-age graphs. However, the relative positions of the various graphs were different as may be seen from the ratios of Table 4. The order of the weight changes from 7 to 142 days, going from the least to the greatest, is N, N3S, N3H, N3F and

N3P whereas the order of the corresponding volumetric changes is N3H, N, N3F, N3S and N3P.

The increase in weight for the 14 days immersion from 142 to 156 days is the absorption from the air dry condition. It will be seen from Table 4 that the absorptions were greater for the blended cements in all cases.

CONCLUSIONS

While the number of specimens and materials tested is too limited for general conclusions, the following statements appear to be warranted.

For the materials and methods recorded in this report:

1. For equal consistencies, blended cements required more water per unit of cementing material than portland cement (there was one exception, see text).

2. The compressive strengths of mortars made with the blended cements were considerably less at early ages than those of portland cement mortars of the same consistency. At later ages (90 days and greater), with continued moist curing and suitable materials greater strengths may be obtained by use of blended cements. For short curing periods such as are used on ordinary construction, the use of the blended cements resulted in lower compressive strengths.

3. During the period of initial drying, the shrinkage of the blended cement mortars was greater than the shrinkage of the portland cement mortars (two exceptions, see text).

4. The effect of pozzuolanic materials varied with different brands of portland cement.

Tests of Bonding of Floor Finish to Slabs of Haydite and Gravel Concrete

BY F. E. RICHART* AND V. P. JENSEN†

INTRODUCTION

The use of reinforced Haydite concrete for floor slabs has naturally raised the question as to the ability of a finish course of mortar or terrazzo to bond to the slab. Some difficulties have been anticipated by designers due to the tendency for coarse Haydite particles to rise to the surface of the base course and due to the differences in elastic behavior of the topping and base concretes in which the first has a high modulus of elasticity and the second a low one. Questions of this sort have usually been answered through experience with a floor in service and this is without doubt the most satisfactory and convincing answer. The writers know of no laboratory tests that have been made on the bonding of floor finish; such tests could hardly be expected to include differential shrinkages of the two courses over large floor areas, or the effect of hard service, such as heavy trucking, impact, abrasion or vibration. However, in an attempt to devise a test that would show whether there were obvious defects in the bonding, and show them within a short time, the following simple tests were made.

Small reinforced concrete slabs, consisting of a 5-in. base course and ¾-in. finish were tested in flexure on a 4-ft. span with ⅓-point loading. With this arrangement there is produced a relatively high horizontal shear tending to separate base and finish courses in the outer thirds of the span. It was felt that if this type of specimen could be tested to failure without crack-

ing the topping from the base it would indicate that no inherent defects could be attributed to the bonding of the two courses. For comparative purposes, slabs were made using both gravel and Haydite concretes for the base course.

The tests were made at the Materials Testing Laboratory of the University of Illinois as a part of an investigation being carried on in cooperation with the Western Brick Co., Danville, Illinois, manufacturers of "Western" Haydite aggregates. The work is being carried on under the administrative direction of Dean M. S. Ketchum, Director of the Engineering Experiment Station, and Prof. M. L. Enger, Head of the Department of Theoretical and Applied Mechanics, University of Illinois. The Western Brick Co. is represented by an Advisory Committee consisting of I. N. Doughty, Manager of Research, and Frank Payne, Engineer. All of the Haydite aggregates used in the tests were furnished by the Western Brick Co.

OUTLINE OF TESTS

Twelve slabs were made and tested. The design details and dimensions are given in Fig. 1. Two types of concrete were used in the 5-in. slab base; one made with sand and gravel aggregates, the other with fine and coarse Haydite aggregates. Two mixes of each concrete were used, (1) a fairly rich structural mix, 1:2¼:2¾ by volume, and (2) a lean mix, 1:4½:5½, approximating floor fill. Three slabs and three 6 by 12-in. control cylinders were made of each mix. The ¾-in. finish or topping for all slabs was a 1:1:2 mix made with sand and pea gravel using a water-cement ratio of 0.67.

MATERIALS

Universal portland cement passing standard specifications was used. Average tensile strengths of 1:3 standard Ottawa mortar briquets were 290 and 390 lb. per sq. in. at the ages of 7 and 28 days, respectively.

A well graded sand from Lincoln, Ill., having a fineness modulus of 2.70 was used in the gravel concrete bases and in the finish course. Two sizes of Wabash river gravel from Covington, Ind., were used. A pea gravel, with a fineness modulus of 5.98, was used in the finish course and a mixture of this gravel with a

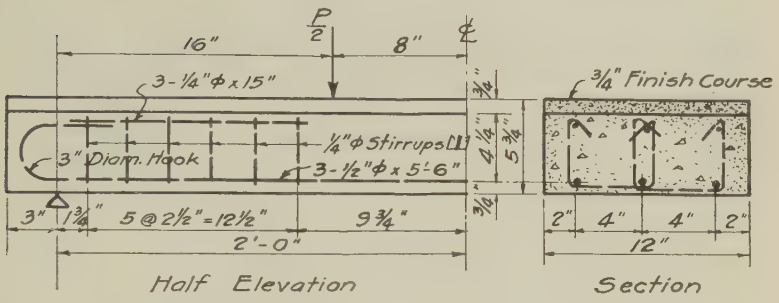

FIG. 1—DETAILS OF TEST SLABS

¾-in. grading, having a fineness modulus of 6.12 was used in the slab concrete.

The Haydite aggregates were the "Western" fine or "A" size, 0—$\frac{3}{16}$-in., with fineness modulus 2.33, and the coarse or "C" size, $\frac{7}{32}$—¾-in., with fineness modulus 5.89.

Each test slab was reinforced with three ½-in. deformed round bars of intermediate grade running the full length of the slab and ending in hooks bent to a 1½-in. radius. These longitudinal bars were tied together in a unit with a double system of ¼-in. round U-stirrups of structural grade spaced 2½-in. apart in the outer thirds of the slab. A typical unit is shown in Fig. 2. None of the reinforcement projected into the finish course of the slab.

MAKING OF SLABS

The slabs were poured in bottomless wooden forms on a sheet of building paper resting on the laboratory floor. Slight leakage

FIG. 2—TYPICAL REINFORCEMENT UNIT

FIG. 3—BASE SLABS

of water and mortar occurred at the bottom edges, particularly with the 1:10 concretes despite the fact that these concretes gave low slumps. The base concrete was mixed in a one-bag batch mixer, hauled to the form in wheel-barrows, shovelled into place and spaded uniformly around the reinforcing steel. The concrete was struck off to a level ¾-in. below the edges of the form. Some settlement occurred after this screeding, especially in the 1:10 mixtures. The settlement was more noticeable in the 1:10 Haydite than in the gravel concretes. After the concrete had stiffened, the surface was struck with a wood float and left exposed to the air until the following day. Three forms are shown in Fig. 3, with the base slabs struck off ready for the finish course.

The finish course was made and placed in general accordance with the recommended practice given in the Report[1] of Committee 802 on Concrete Floor Finish, of the American Concrete Institute. The chief departure from the recommended practice was in the use of a fine sand which was permitted because it was felt that the primary reason for using a coarse sand for floor finish is to improve the wearing quality of the surface, a quality not to be measured in these tests, and that any change in the physical characteristics of the topping, caused by the use of a fine instead of a coarse sand, would have little effect upon the test results.

Twenty-four hours after the base slab was poured, the surface was prepared for the finish course. This was done by wetting

[1] "Good Practice in Concrete Floor Finish" John G. Ahlers, JOURNAL of the Am. Con. Inst., March. 1930, *Proceedings*, Vol. 26, p. 520.

the surface thoroughly and then brushing on a thin coat of neat cement mortar with a wire brush, care being taken to mop up any pool of surface water before brushing in the mortar. The finish was placed immediately after the application of the mortar coat. It was tamped uniformly over the surface of the slab and into the corners of the form to insure a full surface of adhesion in every slab. The surface was then struck off level with the edges of the forms. and compacted and smoothed with a wood float. The surface was trowelled with a steel trowel one to two hours after being struck off.

The average measured thickness of finish used with the four concretes was as follows: 1:5 gravel, 0.74 in.; 1:10 gravel, 0.75 in.; 1:5 Haydite, 0.75 in.; 1:10 Haydite, 0.90 in.

CURING

The forms were stripped one day after the finish course was placed, and the slabs were stored under wet burlap for about five days; they were then removed to the moist room for standard moist curing at 70° F. All cylinder molds were stripped after 48 hours and the cylinders cured in the moist room until the time of test, when they were tested moist.

TESTING OF SLABS

The slabs were removed from the moist room when 28 days old and tested within 6 hours after removal. Loose moisture was wiped from the surfaces and a coating of whitewash was applied to the sides and ends to aid in the detection of cracks. A very marked feature of the 1:10 Haydite concrete slabs was that the moisture present in the base of the slab kept coming to the sides so rapidly that the whitewash was kept from drying during the day of the test.

A general view of the testing apparatus is shown in Fig. 4, which includes a typical slab after test. The work was done in an Olsen testing machine of 300,000-lb. capacity. The load was applied through a spherical bearing block to a grillage made up of four 4-inch channels and thence through rollers and bearing plates to the third-points of the span. The supports permitted free rotation at both ends and horizontal movement at one end. All bearing plates were set in plaster of paris. Load was applied

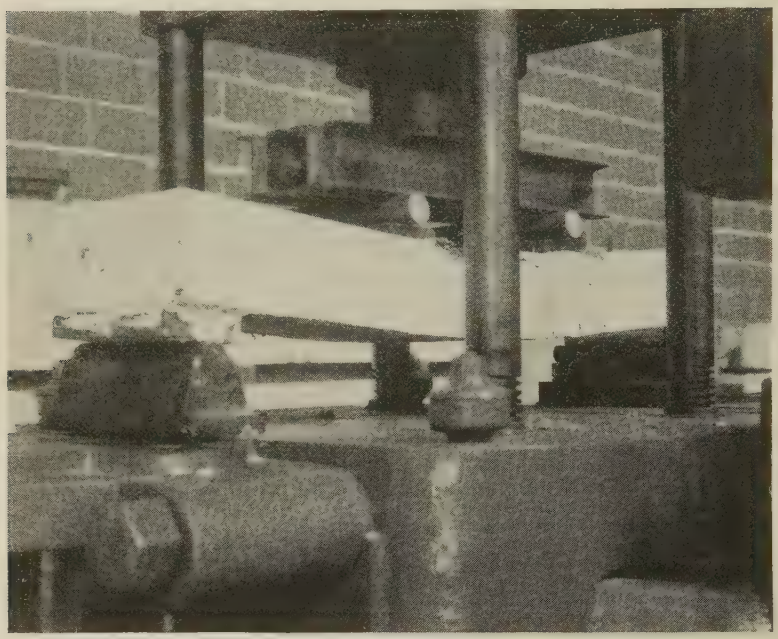

FIG. 4—TESTING APPARATUS SHOWING TYPICAL SLAB AFTER TEST

in increments of 500 to 1000 lb. at the slowest testing speed of the machine. A close watch was kept for cracking of the slab and any indication of loosening of the topping from the base, but no strain measurements were taken. After the steel had passed its yield point, as indicated by a dropping of the weighing beam and opening of tension cracks, a faster test speed was maintained until final rupture occurred.

The modulus of elasticity of the concrete was determined from stress-strain measurements on the control cylinders.

PHENOMENA OF TESTS

With one exception the slabs failed initially by tension in the longitudinal steel. The single exception was a Haydite slab of 1:10 mix which failed initially by diagonal tension at a load of 13,900 lb. In this slab the yield point of the longitudinal steel was reached at a load of 15,700 lb. and the ultimate load carried was 16,300 lb. At failure, a piece split off of the side of the slab

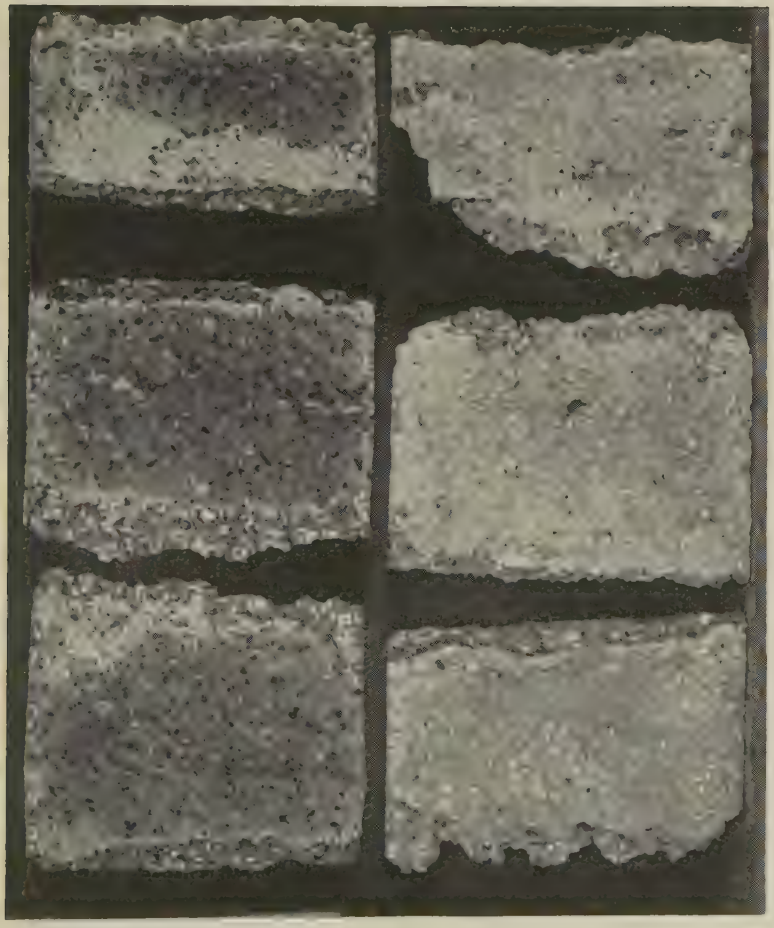

FIG. 5—BOTTOM VIEW OF PIECES OF FINISH WHICH CRACKED OFF AT FINAL FAILURE.

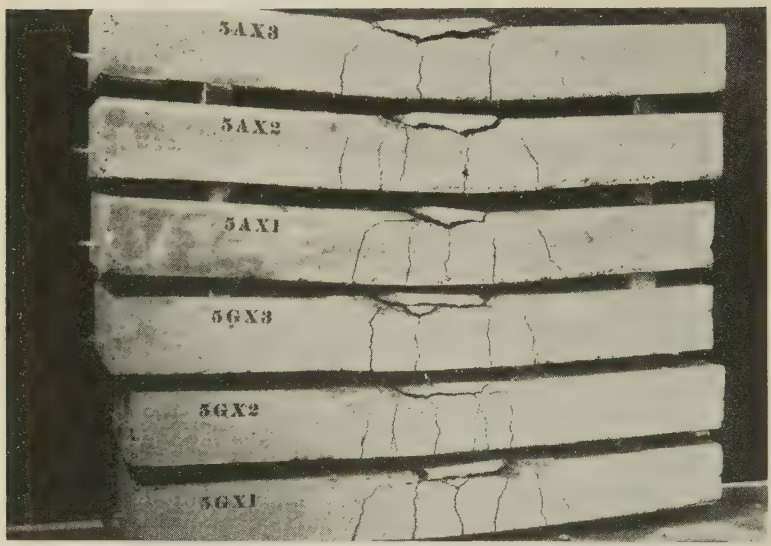

FIG. 6—ALL SLABS OF 1:5 MIX AFTER TEST
(Top three slabs of Haydite base; bottom three slabs of gravel base.)

(No. 10AX3, Fig. 7) near the end, and it was evident that a large amount of slipping of bar and compression of the concrete inside the hook had occurred. There was also evidence of large distortion of the weak and compressible concrete due to high bearing pressure fro n the cast iron plate at the support. While the large amount of movement of the hooked bar indicates that the diagonal cracking may have been due to slip of bar, splitting at the end of the slab occurred well after the yield point of the longitudinal steel had been reached. Complete test data are given for all slabs in Table 1. In no tests did the finish crack loose from the base before the ultimate load was reached. The finish in both Haydite and gravel concrete slabs remained integral with the base with deflections considerably in excess of one inch on a 4-ft. span. At final failure, with deflections of about 1½ inches, crushing of the ¾-in. finish course occurred in the middle third near one of the load points and a section of the topping split off. The sections which split off from the Haydite slabs had portions of the base adhering to the topping, the frac-

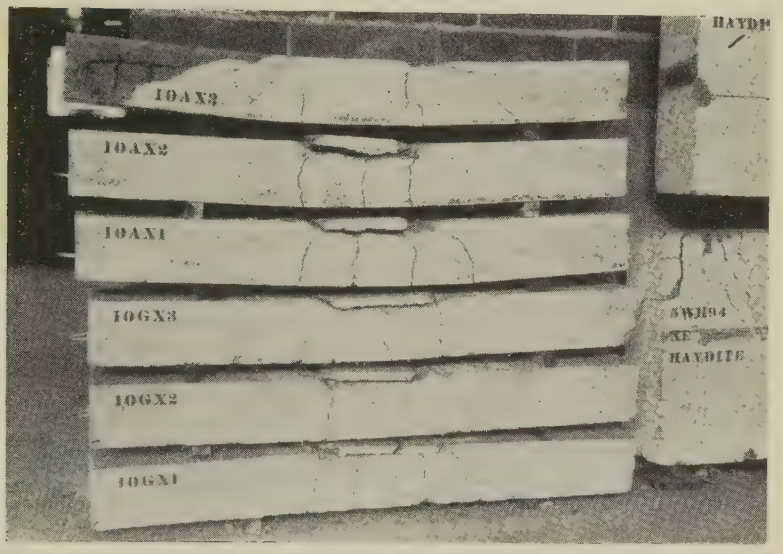

FIG. 7—ALL SLABS OF 1:10 MIX AFTER TEST
(Top three slabs of Haydite base; bottom three slabs of gravel base.)

ture being mostly below the topping. Where the base was of gravel concrete the fracture occurred at the bonding surface between the base and topping. Fig. 5 shows a bottom view of the pieces of topping which split off from the 1:5 concrete slabs. A general view of all the 1:5 slabs is shown in Fig. 6 and of all the 1:10 slabs in Fig. 7. In each figure the upper three slabs are of Haydite concrete and the lower three of gravel concrete.

DISCUSSION OF TEST RESULTS

It is quite evident from these tests that there was no great difference in the bonding of the floor finish to the Haydite and gravel concrete bases. If anything the final crushing failures showed a more definite plane of cleavage between the finish and the gravel concrete than between finish and the Haydite concrete. With care taken in applying the floor finish it is evident that very satisfactory bonding may be secured with either type of base concrete, since in no case was there any separation between finish and base in the outer thirds of the span even at failure of

*Slab 10AX3 failed initially by diagonal tension.

the slab. The separation at the point of final crushing of the top surface of the slab might be expected in view of the great distortions and deflections existing in the slab at failure.

An unexpected feature of the tests was found in the fact that the slabs of lean concrete carried practically as much load as those of the rich mixture. It is evident that the strong ¾-in. finish course developed most of the compressive flexural strength of the slabs made with the lean concrete. With roughly 1 per cent of reinforcement in all slabs it appears that the compressive concrete stress was not excessive until the yield point of the reinforcement has been exceeded; it is of interest that a margin of safety existed in the rich layer of the finish course.

It may be concluded that no weakness in bonding between the floor finish and either of the base concretes was indicated by the tests. On the contrary, the tests give support to the practice

of including the floor finish in computing the effective depth of the slab for design purposes. Although the tests indicate that the finish course produced much more slab strength than an equal thickness of base concrete, the writers do not feel that the amount of data secured justify any new method of analysis or design beyond the inclusion of the finish thickness in computing effective depth of slab. So much depended upon the quality of the finish course in the slabs made with lean concrete that any defect in the finish would have greatly decreased the slab strengths. Furthermore, the 1:10 concretes offered such low resistance to local compression that it is surprising that sufficient anchorage was effected to develop the elastic strength of the longitudinal steel.

As noted in the introduction, the tests described give no indication of the effect of shrinkage or of heavy service conditions on a large floor slab; they are quite reassuring in that no obvious defects in bonding of finish to base course was in any way indicated. In the absence of actual service tests of long duration, these experiments indicate that bonding of a floor finish is equally feasible with base slabs of gravel and Haydite concrete, providing careful workmanship is employed.

Readers are referred to the JOURNAL *for April, 1931, for discussion which may develop. Such discussion should reach the Secretary by March 1, 1931.*

Deflection of Reinforced Concrete Members

*Progress Report of Committee 307**

BY T. D. MYLREA,† AUTHOR-CHAIRMAN

PURPOSE

The scope of this report will be limited for the present to a study of the beam and slab type of construction, leaving the flat slab and other forms of construction for future investigation.

An expression for the calculated deflection of a reinforced concrete member may be desirable for one or more of the following purposes: (1) To provide a criterion of acceptability for a given structure, (2) for the computation of the camber required during construction, (3) as a basis for the development of methods of solving statically indeterminate structures. Obviously, to be satisfactory for any of these purposes, an expression should be one from which deflections may be predicted from computed stresses, that is, one which is independent of measured deformations. It is quite possible that such an expression might fulfil one purpose satisfactorily without necessarily being of much use in the others, and for this reason all formulas were studied and data digested with a view to their applicability to any of the above uses. It is hoped that some of the conclusions may be of assistance to the sub-committee of Committee 501 dealing with load tests.

FORMULAS

Two general types of formulas are commonly known—those of Turneaure[1] and those of Maney. Turneaure's formulas are not derived along conventional lines, and hence have not yet

†Consulting Engineer, Pittsburgh, Pa.

*This report was on the program of the 26th Annual Convention but in the absence of its author was not presented. It has since been approved by P. J. Freeman and A. H. Saurbrey, as critic members of Committee 307.

[1] "Principles of Reinforced Concrete Construction," by Turneaure and Maurer, 3rd Ed. Chap. VI.

been subjected to a critical study. Maney's formula, as originally propounded,[2] is in the following form:

$$\Delta = C\frac{L^2}{d}(e_s + e_c) \qquad (1)$$

In this formula C is a constant depending upon the method of loading and end restraint, and the rest is a matter of plane geometry. Following the usual procedure in expressing nominal concrete and steel stresses, its author rewrote it[3] as follows:

$$\Delta = C\frac{L^2}{dE_s}(f_s + nf_c) \qquad (2)$$

Since to be of service in predicting deflections a formula based on computed stresses is desirable, Formula 2 is in a much more convenient form than Formula 1.

Prof. Hardy Cross and C. A. P. Turner have proposed a modification of Formula 2, which may be expressed:

$$\Delta = C\frac{L^2 f_s}{d(1 - k)E_s} \qquad (3)$$

However, since k must be computed from the relation between f_s and nf_c there seems to be no special advantage in this form.

Formula 2, therefore, was adopted in making all comparisons.

ASSUMPTIONS AND THEIR EFFECTS

Computed deflections are proportional to the quantity within the parenthesis in Formula 2, and the assumptions used in the flexure formulas will of course affect the value of the terms in this quantity. The value of f_s is based upon the assumption that concrete can take no tension. Yet, at the beginning, only the steel crossing a crack can have its computed value. Later, as bond breaks down, stresses in the steel will be high where computations, indicate the existence of low stress. This condition, by its nature, seems to be closely related to the sum of the crack widths, from which deductions may be made later. End slip of bar will add to crack widths.

The value of n, depending upon a value of E_c which is assumed to be constant from the neutral axis to the extreme compression fiber, will have a much greater effect upon f_c than upon f_s. Consulting any table giving values of j for various values of n will

[2]G. A. Maney, "Relation between deformation and deflection in reinforced concrete beams." Proc. Am. Soc. Test. Materials, 1914, p. 310.
[3]Parcel and Maney, "Statically Indeterminate Structures," p. 48-51, Wiley.

show than for a change of 25 per cent in the values of n the corresponding change in j, and consequently in f_s, is generally less than 2 per cent. And this condition does not change much even when E_c is assumed to be variable, as in the so-called "parabolic formulas. Changes in f_c are inversely proportional to changes in n.

Another factor which materially affects the computed deflection of actual structures, as distinguished from isolated specimens, is the assumed width of T. This has a direct bearing on the magnitude of f_c; and until correct T values can be assigned it is futile to conduct load deflection tests with the object of passing upon the merits of a completed piece of construction. This matter will be given further consideration when available test data have been discussed.

Effect of n upon Δ.

Since Δ varies directly as $(f_s + nf_c)$ it is easy to study the part that n plays in computed deflections. As n increases f_c decreases, and vice versa, so that the variation in the term nf_c is much less than the variation in n. For example, assume a beam in which $f_s = 18{,}000$, $f_c = 800$ and $n = 15$. In this beam $p = 0.0089$ and

$$f_s + nf_c = 18{,}000 + 15 \times 800 = 30{,}000.$$

Now had the value of n been 12, in a beam with this steel ratio, f_s would have been 17,800 and f_c would have been 870.

Here $f_s + nf_c = 17{,}800 + 12 \times 870 = 27{,}840.$

In other words, with a change of 25 per cent in the value of n there is a change in deflection of only 7.75 per cent.

The discrepancy is more noticeable in the case which is more usual in building construction, i. e., where the concrete stresses are low because of wide T-flanges. Consider, for example, a beam in which $f_s = 20{,}000$, $f_c = 500$, and $n = 15$. In this beam $p = 0.0034$ and

$$f_s + nf_c = 20{,}000 + 15 \times 500 = 27{,}500.$$

If the value of n had been 12, then f_s would have been 19,850 and f_c would have been 545. Here

$$f_s + nf_c = 19{,}850 + 12 \times 545 = 26{,}400,$$

and in this case a difference of 25 per cent in the value of n would have occasioned only 4.17 per cent difference in deflection.

In flat slab construction where p is always low, the difference in deflection might be even less.

Now in buildings under test the deflections are of the order of hundredths of an inch. An investigator would be hardy indeed to condemn a building as having concrete 25 per cent below par when his deflections varied only a few per cent from some predetermined few hundredths of an inch. The author advances this point for the consideration of the sub-committee on load tests.

On the other hand, the very fact that deflections are not proportionately influenced by variations in concrete strength is of much value in computing camber and in sustaining confidence in computations involving continuity. Accidental variations in strength will not necessarily vitiate computations.

GENERAL OBSERVATIONS ON AVAILABLE DATA

So far the following literature has been examined: University of Illinois Engineering Experiment Station Bulletins No. 4, 12, 28, 29, 64 and 71; United States Bureau of Standards Technological Paper No. 314, and Deutscher Ausschuss für Eisenbeton Heft No. 38. In addition, the author has at hand the data from the tests of 10 large T-beams. These papers with the exception of Bulletin 314, all deal with isolated simply supported rectangular or T-beams. In Bulletin 71 and Heft 38, end slip of the main reinforcing is recorded, the significance of such slip having by this time become evident. In Bulletin 314 the effects of slip are noted carefully. In some of the beams tested by the author slip was permitted and in others it was prevented. A comparison of deflections is being made.

A general characteristic of nearly all tests is that loads were applied progressively to failure, stopping at various increments just long enough to make the required observations and measurements. University of Illinois Bulletin No. 4 has some valuable curves showing the effect of repeated applications of the same load as well as curves showing what took place when each load following a release was higher than the one previous.

COMPARISON OF ACTUAL AND COMPUTED DEFLECTIONS

Published load deflection curves made from actual test data where loads were carried progressively to failure are all curved. For quick reference, the reader is referred to a typical curve of

this nature on page 281 of the January issue of the JOURNAL of the American Concrete Institute. It will be noted that at low loads, say below 2500 lbs. the curvature is sharp, while the remainder of the curve might almost be represented by a straight line. About the middle of the curve is a point labelled "first crack." This test was made before it was discovered at the University of Wisconsin that actual cracks occurred long before they were visible to the naked eye. On the basis of the reported tensile strength of the concrete used, the first crack probably occurred at a load of between 1000 and 1500 lbs.—i. e. approximately at the beginning of the sharp curvature; and it would appear that the shape of the curve below the 3000 lb. load is largely due to the formation and development of fine cracks. The beam is reported to have failed in tension. Had deflection readings been continued beyond the loads shown, a comparison of similar curves indicates that this curve would have deviated again from the nearly straight line condition bending over to the horizontal and perhaps below it. Such a deviation also accompanies end slip of bar as may be seen in the graphs on pages 229-238 of Bulletin No. 71. It is of interest to note in the tests reported in Bulletin No. 71 that while slip of bar along the middle portions of the beams occurred at very low loads, end slip did not make its appearance until steel stresses approximately as high as those in use for general design purposes had been attained. There is a portion of the curve, then, which may be of special significance.

Turning again to Formula (2), since f_s and nf_c, the computed fibre stresses, are directly proportional to the applied load, the curve of computed deflections should be a sloping straight line passing through the origin. Computations in many of the typical cases indicate that this line intersects the curve of actual deflections at such a point as would give a computed steel stress of from 18,000 to 28,000 lb. per sq. in.—generally at about the point marking first end slip. Where end slip is prevented the higher values obtain.

It would be easy to write an equation representing such a curve as the one shown on page 281 of the JOURNAL of the A. C. I., January, 1930, but an equation of this sort would serve no useful purpose, since no portion of this curve would ever be duplicated in this beam. Suppose, for example, that in testing for the first

time the load had been progressively applied up to 4,000 lb. The load-deflection diagram would be as shown in the figure up to point "A." Upon the release of the load the beam would recover, and if the release were gradual an "unload" deflection diagram would be a straight line from point "A" back to the point of zero load but not to the point of zero deflection. There would be a permanent deflection of about .01 in. as indicated by the "set curve." Experiments by the author, in which loads were repeated as many as 55 times, indicate that if this 4000 lb. load were repeatedly applied and released, the load and unload curves would follow up and down this sloping line. Similarly, for any other load, for instance, the 7000 lb. load, the load and "unload" curve would follow up and down an approximately straight line from about the point marked "first crack" to a point on the deflection axis of about .025 in. The process apparently would be repeated until the magnitude of the load was such that end slip of the bar or progressive permanent deformation of the concrete took place. This condition would be apparent by the fact that repetition of the load would produce a "saw-tooth" curve with the peaks all at the same altitude. If any load were applied once and then released, the "unload" curve would be approximately a straight line, but upon the next application of a higher load, the upper end of the ordinate representing the resulting deflection would lie on the curve given on page 281. It is as yet an open question just to what extent tha permanent deformation of the concrete affects the deflection, and this, of course, leads at once to the study of long-continued loads and plasticity. It is apparent, too, that if a beam has once been subjected to a high load, the load-deflection curve for any subsequent progressively applied load will lie below the typical load-deflection curve and will probably more nearly coincide with the curve of computed deflections regardless of the assumed value of n. If it is possible that a rational equation can be found representing the points on a deflection curve plotted for loads following the application of a high load, it may also be possible, (since the effect of the value of n is not of major importance, and since the value of E_c for concrete stresses usually encountered in design does not vary much from the neutral axis to the extreme compression fibre of a beam), that by the test of a bay in a building

the width of floor slab performing flange duty for a beam may be found deductively from Formula (2). For example, if such a test could now be applied to the George Mason Hotel (see Prof. Slater's article in the January 1930 issue of the JOURNAL of the A. C. I.) with loads below 238 lb. per sq. ft., this building, because of the extreme flange width obtainable, might well serve such a purpose.

BEAMS OF UNUSUAL SHAPE

The above observations are all based upon the tests of rectangular or T-beams. The results reported in Technological paper No. 314 however, seem to indicate that any conclusions drawn above may not apply to beams differing much in shape from the usual rectangular or T-shaped beam. In the beams tested for the Shipping Board, from the very beginning in most cases, the actual deflections exceeded the computed deflections—just the reverse of what has been previously discussed. This held true even when actual measured deformations were substituted in Formula (1), and hence when the agreement ordinarily would have been close throughout the whole range of the test. The authors ascribe this discrepancy between the actual and computed deflections to shearing deflection and vertical opening between cracks. From this it seems possible that the neglect of shearing distortions may have a relatively greater effect in deep concrete beams than in short deep beams of other structural materials, and that such deflections may not mean an unsafe structure. It means, too, that any deductions based on tests of such beams in a completed structure must be made with extreme caution.

CONCLUSION

In presenting this progress report the author has attempted to cover the work already done, and to outline the plan for future work, and will appreciate constructive criticism or suggestions from any interested members.

Readers are referred to the JOURNAL *for April 1931 for discussion which may develop. Such discussion should reach the Secretary, by March 1, 1931.*

Continuous Beams and Frames in Building Construction

BY T. U. BERG*

The object of this paper is to present a ready means of determining the bending moments and shearing forces for continuous beams and frames of approximately equal spans. Except as indicated in Appendixes 1 and 2, this is not a general method of solving rigid frames, but a presentation of simple formulas and constants from which the designer of reinforced concrete can directly read maximum bending moments with due consideration for the influence of dead as well as live loads.

The negative moments at supports for critical loadings can easily be determined from the accompanying table or graphs. (The graphs have all been prepared from values given in Table 3). The problem is then reduced to a statistically determinate one, and the moment curves are drawn in the usual way by combining the negative support moments with the moments due to the loading acting on the simply supported span.

The moment at any support and for any system of loading can be written: $M = C_D \cdot K_D + C_S \cdot K_S$ where K_D and K_S are constants respectively for dead and live loads as given in Table 1, Fig. 2. It will be noted that these constants are similar to what are generally called "moment area constants." They are: 1½ times the area of the moment curve for a simple supported beam divided by the span. For combinations of loadings, determine one value for each type of loading and add them together.

C_D is a coefficient to be read directly from the table (or graph). For convenience, D will be used in the following instead of C_D.

FOR DIFFERENT VALUES OF $\frac{I_N}{N}$ FOR COLUMNS BELOW AND ABOVE FLOOR, USE AVERAGE VALUE, $\frac{1}{2}\left(\frac{I_{HM}}{H_M'} + \frac{I_{HN}}{H_N'}\right)$

★ FOR COLS. BELOW FLOOR ONLY USE HALF VALUE ONLY. $I_N/H' = 0.5 \cdot I_{HR}/H_R'$

FIG. 2

C_S is a coefficient depending on the arrangement of live loads, i. e. which spans are loaded or unloaded.

As our aim is to determine maximum values for moments, we must consider the following cases:

Fixed Loads. C_S for live loads of similar nature to dead loads, such as permanent brick walls etc., should be taken the same as for dead loads. $C_S = C_D = D$.

Maximum Positive Moments. This condition occurs for the system of loading as shown in Fig. 1, mark P, i. e. spans alternately loaded and unloaded. For this case we will substitute the mark P for live load coefficient instead of C_S, and the support moment can be written: $M_P = D \cdot K_D + P \cdot K_S$.

Maximum Negative in Middle of Span. See loading as shown in Fig. 1, mark N. Note that the span investigated is unloaded (dead or fixed loads only). All other spans are alternately loaded and unloaded. Use N as mark for coefficient instead of C_S, and we have for support moments: $M_N = D \cdot K_D + N \cdot K_S$.

Maximum Negative Near Support. For a span A-B, the maximum moment at support B will occur for loading same as shown in Fig. 1, mark B, i. e., spans at both sides of support B loaded, other spans alternately unloaded and loaded. Substitute B for coefficient C_S and we have: $M_B = D \cdot K_D + B \cdot K_S$.
In a similar manner we have for support A, loading A, Fig. 1: $M_A = D \cdot K_D + A \cdot K_S$.

In order to draw an accurate curve for moments near A, and B, it is necessary also to determine the moment at the opposite end. Thus, for maximum at B, a moment should also be figured for the other end A. To make this clear, the constants have been given the following marks:

Loading A (maximum moment at support A):
C_S (at left support A) $= A_L$, $M_{AL} = D \cdot K_D + A_L \cdot K_S$
C_S (at right support) $= A_R$, $M_{AR} = D \cdot K_D + A_R \cdot K_S$
Loading B (maximum moment at support B):
C_S (at left support A) $= B_L$, $M_{BL} = D \cdot K_D + B_L \cdot K_S$
C_S (at right support) $= B_R$, $M_{BR} = D \cdot K_D + B_R \cdot K_S$
It should be noted that for each support, values must be determined for M_P, M_N, M_A and M_B, but they are all simple slide rule operations.

TABLE 3

K_D and K_S are assumed to be of constant value for all spans, and $D \cdot K_D$ is figured only once for each support. See combined moment curves, Fig. 1. It is convenient to draw one diagram for total load on a simply supported beam to be used for P, A, and B lines, and one diagram for dead loads on a simple supported beam to be used for N lines. With the aid of dividers all moment curves can be drawn in a short time.

Shearing Forces. The maximum shear at any support equals the shear for a simply supported beam plus a value depending on the slope of the A and B *lines.* This addition for left support is $1/L \cdot (M_{AL} - M_{AR})$, and for right support, $1/L \cdot (M_{BR} - M_{BL})$.

Column Moments. Maximum moments for columns are given in Table 3 or in the graphs in the following manner:

Coefficient for dead load, D_C
Coefficient for live load, S_C
Column moment, $M_C = D_C \cdot K_D + S_C \cdot K_S$

Moments have been considered positive if they turn in a clockwise direction.

The Basic Frame. The coefficients D, P, N, A and B are dependent upon the form of the frame and stiffness of beams and columns. The main table No. 3 has been figured for frames shown in Fig. 3 for 2, 3, 4 and 5 spans and for a typical interior bay.

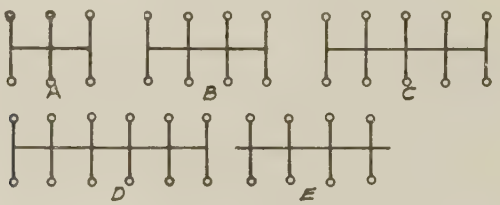

FIG. 3—DIAGRAMS OF FRAMES INCLUDING TWO, THREE, FOUR AND FIVE SPANS, AND TYPICAL INTERIOR BAY

Note the hinged ends of columns for basic frame and see later for use on continuous columns. Each frame has been analyzed for a stiffness ratio of column stiffness I_h/H' to beam stiffness I/L of 0.0 (continuous beams) 0.1, 0.4, 1.0 and 10.0. The resulting

values are given in Table 3 and are also shown in graph form on Figs. 4 to 7 inclusive. The values for $\frac{I_h \cdot L}{H' \cdot I}$ have been drawn on the horizontal axis to a convenient scale. This scale is shown in Table 2, Fig. 2 and its purpose is to make the curves as nearly straight as possible.

Note instructions on Fig. 2 for the use of column stiffness. The stiffness of the exterior columns is frequently different from that of the interior columns. It is recommended that moments for such cases should be adjusted for end bays, using the revised value for column stiffness.

APPLICATION OF THE BASIC FRAME TO CONTINUOUS COLUMNS

The condition as assumed for the basic frame, of column height H' and columns hinged at one end is very rare in building construction. It is necessary to find a relationship between the basic frame and the multiple story building, with story height H.

On Fig. 8A the slope of the elastic curve for a moment $M = 1$ and height H' (the condition similar to the basic frame), is $\phi_1 = \frac{H'}{3EI}$ and on Fig. 8B, the slope for a continuous column (story height H) and for $M = 1$, is

$$\phi_2 = \frac{H}{6EI}\left[3 - \frac{H}{H - B}\right], \text{ for } \phi_1 = \phi_2, \text{ we have:}$$

$$H' = \frac{H}{2}\left[3 - \frac{H}{H - B}\right]$$

The value of B depends on the number of spans, stiffness of columns, etc., but the writer believes that the values given for H'/H in Table 2 are sufficiently accurate for use in practical design. Note that as the story height H is the known value, it will be necessary to make a few trials so that the values for $\frac{I_h \cdot L}{H' \cdot I}$ and H'/H in Table 2 correspond.

The Influence of B Values. Fig. 9 has been prepared to better demonstrate the meaning of B values or H'/H. Although the writer believes that satisfactory results can be reached by using the values H'/H from Table 2 for all types of loadings (for all

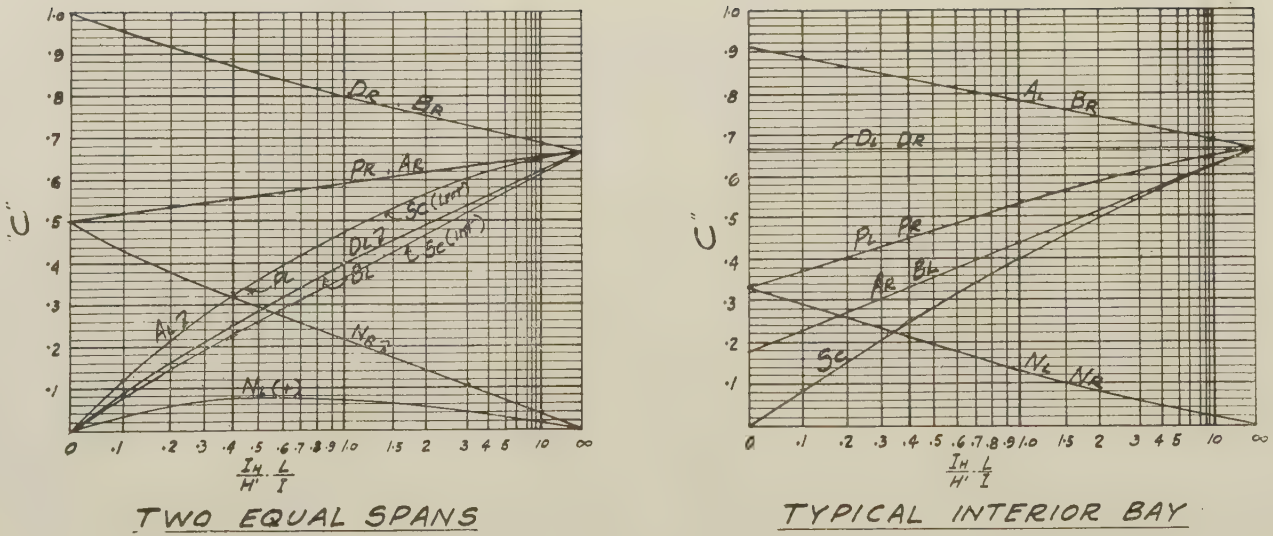

FIG. 4—GRAPH FOR TWO EQUAL SPANS AND TYPICAL INTERIOR BAY

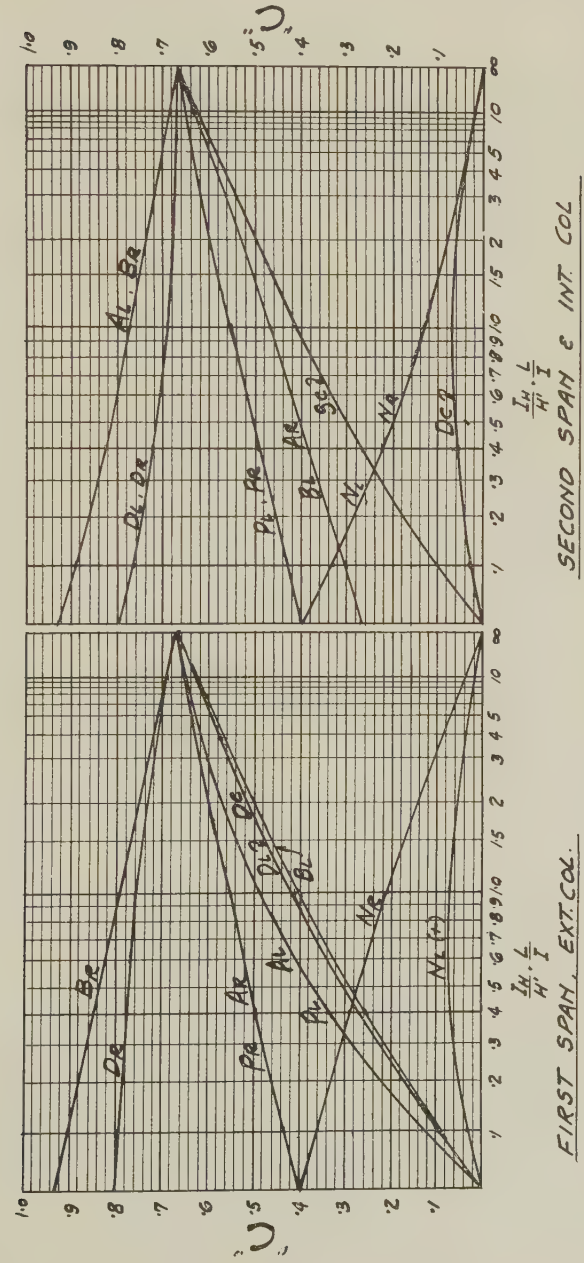

FIG. 5—GRAPH FOR THREE EQUAL SPANS

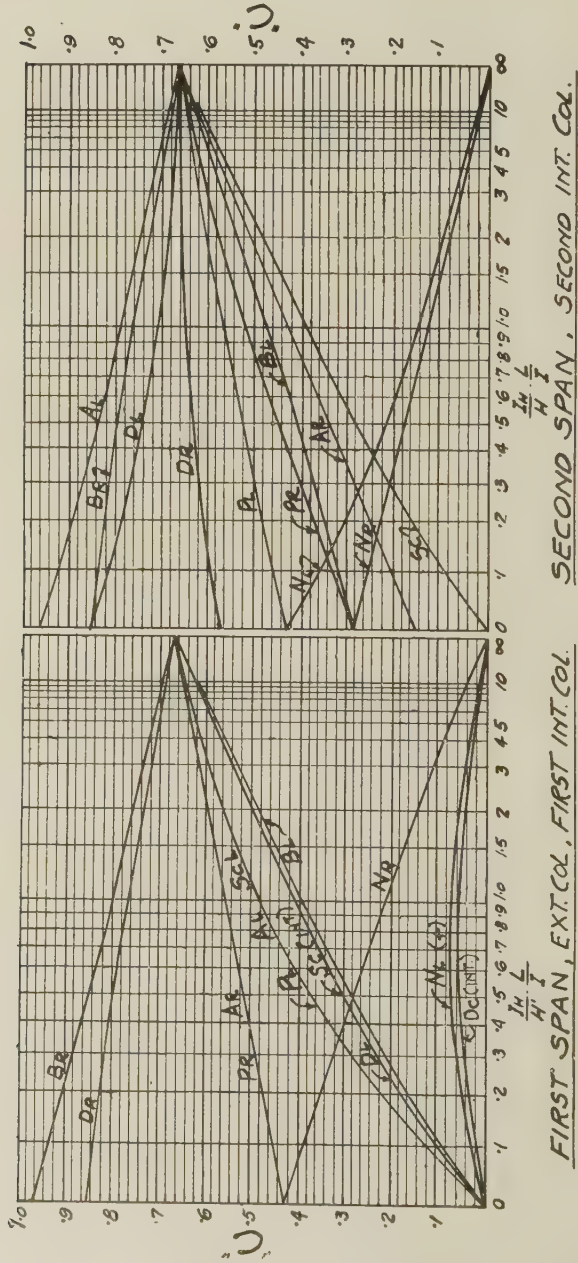

FIG. 6—GRAPH FOR FOUR EQUAL SPANS

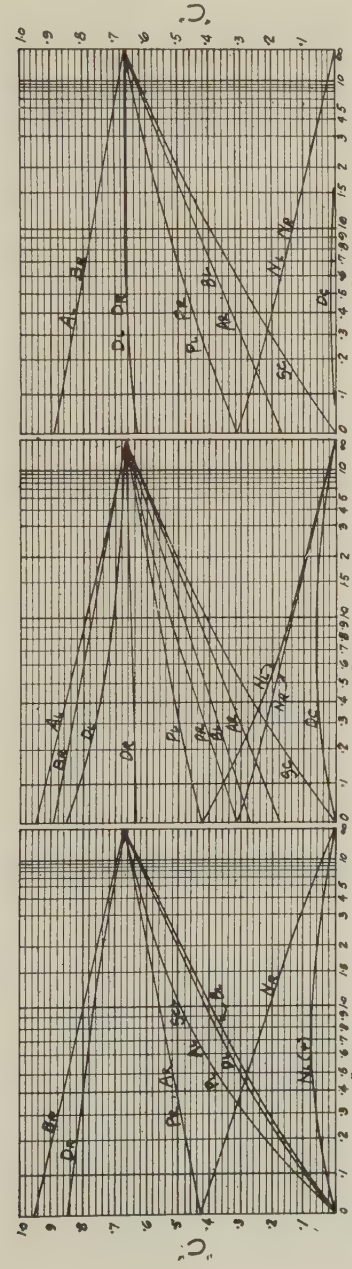

FIG. 7—GRAPH FOR FIVE EQUAL SPANS

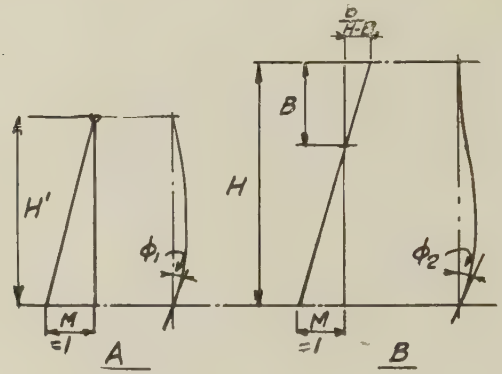

FIG. 8—A AND B

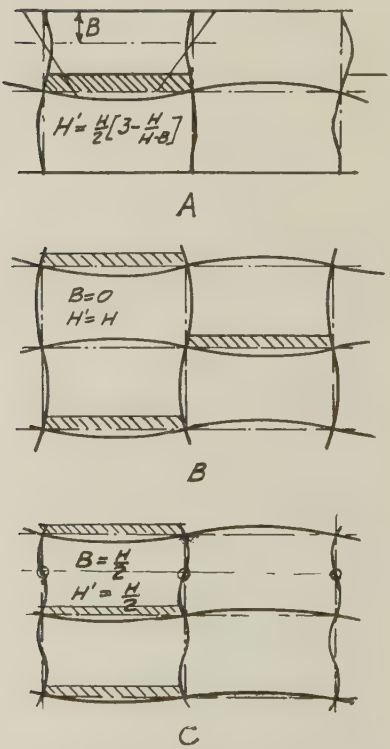

FIG. 9—POINTS OF CONTRAFLEXURE FOR DIFFERENT ARRANGEMENTS OF LOADING

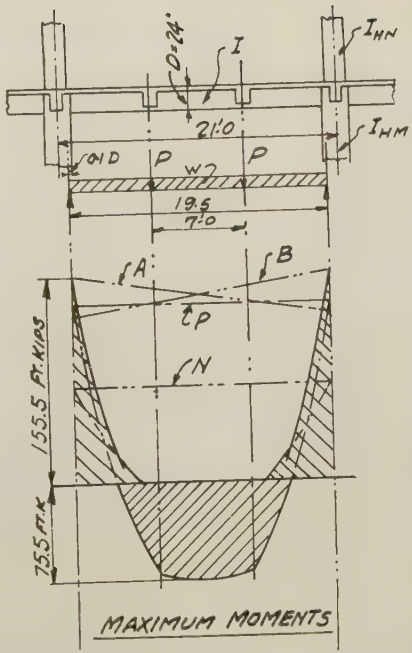

constants), this is not strictly correct, as will be noted from the following: For loading as shown Fig. 9A, typical interior bays, alternately loaded and unloaded (condition of maximum positive moments), and floors over and under uniformly loaded and therefore without effect on columns, the column moment is 0 at a distance B from top, and $H' = \frac{H}{2}\left[3 - \frac{H}{H-B}\right]$

This is the condition as expressed in values for H'/H in Table 2. The condition of loading as shown in Fig. 9B assumes that all stories are alternately loaded and unloaded. The point of contraflexure of the columns occurs at the joint and $B = 0$, $H' = H$. This would give higher values for the positive moments, but as this condition of loading is very unlikely, it is not generally adopted in commercial design.

Points of contraflexure as shown in Fig. 9C would occur when bays are correspondingly loaded and unloaded throughout. $B = H/2$, $H' = \frac{1}{2}H$. This condition of loading is of no practical value except that a similar deformation of columns takes place for dead loads (except for typical interior bays where there is no column bending), making $H' = \frac{1}{2}H$ more accurate in determination of the dead load coefficient. For comparison of results from this method with results derived from the usual application of the slope deflection method, assuming columns fixed at adjacent floors, note that $B = \frac{1}{3}H$, or $H' = \frac{3}{4}H$.

For the practical application of this method, the reader is referred to examples in Figs. 10 and 11.

Side Movements. It should be noted that all floors are assumed to be held in position so that no form of loading can cause any horizontal movement. Dead loads have no such effect, nor does any symmetrical form of live loads. It is only loading not symmetrical about the centre line of the complete frame system that will have any effect, and for many columns in the frame the effect is negligible. For building construction it is fair to assume that not all bays will cause movement in one direction and that the floor will act to even out these tendencies so that they can be neglected.

FIG. 11

CONCLUSION

All constants in Table 3 have been figured following the method originally published by A. Strassner in his book "Neuere Methoden zur Statik der Rahmentragwerke." This method eliminates long equations, and any error is very soon discovered.

The writer wishes to acknowledge helpful suggestions received from M. P. van Buren of J. Di Stasio & Co., New York City.

APPENDIX 1

The Strassner method is a continuation of and improvement on the Ritter method. Both methods are based on Mohrs principle "that the ordinates of the elactic line are the bending moments of the beam from a loading at each point equivalent to the moment area divided by $E.\ I$."

Strassner derives two points, J and K, for each member of the frame system, J near the left support and K near the right support. The location of these points expresses the combined elastic value (stiffness) of all of the structure that lies respectively at the left of J and at the right of K. In the determination of J enter the values of E, I and L for all members, beams and columns, of the left part of the structure, and for K, in a similar manner, values for the right part.

As the basic frame in this paper has columns hinged at opposite ends, the above mentioned fixed points need only be determined for beams. The general equations are shown in Fig. 12. For the various stiffnesses investigated they are for J points:

$I_H/H^1 \cdot L/I$	a_1	a_2	a_3	a_4	a_5	
0	0.0000	0.2000	0.2105	0.2112	0.2113	
0.10	0.0769	0.2170	0.2237	0.2241	0.2241	
0.40	0.1818	0.2480	0.2500	0.2500	0.2500	$\times L$
1.00	0.2500	0.2758	0.2763	0.2764	0.2764	
10	0.3226	0.3232	0.3232	0.3232	0.3232	

The same values apply to K points, but starting at the extreme right support.

The support moments are figured independently for loading at any one span. A load on span CD, Fig 12, created moments at the J and K points, the values of which are directly proportional to the moments at the support. See Fig. 13.

$$M_J = -\frac{a}{L} \cdot \phi_C \cdot \frac{6 \cdot E \cdot I}{L}; \quad M_K = -\frac{b}{L} \cdot \phi_D \cdot \frac{6 \cdot E \cdot I}{L},$$

where ϕ_C and ϕ_D are the angular deflections from the simply supported load only, at supports C and D respectively. Referring to Table 1 in this paper,

$$\phi_C = \phi_D = \tfrac{1}{3} \cdot K \cdot \frac{L}{E \cdot I} \quad \text{or}$$

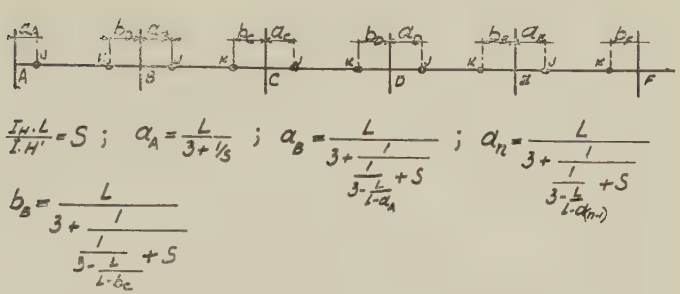

FIG. 12—GENERAL EQUATIONS, STRASSNER METHOD

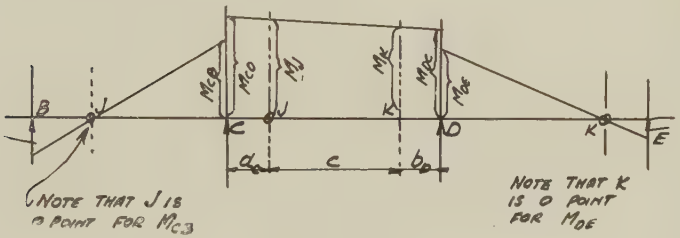

FIG. 13

$$M_C = -\frac{a}{L} \cdot 2K \cdot \frac{L - 2b}{c} \quad ; \quad M_D = -\frac{b}{L} \cdot 2K \cdot \frac{L - 2a}{c} .$$

Having determined the support moments from loading in any one span, it remains to distribute them between adjacent beams and columns.

From span CD in direction CB

$$M_{CB} = M_{CD} \cdot \frac{1}{1 + \frac{L}{H'} \cdot \frac{I_H}{I}\left[3 - \frac{L}{L - a_B}\right]}$$

From span CD in directon DE

$$M_{DE} = M_{DC} \cdot \frac{1}{1 + \frac{L}{H'} \cdot \frac{I_H}{I}\left[3 - \frac{L}{L - b_E}\right]}$$

The differences between the moments at adjacent beam supports are distributed on columns over and under in direct relation to their stiffnesses.

The above mentioned values are, for beams right to left:

$I_H/H^1 \cdot L/I$	*BC* to *BA*	*CD* to *CB*	*DE* to *DC*	*EF* to *ED*
0	1.0000	1.0000	1.0000	1.0000
0.10	0.8392	0.8530	0.8538	0.8538
0.40	0.5844	0.5994	0.6000	0.6000
1.00	0.3750	0.3818	0.3820	0.3820
10	0.0616	0.0616	0.0616	0.0616

Values left to right are determined in a similar manner

APPENDIX 2

The support moments from a concentrated load in any span can be determined (see Fig. 14) as follows:

$$M_L = -\frac{P \cdot X \cdot (L - X)}{L} \cdot \frac{a}{L} \cdot \frac{2L - X - 3b}{C}$$

$$M_R = -\frac{P \cdot X \cdot (L - X)}{L} \cdot \frac{b}{L} \cdot \frac{L + X - 3a}{C}$$

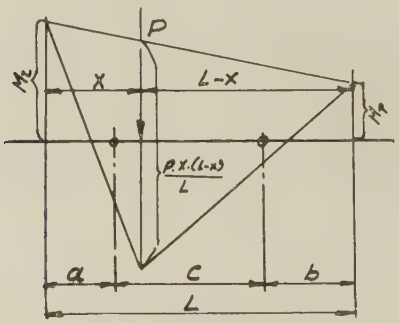

FIG. 14—SUPPORT MOMENTS FOR CONCENTRATED LOAD

These formulas can be used to make allowance for any variation to the assumed symmetrical loading, as the fixed points and distribution of moments can be interpolated from the above tables using the same scale as for the diagrams in this paper.

Readers are referred to the JOURNAL *for April 1931 for discussion which may develop. Such discussion should reach the Secretary by March 1, 1931.*

Discussion of Paper by Willis A. Slater and Inge Lyse

"Compressive Strength of Concrete in Flexure—As Determined from Tests of Reinforced Beams"*

BY FRITZ EMPERGER†

The relation between the compressive strength of concrete in flexure and that in direct compression has recently received increased interest as the methods of designing concrete of a given strength have become better known, and thereby it has become advisable to use lower factors of safety.

In this connection it is not sufficient to have a value like the cube strength which never appears alone in a structure. We have on one side to find the correct column strength, and on the other side the compressive strength in beams. With respect to the columns it is considered established that the column strength is 80 per cent of the cube strength. The question involved is, therefore, to find the multiplication factor for flexural compressive strength.

As a result of my proposal in *Beton und Eisen*, 1903, I tried in 1906, to introduce the use of heavily reinforced concrete beams as control specimens in the construction field, and was able to establish its use at a number of places, as for instance, in the construction of the Building for the Department of War in Vienna. The beam used had a cross-section 70 by 200 mm. (2¾ by 4 in.). The cross-section was later changed to 70 by 96 mm. on account of supporting the steel directly on the form. The loading arrangement was selected such that by the use of a value of n equal to 15, the flexural compressive strength is equal to $P/3$ without further computations.

An investigation by the Austrian Committee for Reinforced Concrete was undertaken in the same year for the purpose of

*A. C. I. Journal, June 1930; *Proceedings*, Vol. 23, p. 831.
†Vienna, Austria.

studying the proper shape and multiplication factor for such a test beam. The given dimensions resulted from the effort at reducing both dimensions and load to such a degree that the beam would be easily handled and could be tested without a testing machine. The studies by the Austrian Committee for Reinforced Concrete included more than 400 beams and a similar number of cubes. The first tests were carried out with fixed beams[1] and later a special series of tests was made.

The voluminous report[2] of these tests was not published until 1916 on account of the war. This discusses different concrete mixtures, beam cross-sections, and reinforcements. The reinforcement used in the beams amounted to 2.02, 4.04, 4.24, 4.97, and 5.83 per cent. Beams of different widths and depths were tested which were constructed according to field methods, as these tests were primarily intended for use on the job. In spite of this fact, the beams showed almost the same variation from the average as that obtained by the tests of the carefully made cubes. The maximum variations for the beams were +19.2 per cent and —16.8 per cent, and for the cubes +13 per cent and —18.2 per cent. The strength of the concrete used was as high as 420 kg. per sq. cm. (6000 lb. per sq. in.). The reinforcement was ordinary steel with a yield point stress of 2400 kg. per sq. cm. (34,000 lb. per sq. in.). It was established that for the ordinary strengths used in constructions, a reinforcement of 4 per cent was sufficient for the concrete in the beam. A width of 7 cm. was considered sufficient to accommodate the maximum size of aggregates used in reinforced concrete construction, since the use of these beams was not considered for large size aggregates.

In the course of progress of these tests, the German Committee for Reinforced Concrete also raised the same question, and received accurate information from us regarding the progress of the work.

The German tests are reported by Bach in Heft 19 of the Committee's publications. The beams were of larger width and had shear reinforcement, and were loaded at the center. As the

[1] "Berichte des Oesterreichischen Eisenbetonausschusses" Heft 4 by Dr. Fritz Emperger.
[2] "Berichte des Oesterreichischen Eisenbetonausschusses" Heft 6 by Hofrat Nähr.

latter method gives only the results for a narrow element across the beam it was soon abandoned.

The publication had the result that many doubts were raised in the German technical literature, while in Austria it had already been decided to adopt the beam test in the specifications. A second publication by Dr. Petry in Heft 50 of the reports from the German Committee for Reinforced Concrete, met the various objections and also showed that the cubes could not be made reliable on the job while the test beam could. Finally, the test beams have been included in the German specifications of 1926, and in the later specifications for concrete control, and at the same time a handy testing machine for the observations of maximum loads has been developed.

Before we discuss the important relationship between cubes and beams, we will study some American tests. The first publication was by Slater and Zipprodt in the *Proceedings* of the American Concrete Institute for 1920,[3] and then by Slater and Lyse in the American Concrete Institute's JOURNAL for June, 1930. It should be first mentioned, that the American engineers have changed from the use of the cube. It was first established in Germany that the cube strength is not even present in the columns and that the prism strength or actual strength of the concrete is about 80 per cent of the cube strength. No conclusion, however, has been drawn from these results, and the cube form has remained an artificial measure of the strength and other properties of the concrete. In North America, however, a cylindrical form of 15 cm. diameter and 30 cm. height has been adopted and this specimen gives numerous advantages over the cubes. It is always easy to make the cylinder mold from a sheet of galvanized iron, and glass plates will serve as end plates. It is of special importance to have a uniform method of filling and this cannot be secured in the corners of the cubes. The same difficulty is present in the capping of the cubes which might produce uneven load distribution. It seems probable that the cylinder sooner or later will be adopted also in Europe. The 30-cm. cubes give 13 per cent higher strength than the cylinder, the 20-cm. cubes give

[3] "Compressive Strength of Concrete in Flexure," by W. A. Slater and R. R. Zipprodt, A. C. I. *Proceedings*, Vol. 16, p. 120.

20 per cent higher strength, and the cylinder strength can be considered equal to the columns. (In order not to confuse the reader, we will use the 20-cm. cube strength throughout the rest of this discussion.)

It is of especial interest to note that the American tests included a further form of flexural strength in its program. This corresponded to the important transition form between pure compression and pure bending by eccentric load on compression specimens, which results in combined bending and direct compression. We see from these tests that the actual distribution of stresses does not correspond completely to that given by the assumption of Hooke's law, and that the error is due to this assumption. The eccentric tests have shown that at maximum load the compressive strength is 20 per cent higher than the cylinder strength, even though the relation between base and height was the same in both cases. In this case the load does not correspond to the ordinary column strength, but to the 20 per cent higher cube strength.

Further studies by Slater and Lyse bring forth that the ratio decreases as the strength of the concrete increases, so that the leaner concrete shows a relatively higher flexural strength than the richer concrete. This is a new proof of the fact that this concrete contains strength properties which should not be underestimated and which is very useful where the structure is expected to deform under secondary stresses.

When we consider the question of multiplication factor it must be remembered that the Austrian specifications assume 1.33, and the German tests show 1.70 and higher. A superficial reader will find a great difference between the results for the German and the Austrian tests. As the Austrian tests and original reports are very little known, it is quite regrettable that the German writers have not taken notice of them. The fact is that the German figure is based on the 30-cm. cube and the beam loaded at the center. According to the limited tests in Heft 19 "Deutsche Ausschuss für Eisenbeton" we find that this arrangement gives 9 per cent too high a value. We have, therefore, first to subtract from 1.7, 9 per cent due to the center load, and then 7 per cent due to the use of the 30-cm. cube when we want to obtain the relation for the 20-cm. cube. We find then, that the

German tests give a result of 1.45 as multiplication factor, or only slightly different from the specified Austrian value. The Austrian value did not correspond to the tests made, but was purposely chosen somewhat lower. The average of the tests in both countries gave approximately the same value. The question arises why the American tests give so much higher values. These tests may not be convincing because they were obtained on a small number of specimens, as also some of the Austrian tests showed higher values in some of the groups of tests. In order to arrive at a useful average, a much larger number of tests and also tests including different aggregates should be made, as the American tests only included one kind of aggregate. In order to obtain a complete view of the situation and summarize the differences obtained, it may be said that the multiplication factor given by the Austrian specifications is too low and instead of 1.33 the number 1.5 corresponds more closely to the actual relation. Otherwise a too high cube strength would be derived from the control beam. One thing should not be overlooked, and that is that the cube strength should not be considered fixed and constant, and the flexural strength liable to large variations. The situation is more clear when we disregard the imagined strength and judge the case by the deformation at failure, and keep in view the fact that the failure neither by cubes nor by beams, is caused by compression, but by the shear stresses which cause the deformation at failure. We will then see that the deformation at failure depends upon the whole set of conditions, that is, from the dimensions of the specimens to the quality of the concrete, and that the ratio is subject to large variations, and cannot be given a fixed value. When, however, we use such a ratio it is necessary to fix the limits which will be within the given factor of safety and not let the selection of the ratio depend on anyone's judgment. The increase in compressive strength obtained by eccentric loading is important when the eccentric load has been neglected in the design of structure. In the building of arch bridges where this should be done with great accuracy, this increase is found to amount to 20 to 50 per cent and increases with the eccentricity.

How sensitive the beam strength is with respect to all kinds of effects is brought forth in my report in *Forscherheft*, 14, 1911,

which contains the use of a strength thermometer by which it was possible to conclude what temperature was present at the time of set of the concrete from the strength results of the test beams.

AUTHORS' CLOSURE

The authors are glad that Dr. Emperger has given some historical information on the Austrian and German investigations designed to determine the compressive strength of concrete in flexure and of the use of small heavily reinforced beams as control specimens. Certain advantages of this form of control specimen are recognized. Its principal disadvantage probably lies in the fact that it is more difficult and expensive to make and test this control beam than it is to make and test a small cylinder or a cube. Due to this fact it would not be feasible to provide control tests from as many batches of concrete as may be sampled for a given cost by means of small cylinders or cubes.

Dr. Emperger indicates that the Austrian values are considerably lower than those given in this paper. Unfortunately we have not been able to compare his results with ours. Finality is not claimed for the results of our tests. Nevertheless, every reasonable effort was made to keep the tests free from effects which would vitiate the results. It is recognized that much more ground could be covered in an investigation which included 400 instead of 36 beams. However, three beams of each kind were made and the close agreement between results for individual beams should be evidence that the work was carefully done. In the absence of any suggestion as to any features in which the methods used were defective, the authors are inclined to believe that the results may safely be applied within the field which the investigation covered.

It is quite possible that if long-time loads had been applied to the beams, lower strengths would have resulted. However, the same is true regarding the cylinder tests, and there is no certainty that the ratio of the compressive strength in flexure to that in direct compression would have been any lower than those found, if all the tests had been made under long-time loading. So far as the authors know, this is the most important feature not covered in the investigation.

An effort was made to review all the previous literature on the subject under investigation, and it is regretted that the tests carried out by Dr. Emperger were not found in the search that was made. His discussion of this paper is highly appreciated.

The authors wish to correct an error which has been pointed out in Table 7 of the paper under discussion. The computed stresses at failure, based upon the observed values, of n as given in Column 6 and the resulting beam-cylinder ratios as given in Column 9 of Table 7 are both somewhat too small. The correct values are:

Column 6	*Column 9*
2340	1.68
3130	1.12
4250	1.04
5050	1.05
5680	.99
3670	1.42
4140	1.00
3550	1.20
3460	1.25
3570	1.23
3080	1.09
4120	1.08

The error is deeply regretted, but fortunately it is not of sufficient magnitude to affect any conclusions in the paper. Even the curves in Figures 21 and 22 are not affected appreciably by the error.

Properties of Mass Concrete

Report of Committee 108

A Summary of Existing Data With A Suggested Program Of Investigation

BY RAYMOND E. DAVIS*, CHAIRMAN, AND G. E. TROXELL†

The hardening of portland cement concrete is a chemical process, and the hydration of the cement, being an exothermic reaction, is accompanied by a liberation of heat. When water is available, it appears that the rapidity of hydration depends upon the chemical composition of the cement, the fineness of the cement particles, and the temperature of the concrete of which the cement is a component part. Other things being equal, the finer the cement and the higher the temperature, the more rapidly does hardening take place. For most portland cements, hydration practically ceases for temperatures approaching the freezing point of water.

The total heat liberated by a given amount of cement from the time of beginning of hydration until hydration has been completed, can not readily be determined, but perhaps within ordinary limits of grinding may not differ as greatly with the chemical composition of the cement as is sometimes supposed, even though the rate of heat generation during the early stages of hardening may be very much greater for one cement than for another.

Any concrete, the temperature of which at the time of mixing is not above that of the surrounding medium, will undergo an increase in temperature, the heat generated by the hydration process being absorbed by the aggregates and uncombined water

*Professor of Civil Engineering, University of California.
†Associate Professor of Civil Engineering, University of California.

and gradually being dissipated by radiation until its temperature corresponds with that of the surrounding medium. At the beginning, temperatures increase rapidly, as does the hydration process. Then, as hydration is retarded, the rate of heat generation becomes less, until when rate of heat generation equals rate of heat dissipation, the maximum temperature is reached. Thereafter, as the rate of hydration gradually declines, the temperature decreases until that of the concrete reaches that of the surrounding medium.

It might be expected, then, that the maximum temperature attained by concrete due to chemical heat and also the time required to reach this maximum temperature would be influenced by (1) chemical composition of cement, (2) fineness of grinding, (3) character of aggregate, (4) richness of mix, (5) water-cement ratio, (6) initial temperature of the concrete, (7) temperature and character of the surrounding medium, and (8) the size and shape of the concrete mass. Thus it appears that there are at least eight factors, a variation in anyone of which may influence to greater or less degree the maximum temperature.

It is a matter of common experience that with our normal portland cements and normal mixes, the temperature rise in structures of thin section is too small to be of consequence. But it is also an observed fact that in concrete of massive proportions such as large dams, heavy foundations, thick arches, and the like, there may be a very considerable increase in temperature of the concrete subsequent to its placement, this increase sometimes amounting to more than 100 degrees F. and the interval during which this increase takes place sometimes being as long as a month or more. Because of the possible effect that these large changes in temperature may have, not only upon the properties of the material itself, but also upon the intensity and distribution of stresses and strains within the structural mass, it is of very great importance that the facts concerning the behavior of concrete in large masses should be known.

What follows is a summary of available information concerning the properties of mass concrete obtained for the most part from published writings, but to a considerable extent from unpublished data. An examination will show that beyond records of tem-

perature in a considerable number of structures, and some rather incomplete laboratory tests to correlate temperature and strength, very little is known of the properties of mass concrete. The observations of massive structures all indicate that the temperature rise is rapid and the temperature decline is gradual, in some cases extending over several years. While little quantitative data are available, it appears that in certain structures the decrease in temperature has been accomplished by cracking, indicating large tensile strains, and that in a general way the width and number of cracks increase with time. There are no data to show whether or not there is still further decrease in volume, after normal temperature has been attained, due to a gradual giving up of moisture within the mass which moisture is not employed in the hydration process; but it seems not unreasonable to suppose that mass concrete exposed to drying conditions may continue to give up moisture and gradually to shrink for many years after it has arrived at a state of practical temperature equilibrium, just as at a more rapid rate does the concrete in structures of thin section.

From such laboratory tests as are available it appears that high setting temperatures in mass concrete lead to high early compressive strengths but that ultimately the strength of concrete cured at normal temperatures is in excess of that which has undergone the more elevated temperatures within the mass. There is also evidence that when the temperatures are considerably above normal, the concrete within the mass may reach its maximum strength within a few days and thereafter may suffer a slight retrogression in strength, but tests are of too short a duration to demonstrate whether this retrogression is not perhaps later followed by a second increase in strength which may equal or exceed the amount of the retrogression. There is no information concerning the elastic or plastic properties of concrete subject to conditions obtained within the mass, nor concerning shrinkage strains.

EARLY TESTS

Results obtained from some investigations to determine the temperature rise due to the setting of cement follow:

Tests reported by J. B. Johnson on the rise in temperature at the center of a mass of portland cement concrete 11.5 ft. thick, show that the temperature rose 85.5 degrees F. in 4 days and reached its maximum increase of 93.6 degrees F. in 7 days, after which it fell off slowly. Data on the mix used are not stated.

The Watertown Arsenal made 12-in. cement cubes using 27 different brands. These specimens were in wooden forms with their tops exposed to the air. For these cubes, having an average initial temperature of 77 degrees F., the maximum temperature was 218 degrees F., showing a rise of 141 degrees in 13 hours. The lowest maximum temperature for any of the portland cements was 117 degrees F., a rise of 40 degrees.

The materials testing laboratory at Lehigh University made an 8-in. cube of 1:3 mortar, which rose from 70 to 160 degrees F. in 18 hours while the laboratory temperature was constant at 70 degrees F.

Tests on 6-in. neat cement cubes and on concrete as actually placed in construction work were made by the Universal Portland Cement Company at Buffington, Indiana. The 6-in. cubes rose from 80 degrees F. to 130 degrees F., a rise of 50 degrees in 8 hours, while the concrete rose from 70 to 110 degrees F., a rise of 40 degrees F. in 40 hours.

BOONTON DAM TESTS

Thaddeus Merriman,[1] one of the early investigators of temperatures developed in mass concrete, carried on tests during the construction of the Boonton dam in New Jersey in 1903. The total length of this dam was 3100 ft. and the maximum height of the full masonry section was 114 ft. Atlas portland cement was used exclusively in its construction. Although the downstream face was faced with ashlar masonry, the interior was of cyclopean concrete composed roughly of 50 per cent of concrete of a 1:3:6 mix and 50 per cent of large stones. All stone used was a syenitic gneiss and the sand was of glacial origin.

As work on the Boonton dam progressed, eleven thermophone coils were placed in the concrete at different elevations and at various distances from the two faces of the dam, but all in one central section. These thermophones were designed to be sensitive and correct to within 1 degree F.

[1]See Bibliography page 418 for all references.

The observed temperature record for thermophone No. 11, which was 8.5 ft. from either face and 11 ft. below the top of the dam, is typical of that for the other positions. The coil was set into the dam on June 24, 1904, and was immediately covered with about 12 in. of concrete which was at a temperature of 74.5 degrees F. Within the next 16 hours, it attained a temperature of about 90 degrees F. Seven days later, when the coil indicated a temperature of 77 degrees F., more concrete was placed above it, so that within 14 days, it was buried to a total depth of 11 ft. A second rise in temperature from 77 degrees to 93 degrees F. occurred in 13 days. This second temperature rise was largely due to the heat from the masonry placed above it, and consequently it can be said that the temperature of the masonry placed above coil No. 11, and insulated from it by 12 in. of concrete already set, must have reached a temperature higher than 93 degrees F.

The concrete in this structure was deposited in thin layers and therefore the heat was quickly dissipated. Merriman expresses the opinion that a temperature rise of 40 degrees F., could have been anticipated had the heat losses been reduced by depositing the concrete in deeper layers.

In the Boonton dam, about one year elapsed before the masonry returned to normal temperature. The Boonton dam records also indicate that minimum and maximum temperatures near the center of the dam due to seasonal temperature variations are reached approximately 30 days after the occurrence of the atmospheric minimum and maximum, respectively, and moreover, the "lag" is proportional in some degree to the distance from the nearest face of the dam.

R. H. Brown[2] reports tests conducted during the construction of canal walls for power development on the Kennebec River in 1909, at Madison, Maine. The concrete was a 1:3:5 mix, placed at a temperature of 70 degrees F. Recording thermometers placed inside a 3-in. pipe at the center of the thick walls (thickness not stated) registered a maximum temperature of 119 degrees F., reached after 8 days, when the depth of concrete over the thermometer was 26 ft. The temperature dropped to 98 degrees F. when the concrete was 20 days old. During these

observations, the outside air temperature averaged about 20 degrees F.

PANAMA CANAL LOCKS

Tests made to determine the setting temperatures in the Panama Canal Locks[3] show that a maximum temperature rise from 106 degrees to 130 degrees F. was attained 12 ft. from the surface. The maximum temperature occurred about 10 days after placing the concrete. Temperatures were observed by means of electric resistance thermometers imbedded in the side walls of the locks. The concrete was a 1:3:6 mix with some large plums.

DES MOINES ARCH BRIDGE

The concrete placed during construction of the Walnut Street arch bridge[4 *and* 6] in Des Moines, Iowa, was tested for rise in temperature while setting. The bridge consists of six 68-ft. reinforced concrete arches, the arch rings being 16 in. thick at the crown and 6 ft. thick at the spring line. Nine electric resistance thermometers were used in the tests. The maximum temperature rise occurred at the spring line, 6 in. from the intrados, where the 1:2:4 mix of concrete, placed continuously during night and day, reached a temperature of 108 degrees F., showing a rise of 32 degrees F. within 44 hours after placing. The mean daily air temperature was about 70 degrees F.

CEMENT PASTE TESTS BY BEALS

To determine the maximum temperature attained, and also to determine the rate of evolution of heat by cement pastes, Louis N. Beals, Jr.,[5] in 1913 reported tests upon small samples. Preliminary tests made by placing 900 g. of cement plus 225 g. of water in a can surrounded by a larger second can with paper insulation between, showed temperature rises varying from 14 degrees F. to as much as 45 degrees F. for the different brands tested.

As the heat due to the chemical reaction is evolved rather slowly and extends over a considerable period of time, the heat losses from the two cans described above were quite large. A second series of tests was therefore run using 1- to 2-lb. samples of cement in a thermos bottle with a secondary jacket to prevent heat losses.

The total calories liberated per gram of cement, corrected for radiation, were computed and plotted against time. It was found that different cements showed an appreciable difference in the rate of heat liberation and in the total heat liberated. It was also established that cements liberating only small quantities of heat, later proved to be unsound.

Beals' graphs show that if the radiation is taken into account, the evolution of heat continues over a period of more than 100 hours. Curves drawn to show the rate of heat generation in calories liberated per gram of cement per minute indicate that "there is a sudden evolution at mixing, then a sharp minimum —probably close to the time of initial set—followed by a longer maximum reaching a peak at about 8 hours, which may mark a more intrinsic property of the cement than the conventional final set. Another minimum and maximum follows, the significance of which may be developed by further investigation." The rate curves differed quite radically in some instances, as some cements indicated very high rates of heat evolution for short periods while others liberated the heat more slowly but for longer intervals. The total heat liberated by these two types of cement may or may not be the same.

W. A. Hoyt[7] states that the amount of heat generated depends upon the size or mass of the concrete, the kind of cement used, the consistency of the mixture, and also upon the richness of the concrete. A 1:2:4 mixture of medium consistency placed at 70 degrees F., in masses 12 in. thick or more, should develop a temperature of 120 to 150 degrees F. within 24 to 36 hours.

ARROWROCK DAM

Temperature changes in the concrete of the Arrowrock Dam, a gravity arch structure 330 ft. high, near Boise, Idaho, are reported by Paul and Mayhew.[8] The major portion of the concrete consisted of 1 part sand cement (45 per cent pulverized granite with 55 per cent portland cement by weight), 2½ parts sand, 5 parts of pebbles, and 2¾ parts of cobbles. A richer face mix, which varied in thickness, consisted of a 1:2:4:2½ mix. The cement in this face mix was composed of 76 per cent sand cement and 24 per cent portland cement by volume.

Ten electrical resistance thermometers were embedded in the concrete, all in one vertical plane, but at various elevations; some thermometers were close to the face of the dam, whereas others were deeply embedded in the dam. The temperature indicator, consisting of a modified Wheatstone bridge calibrated to read temperature units instead of ohms, could be read to 0.1 degree F. The Leeds and Northrup Co., the manufacturers of the coils and indicator, claimed an accuracy of the apparatus as a whole to 0.5 degree F.

Concreting at the location proposed for a thermometer was usually discontinued temporarily and the concrete allowed to set for a few hours before placing the coil. In some cases, concreting was not carried on continuously, directly above the thermometers. The delay in concreting preparatory to placing a coil, the shallow depth of cover of 1.5 to 2 ft. placed in most cases, the use of sand cement and the leanness of the mix used, all worked toward the development of lower maximum temperatures than would have resulted otherwise. As the investigators stated, however, the purpose of their observations was to determine the temperatures produced under average placement conditions for large dams where lean mixes are ordinarily placed in about 2-ft. layers with not more than one or possibly two layers being placed during one shift.

The results of the observations by Paul and Mayhew are presented in Table 1. As a result of these tests which show a maximum temperature rise of 36.7 degrees F., it was concluded that large bodies of concrete deposited at a temperature of about 60 degrees F. develop a temperature of from 90 to 95 degrees F. within a period of 30 days and maintain nearly that temperature for several days thereafter. Also, the effect of the "setting heat" in concrete 20 ft. or more from an exposed face is felt for several years after the concrete is placed. Concrete near the center of the mass of a large dam probably retains some of this "setting heat" for 5 years or more after placing.

Paul and Mayhew also state that the effect of the temperature of the air in counteracting the heat generated in the concrete by chemical action, is illustrated by the fact that all the comparatively low maximum temperatures recorded by several of the

TABLE 1—TEMPERATURE TESTS ON ARROWROCK DAM (PAUL AND MAYHEW)

*Thermometers 7, 8 and 9 directly above concrete 12 days old and under only 1.5 to 2 ft. of concrete cover for first two weeks.

thermometers occurred at points where the distance to an exposed face was comparatively small, and that all the high maximum temperatures recorded by a few of the thermometers occurred at points where the distance to an exposed face was considerable, and over which concrete to a considerable depth was placed during a comparatively short period. Therefore, it appears probable that the speed of placing has fully as much influence on the temperature of mass concrete as either the season of placing or the richness of the concrete. The duration of the rise in temperature, due primarily to chemical action, is undoubtedly

largely dependent on the speed of placing, season of the year, consistency, brand of cement, and quantity of cement per cubic yard of concrete.

In a discussion of the results reported for the Arrowrock Dam,[8] W. M. Smith calls attention to the fact that the proportion of portland cement in the loose materials by volume was only 5 per cent in the bulk of the masonry and 7 per cent in the facing. In the ordinary 1:3:6 concrete mixture, there is 10 per cent of cement by loose volume, and in a 1:2:4 mixture, generally used for reinforced concrete, the cement amounts to over 14 per cent. The statement is then made that had the cement component been higher in the concrete of the Arrowrock Dam, the setting temperatures would have been materially higher.

ASHOKAN RESERVOIR BRIDGE

The effect of a richer mix than that used in the Arrowrock dam is shown by tests on the spillway bridge at the Ashokan reservoir built by the Board of Water Supply of New York City. Several thermophones were placed at various points in the arch to record the temperature changes. Three were placed at the crown, five at a point about midway between the crown and the abutment, and three at the abutment. The arch was 3 ft. 4 in. thick at the crown, 4 ft. 8 in. at the midway point, and 6 ft. 3 in. at the abutment. The temperature rise at the crown was 20 degrees F., the maximum temperature being 88 degrees F. At the midway point, the rise varied from 27 degrees to 40 degrees F., according to the distance from the surface, the maximum temperature varying from 82 to 95 degrees F. At the abutment the rise varied from 30 to 50 degrees F., according to the distance from the surface, and the maximum temperatures varied from 95 to 115 degrees F. In every case, the maximum temperature was reached within 4 days.

In another test to determine the maximum setting temperature of concrete conducted during the construction of a shaft by the Board of Water Supply of New York City, it was found that a temperature of 136 degrees F. was developed.

KENSICO DAM

A very comprehensive series of tests to determine the temperatures developed in massive concrete structures due to the chem-

ical activity of the cement were conducted during the construction of the Kensico dam at Valhalla, N. Y., in 1913 and were reported by George T. Seabury in a discussion of the paper by Paul and Mayhew.[8]

Kensico dam is a gravity structure 1850 ft. long on top; its maximum height is 307 ft. and its volume is about 900,000 cu. yd. It is of cyclopean masonry, 27 per cent of the mass being of large stone; the remainder is of concrete mixed in the proportions of 1:3:6, Atlas and Alsen brands of cement being used. The concrete was handled rapidly in 2-yd. buckets, so that the elapsed time between mixing and placing was very short, usually not more than 5 or 6 minutes.

The portion of the dam chosen for the installation of the 47 sensitive electrical resistance thermometers is near the center. The thermometers were placed in two vertical planes; one near a contraction joint, and the other midway between two contraction joints, or in the center of a section. In each vertical plane the thermometers were placed in corresponding positions, and at various elevations; near the up-stream and down-stream faces, at equal distances from both faces, and at the middle line between these faces.

The central portion of the dam containing the thermometers was built comparatively rapidly. In the fall of 1913, a height of 35 ft. was placed, and in that height 15 thermometers were installed. During the following summer, the masonry was carried to the top—a distance of 165 ft.—in six months, and this part contains the remaining 32 thermometers.

At the Arrowrock dam it was the practice generally to place the thermometers in concrete which had already partly set and had been exposed for a long enough period to lose, by radiation into the air, a portion of the heat that would be normally developed. The thermometers, too, were covered to only a relatively small depth in many cases, permitting more radiation to go on, and so obscure the record of the total heat generated. On the other hand, at Kensico dam, the thermometers were plunged into the plastic concrete the moment it was placed, and were buried as deeply and as rapidly as possible in order to determine, if possible, the maximum temperature to which such a structure would be subjected under rapid placement conditions.

The results of the tests show that for a number of the locations, well away from the face of the dam, the rise in temperature was about 40 degrees F. and this seemed to be unaffected by the temperature at which the concrete was placed. This resulted, in the summer, in a maximum temperature well above 100 degrees. The highest temperature observed—and that which it is believed is probably the maximum in any part of the structure—was 118.5 degrees F., but this maximum temperature was not reached until long after the concrete had attained its final set. When undisturbed by other conditions, the maximum temperatures were reached in about 15 days—some points obtained their maximum temperatures in 5 days and others not for 95 days.

The increase in temperature due to the setting of the cement in the concrete began as soon as the latter was placed, and increased at the rate of about 1 degree F. per hour, for 4 or 5 hours, when the rate gradually increased to from 8 to 10 degrees per hour, for an hour or so, and then suddenly dropped to about 0.5 degrees F. per hour for a considerable time. The period of most rapid heat development corresponds with that of the final set of cement under ordinary conditions. Many observations indicated a rise in temperature of from 25 to 30 degrees F. after this period. As a consequence of this, the investigators raised the question: What is the effect on the strength of a large mass of concrete rapidly placed, if in its interior, a temperature of from 25 to 30 degrees F. is developed after the cement has ob-obtained its final set and the masonry its solidified form? Is the increase in size which results from this heating sufficient to develop disruptive strains in the fresh masonry beyond its early strength?

The opinion is expressed by Seabury that large bodies of concrete deposited rapidly develop a temperature a definite amount greater than the initial temperature of the aggregate, probably dependent almost entirely, if deposited rapidly enough to minimize radiation, on the quantity of cement to the unit of the resulting mass, and that this maximum temperature may be even 135 or 140 degrees F.

Meager evidence showing how the brand of cement affects the quantity of heat generated was ascertained, as there was one place in the Kensico dam where two thermometers were placed

about 5 ft. apart and under conditions which were thought to be identical, with one exception. After each had been covered by about 2 ft. of concrete made with Atlas cement, additional cover over one thermometer was made using the Atlas cement, while Alsen cement was used in the mix over the other thermometer. Within the first 6 hours after being placed, the thermometer under the Alsen cement did not rise as high as the one which was entirely surrounded by Atlas cement, and which had no Alsen near it, but, subsequently, they reached almost exactly the same temperature. The evidence is, then, that the brand of cement appears to make some difference at a certain stage, but not ultimately. However, these two thermometers were too close together to give reliable results unaffected by the heat from the other mix.

Seabury differs with the statement of Paul and Mayhew that "it appears probable that the speed of placing has fully as much influence on the maximum temperature of mass concrete as either the season of placing or the richness of the concrete." It was clearly demonstrated on the work at Kensico that, provided the initial heat acquired in setting be not dissipated through a slight amount of cover, the rise in temperature is a constant for any given mix, irrespective of the season of placing. It appears that the speed of placing has a great deal to do with the rise of temperature so far as reducing it is concerned; but, on the other hand, it seems that with a sufficient amount of cover, the rise will be a constant for any given mix. From this it follows that the season of placing, or rather the initial temperature of the aggregates and mixing water, has much to do with the maximum temperature reached.

The investigators at Kensico concluded that the rise in temperature due primarily to the chemical action, is undoubtedly largely dependent on the speed of placing, consistency, brand of cement, and quantity of cement per cubic yard of masonry but that these factors do not necessarily affect the duration of the rise in temperature as stated by Paul and Mayhew.

EAST CANYON CREEK DAM

Rather meager temperature observations have been reported for the East Canyon Creek dam,[9] built in 1915, near Morgan,

Utah. This is a true arch structure, 190 ft. high, having a thickness of 26 ft. at the base and 5 ft. at the top.

The proportions of the concrete used in the body of the dam were 1 part cement; 3 parts sand, with some screenings up to ¾-in.: and 5 parts broken stone of 3-in. maximum size. Red Devil brand of cement was used, and the cement content ran 4.75 sacks per cubic yard of concrete.

The concrete was deposited in 2-ft. layers, working back and forth. The aggregates were often frozen, but hot water added at the mixer raised the temperature of the fresh concrete so that it was just above the freezing point as it came from the mixer.

The rise in temperature due to chemical changes in setting prevented damage from frost when the concrete in the form was covered at night. Canvas spread over the forms and salamanders burning coke, aided in preventing surface freezing; while the interior temperatures of the mass soon increased sufficiently to remove any frost occurring on the surface, if not too great in quantity.

The removal of 1½-in. pipes which had been placed in the contraction joints afforded a very favorable means of testing the rise in temperature in the concrete while setting. Tests of temperature by lowering a thermometer into the holes, indicated in every case a considerable rise, a typical test showing a temperature of 70 degrees F. at a depth of 15 ft. when the air was 14 degrees F., a difference of 56 degrees F. from the air temperature or a difference of about 35 degrees F. from the initial temperature of the fresh concrete.

TESTS BY YOSHIDA AT UNIVERSITY OF ILLINOIS

While carrying on studies of the cooling of fresh concrete in freezing weather at the University of Illinois, Yoshida[10] also made tests to determine the rise in temperature during the setting of concrete and mortar.

The mixes used in these tests were made with Universal portland cement. The 0 to ¼-in. sand and the ¼ to 1½-in. pebbles came from pits at Attica, Indiana. The concrete or mortar to be tested was poured into a mold of 1½-in. pine lumber large enough for a 12-in. cube. Two thermocouples were embedded

to measure the temperature, one at the center of the cube and the other at 3 in. from the center. The mold was put in the center of a large wooden box and the space around all six surfaces of the mold was filled with sawdust about 8 in. thick, to prevent the cooling of the specimen.

The initial temperature of the fresh concrete or mortar was the same as that of the laboratory. The two thermocouples showed about the same temperature, so the temperature at the center was used in the preparation of Table 2. The total rise in temperature, the rate of increase, and the time interval before the maximum temperature was reached were all variable, depending upon the proportions of the mix and the amount of mixing water.

TABLE 2—RISE IN TEMPERATURE DURING SETTING OF CONCRETE AND MORTAR (YOSHIDA)

Mix	Water-Cement Ratio	Consistency	Initial Temp.	Max. Temp.	Temp. Rise	Hours to Develop Max. Temp.
Mortar			°F.	°F.	°F.	
Neat	0.38	Medium	68	184	116	15

1:2:4	0.81	Dry	73	85	12	30
1:2:4	1.01	Medium	75	87	12	30
1:2:4	1.26	Wet	71	83	12	26
1:3:6	1.29	Medium	71	82	11	29

EMIGRANT CREEK DAM

During construction of the Emigrant Creek dam,[13] holes about 2 in. in diameter extending from the downstream face to within 3 ft. of the upstream face were prepared at three different levels.

The thickness of the dam at the lower, middle and upper levels, was 15.5, 10.5 and 5.5 ft. respectively.

Long wooden rods of a diameter slightly smaller than the openings were then inserted in the holes after several maximum registering mercurial thermometers had been embedded in the

rods. Felt washers were used to prevent circulation of air in the holes. Daily readings taken when setting was progressing most rapidly indicated temperatures as high as 132 degrees F. Data on the concrete mix are not stated.

CALDERWOOD DAM

Tests of the temperatures in the Calderwood dam, a thin-section-arch overflow dam 230 ft. high, indicated a temperature of 148 degrees F. at the center. The concrete mix was 1:3:4.5 with a cement content of 4.5 sacks per cu. yd. The water-cement ratio was about 0.85, producing a slump of 1½ in.

WILSON DAM

A very complete program of temperature observations conducted during the construction of Wilson dam on the Tennessee river has been reported by John W. Hall.[16]

This structure is of the gravity type and has a total length of about 4300 ft. The spillway section, where the temperature tests were made, is about 94 ft. high and was built in 1923 and 1924. The concrete contained 5 sacks of cement per cubic yard and the maximum size of the aggregate was 3½ in. This concrete was mixed at central mixing plants, then dumped in 4-cu. yd. buckets of the bottom dump type and transported by railroad to the place of deposition. Each layer of concrete averaged about 6 ft. in depth.

Electric resistance thermometers were embedded in the concrete of one section of the dam, to determine the maximum temperature developed in the process of curing, and also to determine the length of time required for concrete to lose the effect of heat caused by chemical action of the cement. The resistance coils were placed in two vertical planes, one on the center line of the block, and the other 6 ft. from the expansion joint. Twenty-four thermometers were placed in each of these sections. The degree of sensitivity permitted the temperatures to be read to ¼ degree F.

As the thermometers were 1 ft. below the top surface of the layer being placed, the air temperature affected the thermometer until the next layer of concrete was placed, after which the thermometer recorded the temperature developed in the mass where it was located.

Some of the general points of interest from this series of observations are:

Thermometers 1 ft. from the face showed a rise from 50 to 83 degrees F. in 5 days, and then a fall to 43 degrees in 30 days, after which the temperature increased and decreased with the air temperature.

Thermometers 2 ft. from the face showed a rise of temperature from 64 to 82 degrees F. in 24 hours, and then a fall to 73 degrees in 3 days, at which time a new layer of concrete was placed and the temperature rose again to 86.5 degrees F. in 5 days and then gradually fell till the temperature reached 56.5 degrees F. at the end of 2 months.

Thermometers 9 ft. from the face, showed a rise in temperature from 63 to 79 degrees F. in 2 days and then a fall to 70.5 degrees in 3 days, when a new layer of concrete was placed, excluding the effect of the air temperature. The temperature then rose to 100 degrees in 11 days, after which it gradually decreased, reaching 76 degrees at the end of 3 months.

Thermometers 20 ft. from the face showed a rise of temperature from 64 to 84 degrees F. in 24 hours, and then a fall to 76 degrees in 3 days, when a new layer of concrete was placed. The temperature then rose gradually to 101 degrees in 11 days, after which it fell to 78 degrees in 5 months.

Thermometers 26 ft. from the surface showed a rise from 47 to 113 degrees in 24 days, and then a fall to 81 degrees F. in 7 months.

Information obtained from these temperature records shows that in this mass concrete, the temperature near the face increased slightly for a short period of time, approximately 4 or 5 days, and then fell slowly for as much as 30 days, after which the rise and fall of the temperature was directly affected by the air temperature prevailing. At greater depths in the mass, the temperature rose to as high as 113 degrees F. over a period of approximately 3 or 4 weeks, and then gradually decreased for a period of as much as 8 or 9 months.

It is interesting to note that this concrete was placed in the winter season when the air temperature, varying from 10 to 70 degrees F., but usually from 40 to 50 degrees F., would tend

to decrease the maximum reached by the mass, and yet this maximum was 113 degrees F. Also, it was noted that concrete near an expansion joint, even though in contact with adjoining mass concrete, does not increase to the temperature reached by the center of the mass, although this difference is apparently not over 3 or 4 degrees F. The information shown by this record is that the central portion of any mass concrete is sometimes in a state of expansion while the external surfaces are in a state of contraction, and explains the cracks appearing in the surface of concrete which do not penetrate to the interior of the mass.

Because of the high continuing temperatures in concrete of considerable volume, it was concluded by Hall that, if cracks in permanent work are to be avoided, deposits of concrete should be limited to 4 ft. for any one layer. Such deposits should be allowed to set and cool at least 5 days before succeeding courses are placed. Also, the greatest horizontal dimension for any given deposit should be 25 ft.

STEVENSON CREEK TEST DAM

In 1926, Slater[17] conducted an elaborate series of tests for Engineering Foundation upon the Stevenson Creek Test Dam in California in order to determine the distribution of stresses in arch dams. Temperatures of the concrete were observed from the time the concrete was placed until several months later.

This test dam is 60 ft. high and has a thickness of 2 ft. for the upper 30 ft. but below this the thickness increases until at the bottom it becomes 7.5 ft.

The concrete mix consisted of 1 part Colton cement, to 3 parts fine crushed granite aggregate varying from 0 to $\frac{3}{8}$ in., to 2 parts crushed granite varying from $\frac{3}{8}$ to $1\frac{1}{2}$ in., these proportions being by weight. The water-cement ratio varied from 0.87 to 1.03 and the consistency varied from a 2-in. to 7-in. slump.

In placing the concrete, a lift of 15 in. was deposited from end to end of the dam. The next lift was started at such time that at all points the concrete would have at least an hour in order for some set to take place between lifts. Ordinarily, one day's pouring consisted of four such lifts, or 5 ft. total. In general, about four days elapsed between pourings.

The setting temperatures of the concrete were measured by means of 140 electric resistance thermometers set at various points in the mass; some were close to the forms while others were deep seated in the concrete; some were at the middle vertical sections while others were at the abutments.

On the center line of the dam and 4 ft. above the base, where the thickness of concrete was 6 ft. 2 in., the temperature in the center of the mass rose from 73 degrees F. to a maximum of 116.5 degrees F. in about two days. From then on it gradually decreased, becoming constant at about 63 degrees F. after 3 weeks. At 2 in. from the face, the temperature rose from 72 degrees F. to a maximum of 95 degrees F. within one day, and from then on decreased at about the same rate as at the center, reaching a steady temperature of about 52 degrees F. after 2 weeks. The average air temperature was about 72 degrees F. when the maximum temperatures were reached. The minimum daily air temperatures averaged about 55 degrees F., and the maximum daily air temperatures averaged about 81 degrees F. during the first 3 weeks while the above mentioned tests were in progress.

MINNEAPOLIS BRIDGE

Jakkula[18] reports tests made in 1927 to determine the setting temperatures in the concrete piers of the Cedar Avenue bridge in Minneapolis. The concrete in this structure was made of portland cement, washed sand and trap rock, and the average field mix was 1:2.9:4.6. An inundator was used to measure the quantity of sand and to eliminate bulking. The average fineness moduli of the sand, trap-rock, and mix were 2.6, 7.8 and 5.6 respectively. The water-cement ratio was kept constant at 0.90.

Thermocouples were used for measuring the temperature of the concrete. Three of these were embedded in the central pier which was 8 ft. high, 50 ft. long and 25 ft. wide. The thermocouples were placed 4 ft. from the bottom on a line perpendicular to the center of the 50-ft. face, and at distances of 8.5 ft., 12.5 ft. and 16.5 ft. from that face.

Three thermocouples were also installed in each of the two shafts of the shore piers. These shafts were 16 ft. high, 14 ft. wide and 15 ft. long. The thermocouples were placed 3 ft. from

the bottom on a line perpendicular to the center of the 15 ft. side at distances of 1, 5 and 9 ft. from that side. All pourings were continuous at the rate of about 20 cu. yd. per hour.

Before any pouring was started, the forms were thoroughly warmed by salamanders. The sand, trap rock and water were heated by means of steam pipes. When each pour was finished, the entire section was covered with a tent-like arrangement of tarpaulins within which were placed salamanders heated with charcoal. Heating of the center pier was continued for 33 hours, of the downstream shaft of the shore pier for 54 hours, and of upstream shaft for 72 hours.

The records for the center pier show that the concrete was placed at 60 degrees F. when the surrounding air was at 40 degrees F. Between 8 and 38 hours after placing, the surrounding air averaged about 65 degrees F., and during this period the temperature of the concrete at all thermocouples rose 35 degrees to a maximum of 95 degrees F.

In the upstream shaft of the shore pier, the concrete was placed at a temperature of 45 degrees but fell to 40 degrees F., the temperature of the surrounding air, in 3 hours. Thereafter, the temperature of the air averaged about 65 degrees for 70 hours, at the end of which period the temperature 1 ft. from the face reached a maximum value of 92 degrees F. The temperature at 5 ft. from the surface continued to rise to a maximum value of 100 degrees F. at the end of 140 hours, at which time the air temperature was 30 degrees F.

In the downstream shaft of the shore pier, the concrete was placed at a temperature of 75 degrees but at the end of two hours fell to 69 degrees, when the air was at 38 degrees F. The air temperature gradually increased to 75 degrees F. at the end of 40 hours, and then fell to 66 degrees at the end of 54 hours. In the meantime, the concrete 1 ft. from the face rose to a temperature of 102 degrees F. at the end of 49 hours, and the temperature 5 ft. from the face increased to 105 degrees F. at the end of 54 hours.

PARDEE DAM

The Pardee dam, constructed in 1928, is a gravity type arch structure 350 ft. high above stream bed. The width at the base

of the dam is 244 ft., and the width at the top is 16 ft. The length of the dam is 1337 ft. and the volume of concrete is 615,000 cu. yd.

The concrete contained 4 sacks of Calaveras cement per cu. yd. and the aggregate in the mix, measured by volume, consisted of 30 per cent of 0 to ⅜-in. sand, 28 per cent of ⅜ to 1½-in. gravel, and 42 per cent of 1½ to 6-in. cobbles. Enough water was used to produce an average slump of 6 in.

In December 1928, when the dam had reached an elevation of 180 ft. above stream bed and 170 ft. below the top, five thermocouples were embedded in a line along the center of a block 75 ft. wide, located just south of the center line of the dam. The thermocouples were at 2 ft., 12 ft. and 55 ft. from the upstream and downstream faces, the latter point being at the center of the dam, as at this elevation the dam is 110 ft. thick. After placing the thermocouples, the concrete was poured in 5-ft. lifts at the rate of about one lift every 5 days.

The concrete was placed at a temperature of 71 degrees F. when the outside air was 39 degrees F. The temperature at the point 55 ft. from the two faces of the dam continued slowly to increase until it reached 102 degrees F., an increase of 31 degrees F., nearly seven months later when the air temperature was 77 degrees F. The average air temperature during this interval was 57 degrees F. The maximum rise in temperature 12 ft. from the face was 36 degrees F., occurring within 20 days, and the maximum rise 2 ft. from the face was 27 degrees, occurring within 12 days.

RESERVOIR WALL

In a discussion on high early strength concrete, H. V. McCall[19] states that in a series of tests upon a reservoir under construction during the winter where the concrete was placed at an initial temperature varying from 55 to 75 degrees F., the temperature developed within 3 days, in sections about 8 ft. thick, was approximately 60 degrees F. higher than when the concrete went into the forms.

PUTNAM COUNTY ARCH BRIDGE

Setting temperatures were determined during the construction of an arch bridge near Eatonton in Putnam County, Georgia[20].

This structure has an open spandrel arch with a span of 160 ft. and a rise of 46 ft.

The proportions of the concrete mix were 1:2:4 by volume, the fine aggregate under ¼ in. being a well-graded, clean quartz and the coarse aggregate, which varied from ¼ to 1½ in. in size, consisting of 50 per cent of quartz gravel and 50 per cent blast furnace slag. The time of mix was 2 to 5 minutes and the slump varied from 3½ to 4½ inches. The concrete was deposited in batches of about ⅓ cu. yd.

Temperatures were observed by means of electrical resistance thermometers embedded at different points within the mass. As typical of the temperature record, the concrete at the center of a quarter-point of an arch rib developed a maximum temperature of 131 degrees F. after 7 days, the initial temperature having been 77 degrees F. and the air temperature being 73 degrees F. at the time of occurrence of the maximum temperature in the concrete. The size of the arch rib at this point is not reported.

CHUTE A CARON DAM

Tests of the setting temperatures of the concrete entering certain auxiliary structures in connection with the Chute a Caron Dam in Quebec, Canada, are reported by I. E. Burks.[21]

The concrete in these structures had a water-cement ratio of 0.90 and the mix was approximately 1 part cement, to 2.3 parts of sand, to 4.8 parts of crushed stone by volume. The pit sand varied in fineness modulus from 1.9 to 3.6. The crushed stone was a feldspar obtained at the dam-site ranging in size from 2 to 6 in., and having a fineness modulus varying from 8.8 to 9.5. The concrete had no particles between ⅜ in. and 2 in. The compressive strength of the concrete was about 3,000 lb. per sq. in.

After a 2 to 3-minute mixing period, the concrete was hauled to the dam in 4-yd buckets, and placed with the aid of vibratory tampers. The time interval between mixing and placing varied from 15 to 50 min.

In winter, the concrete materials were heated so that the concrete left the mixer at from 70 to 95 degrees F. and in some instances lost as much as 8 degrees before it was placed in the forms. After placing, the concrete was kept above 60 degrees F.

for 72 hours by covering with tarpaulins and heating with steam coils.

The temperatures within the concrete were observed by placing thermometers in wells made of ½ in. pipe from 3 to 8 ft. long. Concrete placed at a temperature of 78 degrees F. in Penstock No. 1, which is a mass 8 ft. thick, rose to 112 degrees F. at 2 in. from the exposed face at the end of 36 hours and the temperature at the center of the mass rose to 132 degrees at the end of 66 hours. The temperature of the air under the tarpaulin is not stated, but the outside air averaged about minus 5 degrees F.

In an obelisk pier, concrete placed at a temperature of 90 degrees rose to 157 degrees F. at a depth of 30 in. within 12 hours after placing. The air temperature outside the tarpaulin, averaged about 22 degrees F. during this interval.

TESTS AT THE UNIVERSITY OF CALIFORNIA

In 1929, under the direction of R. E. Davis and G. E. Troxell, several series of tests which have not been previously reported were carried on at the University of California, to determine not only the maximum temperature developed in mass concrete, but also to determine the effect of the high setting temperatures upon the compressive strengths at various ages.

For the first series of tests there were employed three different mixes of gravel concrete, as shown in the following table. The consistency of all mixes was kept constant at a 4-in. slump.

Mix No.	Water Gal. per Sack	Water-Cement Ratio	Approx. Mix	Proportions by Volume			
				Santa Cruz Cement	Sand	¼ to ¾ in. Pebbles	¾ to 1¼ in. Pebbles
1	4½	0.60	1:3	1	1.20	0.90	0.92
2	6	0.80	1:5	1	2.11	1.54	1.57
3	8	1.07	1:7	1	2.82	2.07	2.08

The sand was a well graded material varying from 0 to ¼ in. and having a fineness modulus of 3.03. The ¼ to ¾-in. pebbles and the ¾ to 1¼-in. pebbles had fineness moduli of 6.33 and 7.81 respectively.

TABLE 3—TEMPERATURES OF CUBES AND STRENGTHS OF CYLINDERS (DAVIS AND TROXELL)

Mix No.	Approx. Mix	Proportions by Volume	Gal. Wtr. Per Sk. Cement	Cylinders	Storage	Room Temp. °F.	Cube Temp. °F.			Hours to Max. Temp.	Compressive Strength, lb. per sq. in.					
							Initial	Max.	Rise		1-Day	3-Day	7-Day	28-Day	90-Day	1-Year
1	1:3	1:1.20:1.82	4.5	Inner	Cube	77	71	154	83	33	3110	3130	3720		4120[2]	4030

3	1:7	1:2.82:4.15	8	Control	Air at 70°[5]											4050

[1]Specimens in air at about 60 degrees F. stored in paraffined cardboard molds with slip covers.
[2]After 7 days storage as indicated, cylinders were removed, coated with asphalt and stored at 70 degrees F. and 70% relative humidity.
[3]Specimens stored in fog at 70 degrees in paraffined molds without covers, for 28 days. Cylinders then sealed with tin covers, coated with asphalt and stored at 70 degrees F. and 70% relative humidity.
[4]Molds removed after 1 day.
[5]Specimens in cardboard molds sealed with tin covers, coated with asphalt and stored at 70°F. and 70% relative humidity.

For the 1:3 mix (using 4½ gal. of water) three cubes, each 3 ft. on a side, were made. Each cube was cast in a wooden form made of 2-in. lumber, placed inside of a second form of 1-in. lumber with a 6-in. space between, this space being filled with dry sawdust. While pouring the cube, twelve 6 x 12-in. cylinders of the same mix, in paraffined cardboard cylinders with metal covers at each end, were embedded in the cube as close to the center as possible—four in an inner circle and eight in an outer circle. Several of the cylinders had iron-constantin thermocouples embedded in them so that the temperatures developed in the concrete might be observed. Other thermocouples were placed at various positions in the cubes in order to observe the temperature differentials between the various parts of the mass. After completion of the cubes, their tops were covered with waterproof building paper and with 6 in. of dry sawdust. Thereafter, frequent observations were made of the temperatures within the mass and of the air in the room where the cubes were stored.

At the same time that the cylinders were embedded in each cube, 10 similar specimens were made to serve as control cylinders. Of these control cylinders, 4 were left uncovered in a fog room at 70 degrees F., while the remaining 6 were stored under normal atmospheric conditions at about 60 degrees F.

Four similar cubes, except for a 12-in. insulation of sawdust instead of 6 in., were made of the 1:5 mix (using 6 gal. water) and 3 were made of the 1:7 mix (using 8 gal. water). Some of the control cylinders for these cubes were removed from their forms after 24 hours and stored in the fog room at 70 degrees F. The remaining control cylinders were sealed in molds with tin covers, the entire mold coated with an asphalt emulsion, and the specimens then placed in the fog room at 70 degrees F.

The cubes were broken into fragments at ages varying from 1 day to 1 year, and the embedded 6 x 12-in. cylinders were tested in compression together with the corresponding control cylinders for the cube.

The critical data regarding setting temperatures of the cubes and the strengths of the 6 x 12-in. cylinders are given in Table 3.

From a study of the data of Table 3, it will be observed that the compressive strength of rich concrete cured in mass at high tem-

peratures is high, even at the early age of 1 day. It will also be noted that the gain in strength thereafter is slow. These data show that the use of rich mixes of portland cement concrete to obtain high early strength is feasible if provision is made to prevent the dissipation of the heat of chemical reaction for the first day or so. However, there is no advantage in retaining the chemical heat of rich mixes if high strength is not desired before 3 days, since at that age, concrete water-cured at normal temperatures would have equal strength. The superiority of concrete water-cured at normal temperatures over concrete cured in mass at high temperatures is plainly shown by the results of the 28 and 90-day and 1-year tests.

While observing the temperatures developed in the concrete cubes, it was noted that the temperature drop between the inner cylinders and a point 1 in. from the face of the cubes amounted to as much as 13 degrees F. for mix No. 1, whereas it was only 2 degrees F. for the other mixes. Part of the difference is undoubtedly due to the use of only 6 in. instead of 12 in. of sawdust for the richer mix, but some of the difference is due to the higher temperature attained by Mix No. 1.

A second series of tests was conducted using the two richer mixes of the first series. Three groups of cylinders were made for each mix. The first group were sealed in cans and subjected to the same temperature variations as the concrete in the 3 ft. cubes of series 1. The specimens of the second group were stored without forms in the fog room at 70 degrees F., while those of the third group were sealed in cans and kept at 70 degrees F.

For Mix No. 1, the specimens cured at the high temperatures gained strength quite rapidly for 3 days. A slight further rise was shown at 7 days, but some retrogression in strength was shown between 7 and 28 days. No further retrogression occurred at 90 days. The fog cured specimens, and those sealed and cured at 70 degrees F., gained in strength consistently during the 90-day period, the fog cured specimens indicating about 15 per cent higher strength than those sealed at 70 degrees F. The strength of the latter groups surpassed that of the first group at the ages of 28 and 90 days.

For Mix No. 2, the specimens cured at the high temperatures gained in strength for 28 days, and then showed a slight retrogression at 90 days. The other two groups gained strength more slowly at first, but attained nearly the same strength as the first group at 28 days. At 90 days, the strength of the fog cured specimens exceeded that of the cylinders cured at the higher temperatures.

In order to determine the effect of the brand of cement upon the maximum setting temperature and to ascertain the effect of this temperature upon the compressive strength, Davis and Troxell conducted a third series of tests upon 9 different brands of portland cement.

The proportions by weight of the concrete mix for these tests were 1:1.50:1.85, with a water-cement ratio of 0.67 by volume and a slump of 3 to 3½ in. The sand was well graded from 0 to ⅜ in. and had a fineness modulus of 3.71. The coarse aggregate was a crushed stone graded from No. 14 mesh to ½ in. and had a fineness modulus of 5.82.

Four 18-in. cubes were poured at one time. These 4 cubes were placed in a single large enclosure about 6 ft. square and 3½ ft. deep so that each 18-in. cube could be insulated with 12 in. of dry sawdust on all sides, and on top and bottom. Thermocouples were embedded at the center of each cube to observe the setting temperatures. The air in the room where the tests were in progress was kept constant at 70 degrees F.

The results of these temperature observations are shown in Table 4.

The compressive strengths of the concretes made from these 9 cements under various curing conditions were obtained by filling 45 tin cans 3 in. in diameter and 6 in. high, with each of the 9 mixes. Tin covers were fitted to the cans after filling. Of these 45 specimens made with each cement, 15 were stored in a room at 70 degrees F. and 50 per cent relative humidity, 15 were stored in fog at 70 degrees F., and 15 were stored in a high temperature chest in which the temperature was varied according to a time-temperature curve in close conformity with the setting temperatures of the mass concrete made of the various mixes. The 9 brands of cement were separated into three groups

TABLE 4—SETTING TEMPERATURES OF CONCRETE MIXES USING PORTLAND CEMENTS (DAVIS AND TROXELL)

	9	1230	2900	3940	2640	3425	3450

Groups A, B, and C cured at maximum temperatures of 163, 173 and 180 degrees F. respectively.
Compressive strengths in lb. per sq. in.

—A, B and C—as shown in Table 4, and all specimens of each group were subjected to the same heat treatment.

Due to the fact that there was not a large difference in average maximum temperatures for the three groups, it was decided arbitrarily to raise the average maximum temperature of Group C and then to raise the maximum temperatures of the other groups

proportionately, but still to retain the same age in attaining the maximum temperature and the same shape of the time-temperature curves. This change in the maximum temperature was made to see if the differences, if any, in the cements could be better shown. A maximum temperature of 180 degrees F. was assumed for Group C. This established the maximum temperatures for Groups A and B at 163 and 173 degrees F. respectively.

Five cylinders of each mix were tested at the ages of 1, 2 and 7 days; the results of the tests being shown in Table 5.

From a study of the data, it will be observed that for all tests at the ages of 1 and 3 days, the cylinders cured at the high temperatures exhibited higher strengths than those cured at 70 degrees F. At 7 days, the strengths of the high-temperature cured cylinders exceeded the strengths of the cylinders stored at 70 degrees F. for 5 cements out of the 9 tested.

PORTLAND CEMENT ASSOCIATION TESTS

The results of a series of tests made in the laboratory of the Portland Cement Association (submitted by McMillan by letter), which have a bearing on the effect of temperature in the concrete mass on the compressive strength, are shown in Table 6. The specimens were all made from materials at room temperature, then placed in steel forms with cast-iron base and cover plates and submerged in water at various temperatures for the entire period of the test, the forms being removed after 24 to 48 hours. This storage permitted the specimens to acquire the temperature of the surrounding water which could be easily measured.

From a study of the data in Table 6, it is seen that at all ages tested, there is a noticeable increase in strength for all temperatures up to 212 degrees F., with the one exception of the 28-day strength for the highest temperature. For the 28-day tests, the concrete cured at 125 degrees F. showed a slightly greater strength than that cured at 212 degrees F.

CEMENT PASTE TESTS MADE AT U. S. BUREAU OF STANDARDS

Tests were made by P. H. Bates[22] at the U. S. Bureau of Standards upon 32 brands of portland cement to determine the maximum temperatures attained during the setting process and to ascertain the rate of temperature rise. The cements tested were

TABLE 6—EFFECT OF TEMPERATURE OF STORAGE ON THE COMPRESSIVE STRENGTH OF CONCRETE (McMILLAN)

Temperature of Storage, °F.	Compressive Strength, lb. per sq. in.			
	2-Day Storage	3-Day Storage	7-Day Storage	28-Day Storage
33	150	250	830	2480
42	280	410	1210	2690

125	1680	2020	2710	3690
212	2000	2360	2930	3480

those selected for other investigations and reported by Committee C-1 of the American Society for Testing Materials (Proc. A. S. T. M., 1928, Part I, p. 233).

In conducting these tests 200 grams of cement were mixed with 67.5 grams of water by a high speed motor-driven stirrer for one minute, in a tinned can $2\frac{3}{8}$-in. in diameter and 3 in. high. This was then placed in a thermos jar, closed and placed in a cabinet maintained at 70 degrees F. for 24 hours. The temperature was read by multiple junction base metal thermocouples and recorded by a sensitive potentiometer.

The time-temperature curves plotted from the observed data show an appreciable difference between the rates of temperature rise and the maximum temperatures attained, the latter values being shown in Table 7.

CEMENT PASTE TESTS BY MERRIMAN

Tht same cements used at the Bureau of Standards were also tested by Thaddeus Merriman, Chief Engineer of the New York Board of Water Supply[22]. The procedure followed was to mix 450 grams of cement with 112 ml. of water in a tinned can, 3 in. in diameter and 3 in. high. This was placed inside of a specially constructed calorimeter and the temperature of the mixture determined by the use of thermometers read at 15 minute intervals. The heat losses of the calorimeter were also determined at different temperatures and the temperatures read on the ther-

32	32	16	129	138

mometer corrected according to the previously determined heat losses. The results are presented in Table 7, along with those obtained at the Bureau of Standards.

There is no assurance that the maximum temperatures developed in large masses of concrete made from the 32 cements of Table 7 would have the same relationships as for the neat cements in small amounts. Some cements which indicated a slow liberation of heat and a relatively low maximum temperature in the tests by Bates and Merriman, might have shown

much higher temperatures relative to those attained by the other cements, if used in large masses of concrete; and the reverse might be true for those cement pastes which exhibited high temperatures.

PROPOSED EXPERIMENTAL PROGRAM

From a review of what has gone before, it appears that very little is known concerning the properties of concrete in large masses. To determine these properties and the influence of various factors upon them obviously is not a simple matter, first by reason of the large number of variables involved, second because we are dealing with large volumes, and third because of the necessity of long-time studies.

It is believed that a comprehensive series of laboratory tests should be made to determine the effect upon: (a) rise in temperature, (b) compressive strength at various ages, (c) modulus of elasticity at various ages, (d) flow at various ages, (e) residual strains, (f) residual stresses, (g) permeability, (h) durability, and (i) volume changes as affected by: (1) chemical composition of cement, (2) fineness of cement, (3) admixtures, (4) richness of mix, (5) water-cement ratio, (6) initial temperature, (7) character of aggregate, and (8) size of mass.

Supplementing the laboratory tests there should be field investigations which may be properly divided into two parts: first, those which have to do with structures already built and in service; and, second, those concerning new work where conditions as regards materials and methods of construction may be closely controlled. It is clear that one of the very important functions of the committee is to promote the cooperation of those in charge of construction enterprises from which pertinent information may be derived. Acting as a guide, the committee should be in a position to do much in promoting field research and preventing duplication of effort.

The principal masses with which the committee is interested are dams, but heavy foundations, bridge piers, massive arches, large anchorages, and thick tunnel linings ought not to be overlooked, for, because of the use of rich mixes, the temperatures of these latter structures may considerably exceed those normally reached in dams.

It is evident from the summary presented earlier in this report that, aside from records of temperature, there has been published comparatively little quantitative data concerning the behavior of mass concrete structures. However, during the past few years attempts have been made to measure dimensional changes as well as temperatures in a number of dams in this country, using the electric telemeter for determining interior changes and the strain gage for observing surfaces changes. While it appears that many of the unpublished data thus obtained are not reliable, owing to the inexperience of observers or to the inaccuracies of measuring instruments, information from these sources should be brought together and the results summarized.

Of considerable value also would be the principal facts concerning the physical condition of dams and other mass structures which have been in service for some time (particularly the location and width of cracks) together with details regarding the concrete materials and the manner of mixing, placing and curing.

The question of whether or not there is a gradual shrinkage, over a long period of time, of dams located in arid regions due to a gradual dissipation of uncombined water is one of considerable importance. Strain-gage measurements should be begun on a considerable number of these structures when the facts concerning the quality of the concrete are known, and these measurements should be extended over several years.

Attention should be given to developing a test program calculated to produce reliable and fairly complete information concerning the behavior of mass concrete in actual structures, particularly dams, under the wide variety of conditions met in practice, beginning with the construction period and extending over at least ten years. In order best to coordinate this field work it is considered imperative that the program as a whole shall be carried out under the general direction of a single organization, with the cooperation of those in charge of the individual enterprises. Insofar as possible, the field tests should supplement the laboratory program, being calculated to furnish quantitative data regarding the effect of variations in materials and processes, and in size and shape of mass.

Introducing Two Papers on Slump Tests and Flow Table Determinations

Here we discover two pairs of experienced investigators, working independently, studying slump tests and flow table determinations as measures of that yet-to-be-satisfactorily-measured characteristic of concrete mixtures—workability. They have both established the important fact that relation of flow to slump is not constant—that the slump is relatively larger for the richer mixtures. Yet they arrive at opposite conclusions. Smith and Benham are for the flow table; Lyse and Johnson are for the slump test. Are there not other seekers after this important yard-stick of that characteristic, workability (which is now written into specifications, yet lacks definite clues to its identity) who, in the combined data reported in the two papers which follow, can discover a common ground —a reconciliation of interpretation, which to one authority is one thing and to the other something different? As a welcoming gesture toward such a reconciliation, the two papers, submitted to the Institute within five days of each other, are published together, and the discussion (May 1931 Journal) *will be combined. One member of the Publications Committee, while approving each paper in turn as a worthy contribution deserving publication, considers it an unavoidable imposition on the membership to publish two, where, under happier coordination, one might have sufficed. If in the ensuing discussion there should be even an approach to that coordination, the "imposition" may be justified.*—Editor.

A Study of the Flow-table and the Slump Test

BY GEORGE A. SMITH* AND SANFORD W. BENHAM†

The slump test, long used as a suitable and convenient means for measuring the consistency or wetness of concrete is recognized, nevertheless, as only a rough test for determining that condition or property. In the laboratory where more accurate control of the consistency is desirable the flow-table is frequently used and is generally looked upon as being the more satisfactory. There is always, however, considerable difficulty in attempting to compare flow-table data obtained by different experimenters because there is no standard method of operating the apparatus. The size, weight, height of drop, and speed of operation are not standardized. In order that wetness of concrete may be visualized from flow-table data it is imperative that the data be obtained under fixed conditions, as is the case with slump test data. Before such a condition can be brought about, information as to the functioning of the flow-table under different conditions is necessary.

In view of renewed interest in this subject the authors feel that the data here presented not only are opportune but point out characteristic tendencies which should be brought to the attention of others. It is believed that the results of this series of tests may be helpful torward establishing a standard method for performing the flow-table test.

PURPOSE AND SCOPE

It has been pointed out by several investigators that for a given condition of wetness as determined by the flow-table those mixes which contain the larger amounts of cement, and which are the more workable, quite consistently give the greater slumps. This condition has been observed by the authors for a long time

*Concrete Engineer, Johns-Manville Research Laboratories, Manville, N. J.
†Assistant Concrete Engineer, Johns-Manville Research Laboratories, Manville, N. J.

and it has been felt that where the laboratory is endeavoring to simulate, in many ways, actual field conditions, either the same method of measuring the consistency should be used or a method which, though on a different basis, will give comparable results.

The tests with which this paper deals were made to determine the necessary flows to be used to give definite slumps so that more careful measurement of the wetness of the concretes could be made using the flow-table instead of the slump test. Though 15 ⅛-in. drops has been our usual measure for the work done in making the flow-table test, the program was extended to include both five and ten ½-in. drops because it was thought that the more vigorous action of the greater drop might give results paralleling the slump test more closely than did results with the ⅛-in. drops, and also because the ½-in. drop is used in a number of other laboratories.

The data were obtained on five mixes, from a 1:3:6 to a 1:1½:3, gaged to three slumps within the range 2 in. to 8 in. Consistency determinations were made using the slump test and the three different methods of making the flow-table test. The work was carried through all conditions both with and without Celite as an admixture. Incidental to the studies of consistency, the concrete was cast into cylinder specimens and tested in compression at 28 days.

In all, the study involved the making of 300 slump tests and 450 determinations of the flow and the testing of 300 compression specimens.

MATERIALS AND TEST METHODS

The cement used in this study was part of a 50-barrel lot of portland cement purchased from a local dealer. On delivery the cement was emptied on a concrete pavement, turned over twice and then stored in steel drums until used. Physical tests indicated that the cement met A. S. T. M. standard specifications for portland cement.

Air-dry, washed bank sand from Spring Lake, N. J., was used as fine aggregate. The sand was graded 0 to No. 4, had a fineness modulus of 2.90, and weighed 103.8 pounds per cubic foot. The sand as received was separated on the No. 8 and the No. 16 sieves.

Five sieve analysis were made on each fraction and the three sizes combined to give the desired fineness modulus when preparing individual batches.

The coarse aggregate consisted of air-dry, washed gravel from the same source as the sand. This was separated into four sizes and later recombined. The combined gravel was graded No. 4 to 1 in. (square openings), had a fineness modulus of 7.04, and weighed 105.2 pounds per cubic foot. Neither the fine nor coarse aggregate contained appreciable organic impurities and in an air-dry state showed practically zero absorption.

In all mixes containing an admixture commercial Celite for concrete was used.

PROPORTIONS

All mixes were proportioned on a dry rodded volume basis for the fine and coarse aggregate, using 94 lb. per cu. ft. as the unit weight of the cement. Throughout the study the ratio of sand to gravel was one to two by volume and the quantity of aggregate per batch was constant, viz., 0.10 cu. ft. (4.709 kg.) of sand and 0.20 cu. ft. (9.539 kg.) of gravel. To effect variations in the richness of the mix the quantity of cement alone was varied to obtain the following mixes:

Mix (by Volume)	Per Cent Cement	Cement Used (Kgs.)	Celite Content Lbs. Per Sack
1:1½:3	133	2.843	2.25
1:1⅔:3⅓	120	2.558	2.50
1:2:4	100	2.132	3.00
1:2½:5	80	1.706	3.75
1:3:6	67	1.421	4.50

Based on the cement content of the 1:2:4 mix these mixes represent cement contents varying from 67 to 133 per cent as indicated in the table above.

When Celite was used as an admixture the quantity used per batch was constant (68 grams). The resulting Celite content, in pounds per sack of cement, and the quantity of cement used per batch are also shown in the table above.

These quantities resulted in a quantity of concrete sufficient to fill the slump cone with a small excess.

MAKING TESTS

Without going into specific detail as to making the tests, suffice it to say that batches for one complete run of 30 mixes (a days' work) were prepared and standard practice followed in performing the remainder of the work. With regard to making the flow and slump tests some explanation, however, is necessary. Each of the five mixes was gaged to give what would appear to be 2-, 6- and 8-in. slumps. The first run was made determining the flow with 15 ⅛-in. drops followed immediately by a slump test. The second run, on the day following, was made duplicating all conditions except for the manner of making the flow test, when five and ten ½-in. drops were used instead of 15 ⅛-in. drops. In obtaining the flow, using ½-in. drops, the specimen was first jolted five times, measured and then given five additional jolts and the diameter (average of four) again determined. This procedure resulted in ten slump tests and five flow-tests for each of the three different methods of operating the flow-table. The work involved the making and testing of ten separate batches of concrete for each condition as to mix and wetness. The flow is expressed as the percentage increase in diameter of the specimen.

After the consistency test was completed the concrete was cast in a 6 by 12-in. cylinder mold, capped when one day old and cured in a fog room at about 70° F. for 28 days at which time it was tested.

It is felt that because of the various types of flow-tables used in different laboratories a partial description of the table used in these tests is warranted. The apparatus was purchased from the H. C. Cragg Mfg. Co., Washington, D. C., and is similar to that designed by the Bureau of Public Roads and to the table used at the Bureau of Standards. Specifically the top weighs 122.5 pounds, has a diameter of 29.5 in., and a thickness of 0.5 in. It is made of bronze reinforced with eight ribs 0.25 in. thick, tapering from ⅜-in. near the circumference to a depth of 2.5 in. at the hub. The drop was changed from ⅛ in. to ½ in. by removing a washer

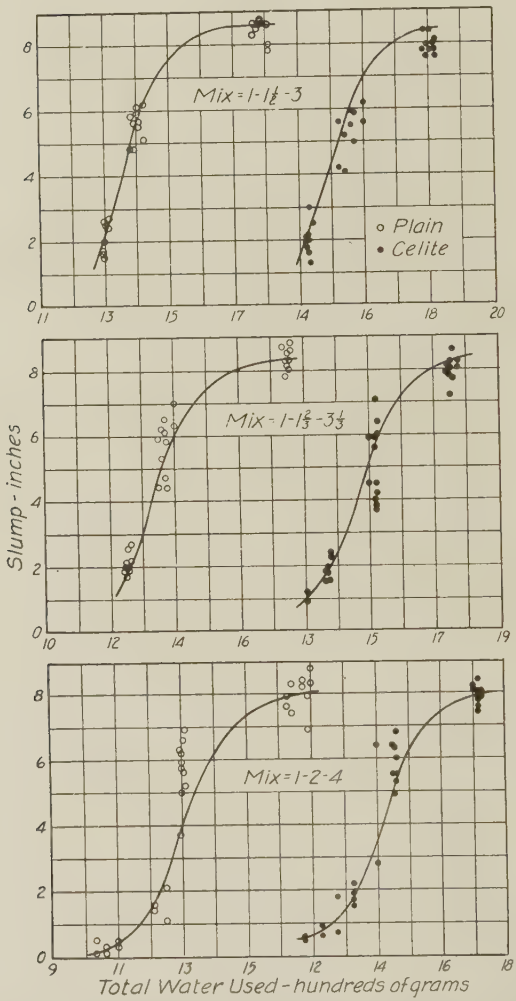

FIG. 1—RELATION BETWEEN SLUMP AND TOTAL WATER USED FOR VARIOUS MIXES

$\frac{3}{8}$ in. thick from the supporting shaft of the flow-table as used for the $\frac{1}{8}$-in. drop.

RESULTS OF TESTS

Rather than encumber this paper with tables of data, results of individual tests are plotted to show the grouping and variations in the data as well as the trends of the results. In all curves presented the open characters represent values for mixes without admixture and the solid characters those for concretes containing Celite. Figs. 1 and 2 show the slumps plotted against the actual weight of water used. Figs. 3 and 4 present similar data obtained for the three methods of using the flow-table.

The three methods of using the flow-table are again shown in Fig. 5 to indicate the change in water content for a given flow as the quantity of cement varies. Fig. 6 shows the change in flow for 15, $\frac{1}{8}$-in. drops and for the various mixes with change in water-cement ratio. All points indicated in Figs. 5 and 6 have been taken directly from the curves indicated in Figs. 3 and 4.

Fig. 7 shows the relation between the different methods of operating the flow-table based on data from all mixes.

Fig. 8 has been prepared to show the relation that existed between the slumps and the flows obtained when 15, $\frac{1}{8}$-in. drops were used.

Results obtained from the compression tests are shown in Fig. 9 where the average strengths from ten tests for each condition are plotted against the average water-cement ratio.

In Figs. 1 and 2 it may seem that part of the data in the region of intermediate slumps has been largely disregarded when drawing the curves. Such, however, is not the case. When experimental data are obtained using systematic variations in conditions the resulting trends obtained are usually systematic in their arrangement. It would, therefore, be natural to suppose that the relations of slump to flow would show the same or parallel trends when varying the mix. See Fig. 8.

In order to obtain the systematic arrangement of the curves shown in this figure it was necessary to make some adjustment of the water-slump curves. Since the trends of the flow data would permit little or no adjustment most of the adjusting was confined to the curves of water versus slump. Therefore, the

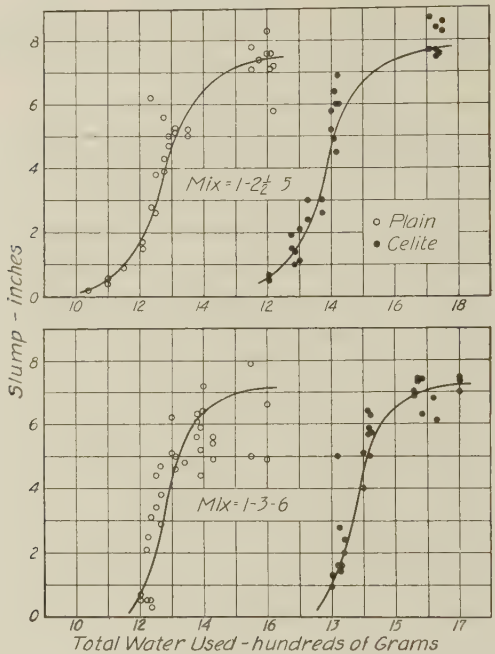

FIG. 2—RELATION BETWEEN SLUMP AND TOTAL WATER USED FOR VARIOUS MIXES

position and shape of a single water-slump curve, shown for any given mix, are governed not only by the data obtained for that mix but are influenced by the data obtained for all other mixes.

DISCUSSION OF RESULTS

The results obtained from the slump test (Figs. 1 and 2), though self-explanatory in many ways, call for some comment. It will be noted that the general shape of the curves is approximately that of a reversed curve with the point of inflection in the region of a 4-to 5-in. slump and limiting tangents at zero, probably, and in the region of 8 in. The curves are about the same shape as those shown by McMillan and Johnson[1] for similar mixes. For mortars and highly sanded mixes it is not improbable that the 8-in. upper limit may be increased as has been shown.[1]

[1] "Further studies of the Water-Cement Ratio Strength Relation in Concrete"—Report of the Director of Research, Portland Cement Association, November 1928, p. 16.

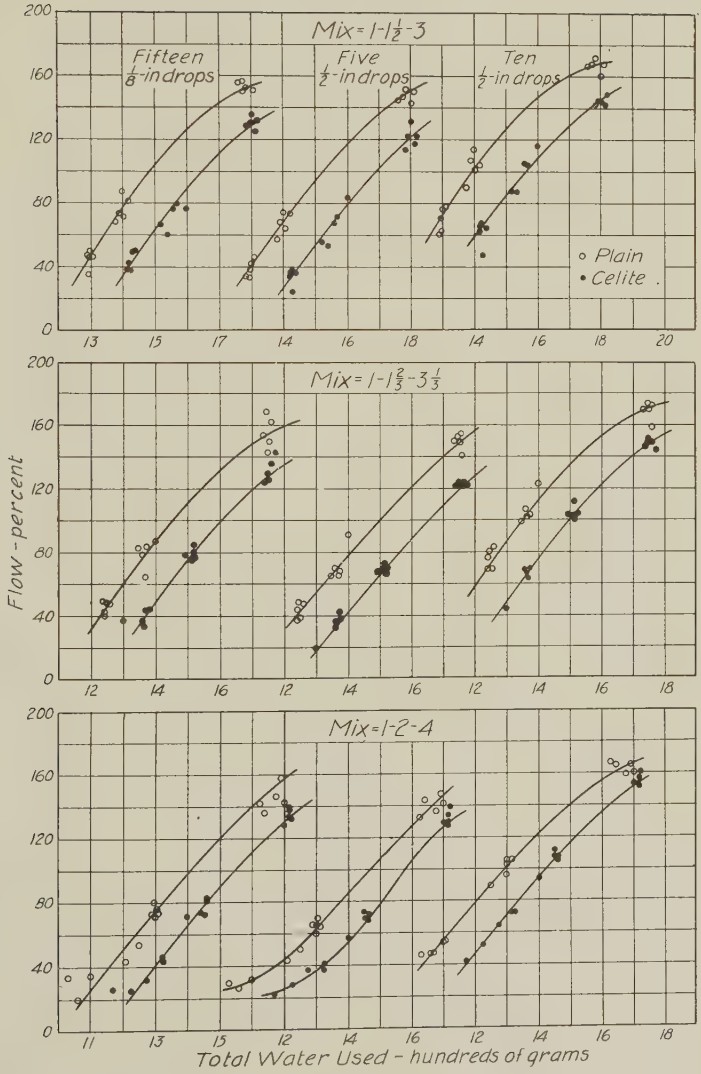

FIG. 3—RELATION BETWEEN FLOW AND TOTAL WATER USED FOR THREE METHODS OF OPERATING THE FLOW-TABLE

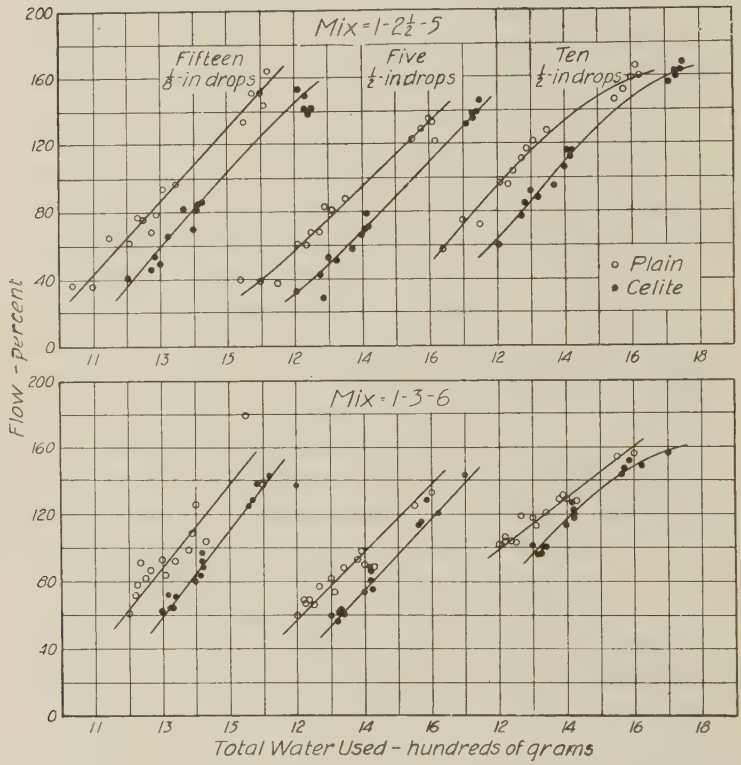

FIG. 4—RELATION BETWEEN FLOW AND TOTAL WATER USED FOR THREE METHODS OF OPERATING THE FLOW-TABLE

At both the low and high limits the test is less sensitive to change in water content than it is in the central range, if the condition indicated by the curves is taken as a criterion of the sensitivity of the test. In the range of intermediate water contents the individual data indicate that the test appears to function in a very uncertain manner.

During the making of the tests four characteristic conditions as to general shape of the resulting slump specimen were observed.

1. Specimen slumped only small amount and retained somewhat the same shape as the molded sample.

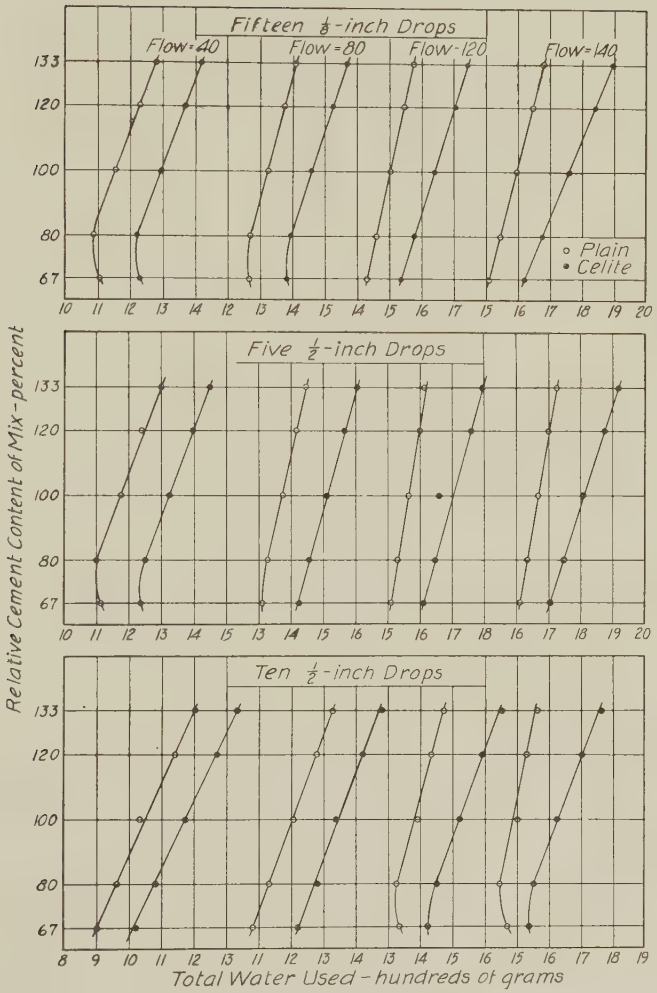

FIG. 5—RELATION BETWEEN THE RELATIVE CEMENT CONTENT OF MIX AND THE QUANTITY OF WATER REQUIRED FOR GIVEN FLOWS. CEMENT CONTENT OF MIXES IS BASED ON THAT OF A 1-2-4 MIX AS 100 PER CENT

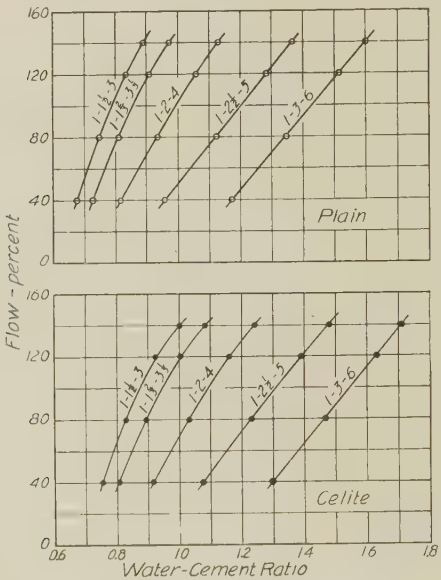

FIG. 6—RELATION BETWEEN FLOW AND WATER-CEMENT RATIO USING FIFTEEN ⅛-INCH DROPS OF THE FLOW-TABLE

2. Specimen slumped several inches but held together, bulging out uniformly as the slump took place.

3. A portion of the specimen stood up on one side and the remainder fell away. Not a usual condition and always checked by a second trial.

4. Top slushed down leaving a mound, generally of compacted aggregates, in the center.

In the region of 1- to 2-in. slumps, where the specimen conformed to Condition No. 1 above, the variation in slump for a given water content was relatively less than in other regions and in this region the slump test would appear to give some consistent indication of wetness.

In the upper region, 7- or 8-in. slumps, after a definite quantity of water had been used no change in the slump was produced by

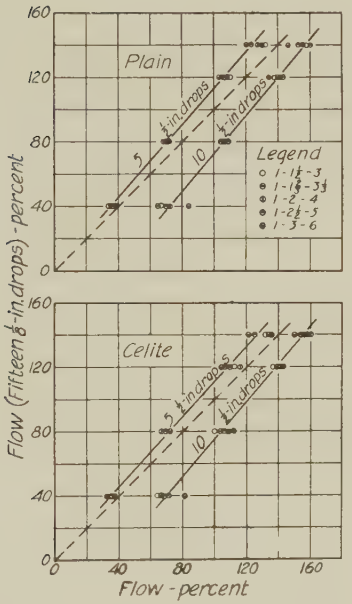

FIG. 7—COMPARISON OF DIFFERENT METHODS OF OPERATING THE FLOW-TABLE

increasing the water. In this case the test was characteristically that indicated by Condition No. 4. Due to segregation and compacting of the coarse aggregate a cone of approximately constant height was left as the upper part of the sample flowed down on all sides.

In the intermediate region of wetness (slump approximately 4-to 6-in.) the slump test was at its worst as is indicated by the wide range of slumps that were obtained with a constant quantity of water. Though the results generally showed somewhat better agreement in the richer and more workable mixes it was only in the richest mix considered that reasonable checks were obtained in this region. When trying for 6-in. slumps it was observed that the specimens assumed different shapes as represented by Conditions Nos. 2 and 3 or 4. That is, there appeared to be no con-

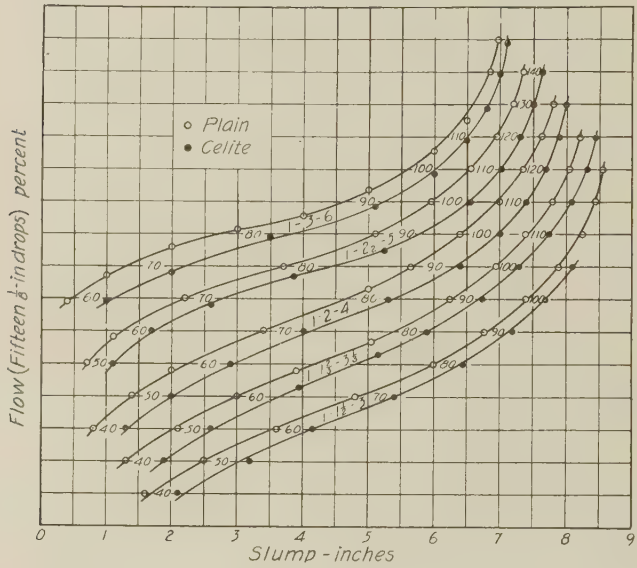

FIG. 8—RELATION BETWEEN FLOW AND SLUMP

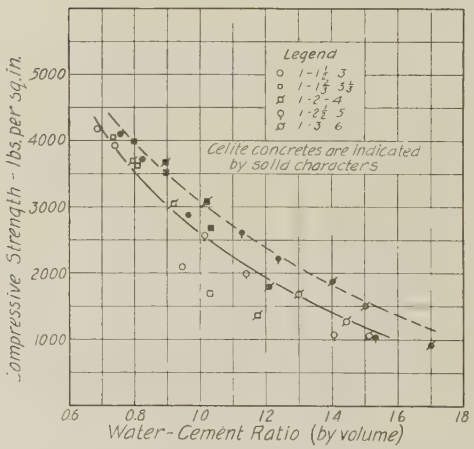

FIG. 9—RELATION BETWEEN WATER-CEMENT RATIO AND COMPRESSIVE STRENGTH AT 28 DAYS

sistent performance as was generally noted in the 2-in. or the 8-in. slumps. If Condition No. 2 obtained the slump would be small. If No. 4 obtained the slump would be large. If No. 3 obtained the slump might be any amount in between the slumps given by Conditions Nos. 2 and 4. The fact that each curve shows a point of inflection would appear to indicate that in this region the test was ceasing to function in one manner and beginning to function in another. This appears to be consistent since for moderate slumps, 4 in. or less, the test is usually a true slump or a settling of the mass as a whole if we omit the lean, harsh mixes which in this discussion have been given less weight than have the plastic workable mixes. Beyond the true slump condition the wetness is such that the ability of the paste to hold the mass together is overcome and the mix acts more as a semi-fluid mass.

Individual results from the flow tests (Figs. 3 and 4) show consistent conformity to average curves, unusually so when compared with the results obtained with the slump cone. An exception to this is shown in Fig. 4 for the 1:3:6 mix. Here, as in the slump tests, it is believed that lack of quantity and quality of the cement paste resulted in extreme harshness and segregation which are always undesirable and certain to give erratic results. However, even in the lean mixes, the flow-table data are in better agreement than are the slump data.

Within the range that may be classed as plastic concrete the flow is practically a straight line function of the quantity of water used. This holds quite generally regardless of the mix and regardless of which method is used in making the flow test. In this connection it should be kept in mind that the volume of aggregate was constant and that different conditions of richness were obtained by varying only the quantity of cement. In other words the volume of concrete resulting from each batch was practically constant. In the upper reaches of the curves there appears to be more of a tendency for the curves to flatten indicating somewhat less sensitivity to increased water. This is particularly true in the richer mixes and in the case of the ten, ½-in. drops.

Relative to the functioning of the flow-table when using the different operations there appears to be but one outstanding

difference. This difference is only a question of the magnitude of the flow (see Fig. 7) and exists between the five, and the ten, ½-in. drops. It would be expected that the greater number of drops would increase the diameter of the specimen but that the increase in flow should be constant regardless of wetness, mix, or the presence of an admixture, does not at first appear to be logical. The parallelisms existing in Figs. 3 and 4 are brought out in Fig. 7 where the flows for the five, and ten, ½-in. drops are plotted against the flows for the 15, ⅛-in. drops. The fact that the curve of flows for the ten drops is parallel to that for the five drops indicates that when the first five drops have been administered the characteristics of a mix as to wetness or differences in consistency have been brought out and that the additional drops have no part in differentiating between conditions of wetness.

It was pointed out that it was thought the more violent action of the ½-in. drops might bring out differences similar to those that had been observed between the flow obtained with ⅛-in. drops and the slump test. Quite the opposite is to be noted. The fact that the slope of the curves for the ½-in. drops is steeper than the 45 degree line which represents the flow for 15, ⅛-in. drops (see Fig. 7) indicates that the ½-in. drop is not so sensitive as the ⅛-in. drop, since slightly greater changes in flow were obtained for the latter for a given change in consistency than were obtained for the ½-in. drops. Because the several points plotted, representing the five mixes, arrange themselves in no definite order it would appear that rich mixes show no action on the flow-table different from lean mixes. It will be noted that the curves in the lower portion of Fig. 7 coincide with those at the top of the figure indicating that the above discussion applies also to concrete in which Celite is used as an admixture. The conclusions with reference to the functioning of the flow-table are strengthened by the fact that in both group of tests, with and without an admixture, the same condition obtains.

The distinct parallelism that exists between the different operations of the flow-table is to be seen from a comparison of the curves in Fig. 5 in which richness or relative quantity of cement used is plotted against the quantity of water required to give a certain flow. Here the quantity of water varied uniformly with the richness of the mix irrespective of the method used. This

straight line relation between richness of mix and gaging water for a given consistency parallels other tests of similar nature by Prof. D. A. Abrams.[2]

An examination of Fig. 8 will indicate that previous observations pertaining to the relation of slump to flow have been confirmed where the richness of the mix is increased and when the admixture is used. For a given flow the slump showed a distinct tendency to increase with increased quantity of cement and with the use of Celite. Within the range of plastic mixes this increase in slump is closely proportional to the cement content.

Results of the tests do not take into account such conditions as disruption of the sample and segregation of the ingredients. In the case of the lean mixes the lack of paste resulted in considerable crumbling of the sample regardless of the method of operating the flow-table. This, however, was more pronounced for the ½-in. drop than for the less violent ⅛-in. drop. Even in the case of the stiff rich mixes the severity of the larger drop was evidenced by a more pronounced breaking up of the sample.

Although no study was made to determine the time required for performing the flow test by any of the three different methods it seemed to require no more time to make the 15, ⅛-in. drops than was required for the five, ½-in. drops. This was due to the necessity for stopping rotation of the hand wheel just as each half-inch drop occurred, to prevent the vertical shaft of the table from striking on the cam. Even if there were a saving in time of operation the authors feel inclined to recommend the use of the 15, ⅛-in. drops because of its slightly greater sensitivity to change in wetness, because the action is less violent, and because of the smoother and apparently better functioning generally.

Though the strength study made was purely incidental to the consideration of the slump-flow relation, the data are of some interest because of the tendencies and conditions brought out. In Fig. 9 the strength obtained for the different mixes (average of ten tests each) are distinguished by different notation. The two higher strengths for each mix were obtained for concretes gaged to slumps of approximately 2 in. and 6 in. These strengths

[2] "Tests of Powdered Admixtures in Concrete"—Proceedings Am. Society Testing Materials Vol. XXIX, Part II, p. 643, 1929.

alone have been used in locating the curves both of which are of the form $S = \frac{A}{B^x}$.

It is to be noted that, for the wide range of mixes considered, when the concrete was gaged to reasonable wetness or to give moderate slumps the resulting strengths conformed quite closely to a water-cement ratio-strength relation. When the slump was increased to about 8 in., requiring a larger amount of mixing water, the strengths did not conform to this relation and indicate that, for a given mix, the strength is approximately inversely proportional to quantity of water used. This relation appears to vary with the richness of the mix and to be more critical the richer the mix. This brings out the marked advantage to be obtained by limiting the wetness to moderate slumps in practice when high strengths are required. Increasing the wetness to the extent indicated in the case of the three richest mixes caused a 50 per cent reduction in the strength based on the potential strength at 28 days when moderate slumps were used. When reasonable consistencies are used the resulting strength may be indicated by the water-cement ratio-strength relation over a wide range of mixes.

With reference to the concretes in which Celite was used, it will be noted that the strength for a given water-cement ratio was higher when the admixture was used. When gaging the concretes to the same consistency it was necessary to add a certain amount of water to compensate for the absorption of the admixture. When correction is made for this it will be noted that the strength of the Celite concrete is equal to that of the plain concrete. It is to be noted that similar indications with regard to changes in water-strength relation with change in mix were obtained for the concretes containing Celite as were secured for the plain mixes.

CONCLUSIONS

Strength data obtained incidental to this study indicate that within the region of reasonable wetness, about 2- to 6-in. slump, the strengths conform quite closely to a water-cement ratio-

strength relation of the form $S = \frac{A}{B^{x}}$. Beyond the 6-in. slump, however, a separate water-cement ratio-strength relation appears to exist which varies with the mix and which is more sensitive to change in water in the richer mixes.

Though the concretes containing Celite produced higher strengths for a given water-cement ratio, when brought to the same slump by increasing the water somewhat to compensate for the absorption of the admixture, the strengths were equal to those obtained for plain concrete.

Although the slump test is without question more convenient for use in the field than is the flow-table, it is uncertain in its functioning particularly within the range where a sensitive and accurate determination of the wetness is desirable. This appears to be due to the slump's ceasing to function in one manner and beginning to function in another as evidenced by the shape or form of the specimen after slumping.

The results indicate that the flow test is more sensitive than the slump test in differentiating between changes in the wetness of concrete with changes in the quantity of water used. The change in flow within reasonable limits is approximately proportional to change in water regardless of the mix. For a given wetness or flow the quantity of water required is proportional to the quantity of cement used except possibly in the case of very lean mixes.

Using drops of different magnitude and varying the number of drops indicated that the change in flow with change in water was approximately the same for all methods used. The 15, ⅛-in. drops was somewhat more sensitive than the five or the ten, ½-in. drops, giving slightly greater increments of flow for a given change in water content.

For a given wetness or consistency as measured by the flow the slump changed considerably and quite consistently with change in richness of mix, increasing as the quantity of cement increased and when Celite was used to improve the workability.

The data on the whole indicate that, where a consistent indication of the consistency or wetness of concrete is desired, the flow test is preferable to the slump test because of its more nearly

uniform functioning. Because of easier action and greater sensitiveness to change in wetness the 15, ⅛-in. drops are to be preferred to either the five, or the ten, ½-in. drops.

A Study of Slump and Flow of Concrete

BY INGE LYSE* AND W. R. JOHNSON†

INTRODUCTION

The first efforts to control the quantity of mixing water in concrete were directed toward the development of some method of measuring the consistency. The slump test was the first method that met with any general application. This was followed by the development of the flow-table. Both these tests, which have been standardized by the American Society for Testing Materials, have been quite widely used for the control of consistency in laboratory investigations and to some extent in the control of consistency in the field. The slump test has achieved a much wider use in the field than has the flow-table, largely because of the greater simplicity in the apparatus required.

One of the earliest uses of these methods for measuring consistency was in the study of integral admixtures. Neither method, however, met with general favor in this field nor have they been widely accepted as suitable measures of the elusive property called workability. The deficiencies of these methods have been further emphasized by the recent development of the water-cement ratio specification for concrete in which the requirement of "plastic and workable" mixes is substituted for a direct specification of both grading and proportions of aggregates.

In spite of the recognized deficiencies of these methods, there is still much to commend them, and pending the development of a more applicable form of measurement it seemed desirable to investigate somewhat more thoroughly than has been done heretofore, the possibilities of these methods and to obtain a direct comparison between the two. The tests reported in this paper were undertaken with this in view, as a part of a general investiga-

*Asst. Engineer, Research Laboratory, Portland Cement Association, Chicago.
†Formerly Asst. Engineer, Research Laboratory, Portland Cement Association, Chicago.

tion of admixtures under way in the Research Laboratory of the Portland Cement Association. The tests were carried out in such a way that in addition to the direct comparison between slump and flow under the Standard A. S. T. M. procedure, various other comparisons were possible. In the flow test, readings were taken at 5, 10, 15 (standard) and 25 drops of the flow-table. Also the slump of the flow cone was measured just as in the slump test. This was done when the form was first removed and at the time of each successive reading of the flow. In addition, the specimen formed by the slump cone was treated in the same way, reading slumps and flow after the various number of drops. This gave an opportunity to observe the behavior of the concrete under the action of the flow-table for both types of specimens and the readings provide a numerical basis upon which the methods can be compared.

OUTLINE OF TEST

The cement used in this series of tests consisted of a mixture of equal parts of four brands of portland cement purchased in Chicago. The aggregate was calcareous sand and gravel from Elgin, Illinois. The sand was naturally graded 0-No. 4 and the gravel was No. 4-1½ graded as follows: 25 per cent No. 4-⅜ in., 50 per cent ⅜-¾ in., and 25 per cent ¾-1½ in. The concrete was mixed by hand in batches sufficiently large to fill one 6- by 12-in. cylinder. Two batches were made of identical mix. On the first batch, slump was measured in accordance with standard method. In this test the slump cone was supported on the 30-in. flow-table so that immediately following the measurement of the slump the table was lifted and dropped in exactly the manner used in the standard flow test, the height of drop being ½ in. Both the slump and the flow or the spread of the concrete cone were measured after dropping the concrete for 5, 10, 15 and 25 times. In this manner both the flattening and spread of the slump cone were obtained for different number of jiggings on the flow-table.

The next batch of identical concrete was placed in the standard flow cone and both flattening of the cone and the flow were taken for 0, 5, 10, 15 and 25 drops of the flow-table respectively. Each test was repeated on three different days and the averages used for this study.

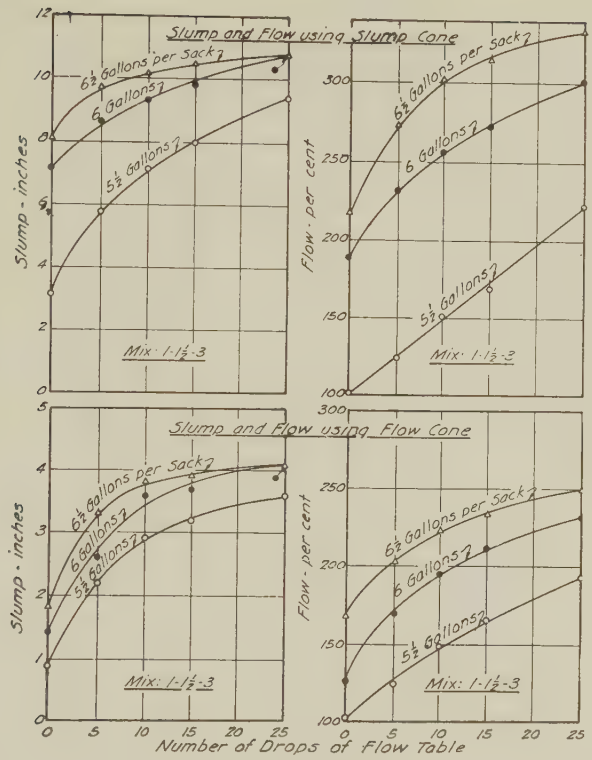

FIG. 1—EFFECT OF NUMBER OF ½-IN. DROPS OF FLOW-TABLE ON SLUMP AND FLOW OF CONCRETE

Five different concrete mixes were used: 1:1½:3, 1:2:3, 1:2:4, 1:2½:4 and 1:2½:5, by compacted volumes. Of these mixes the 1:1½:3, 1:2:4 and 1:2½:5 were repeated with the addition of 2, 5 and 10 per cent (by weight) of Celite, Pumicite and hydrated lime respectively, and with 2, 5, 10 and 20 per cent of portland cement as admixture. At least 3 different water-cement ratios were used for each mix, percentage and kind of admixture. The admixture was added to the dry materials before mixing.

TEST DATA

A complete set of test data is given in Tables 1 and 2. Table 1 gives the data obtained for slump and flow using the slump cone,

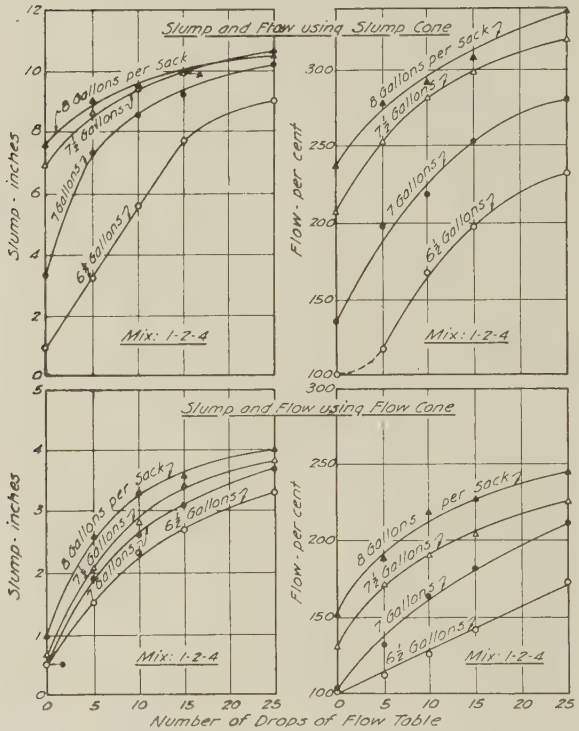

FIG. 2—EFFECT OF NUMBER OF ½-IN. DROPS OF FLOW-TABLE ON SLUMP AND FLOW OF CONCRETE

and Table 2 the corresponding values with the standard flow cone.

The effect of the number of ½-in. drops of the flow-table on slump and flow is shown in Figs. 1 to 3. The upper diagrams in these figures represent the values obtained with the slump cone while the lower diagrams show the corresponding values for the flow cone. Fig. 1 represents a concrete mix of 1:1½:3 by compacted volumes; Fig. 2, a 1:2:4 mix; and Fig. 3, a 1:2½:5 mix. The effect of an addition in water content on slump and flow is also seen from these figures.

Fig. 4 shows a comparison between flows obtained with the flow cone and with the slump cone for 5 drops of the flow-table.

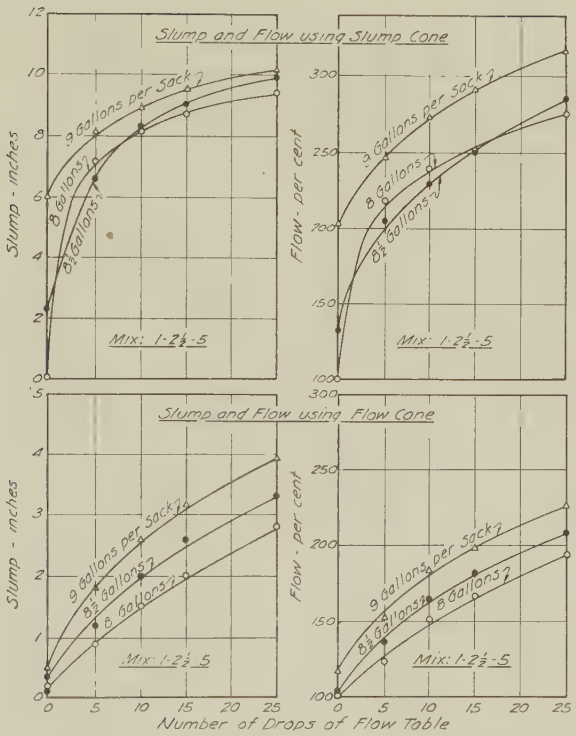

FIG. 3—EFFECT OF NUMBER OF ½-IN. DROPS OF FLOW-TABLE ON SLUMP AND FLOW OF CONCRETE

Figs. 5 to 8 give the relation between the standard methods of measuring slump and flow for plain concrete mixes and for concrete containing portland cement, Celite, Pumicite, and hydrated lime admixtures respectively, and Figs. 9 to 12 show a comparison between slump measured in the standard manner and flow measured with the slump cone after five ½-in. drops on the flow-table using concrete mixes containing the above admixtures. Fig. 12 and 13 give the effect of the admixture on both slump and flow of concrete for given water-cement ratios.

DISCUSSION OF DATA

Effect of Number of Drops of Flow-Table

Each ½-in. drop of the flow-table will shake the concrete to

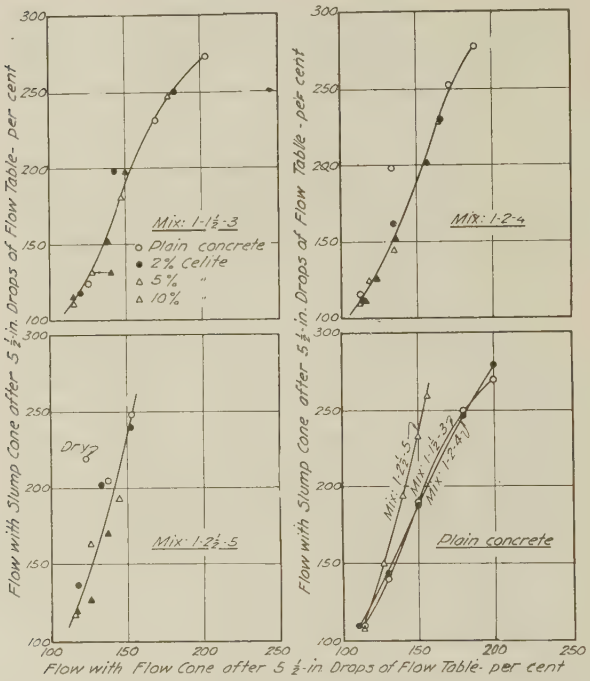

FIG. 4—RELATION BETWEEN FLOW OF CONCRETE USING FLOW CONE AND SLUMP CONE

such an extent that both the flattening and the spread of the cone will increase. Both slump and flow will therefore increase with the number of drops of the flow-table when using either cone as shown in Figs. 1 to 3. This increase will be rather uniform if the mix is fairly plastic and workable. With a harsh or very dry mix, a crumbling of the materials takes place, giving a sudden increase in both the slump and flow. This is more pronounced with the slump cone specimen. A typical example of the effect of crumbling on the slump and flow obtained with the slump cone is shown in Fig. 3 for 5 drops of the flow-table for a 1:2½:5 mix having 8 gal. of water per sack of cement. The crumbling of the cone during the shaking of the first few drops gave a large index of flow even though no actual flow of the concrete occurred. Slump

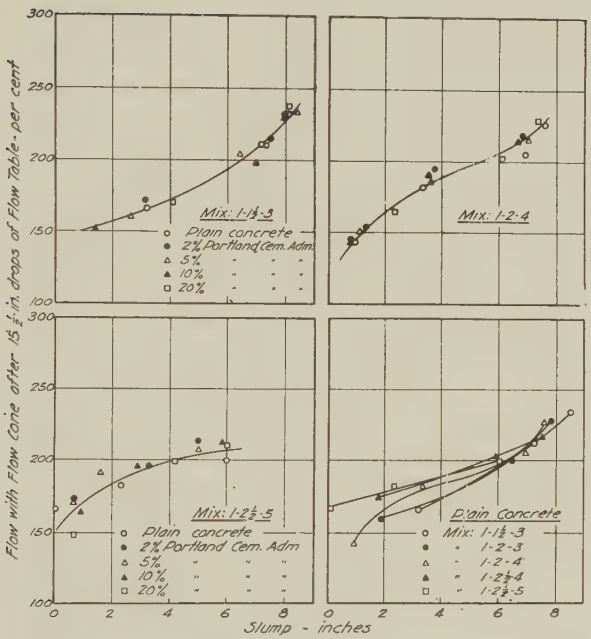

FIG. 5—RELATION BETWEEN STANDARD MEASURES OF SLUMP AND FLOW OF CONCRETE

or flow obtained on concrete which crumbles may be misleading when judging the consistency or placeability of concrete mixes.

In most cases the increase in slump and flow is greater for the first few drops of the flow table than for a larger number. Practically all the curves therefore have a steeper inclination for a small number than for a larger number of drops. This applies to both slump and flow with either cone. In the case, however, of the slump as measured on the slump cone, the curves also approach each other as the number of drops is increased. This means that the dry and stiff mixes show a larger increase in the slump with the increase in shaking of the concrete than do the wet and more plastic mixes. The sensitivity of the slump is therefore decreased with the number of drops. The resulting conclusion is that a slump test should be taken with no shaking

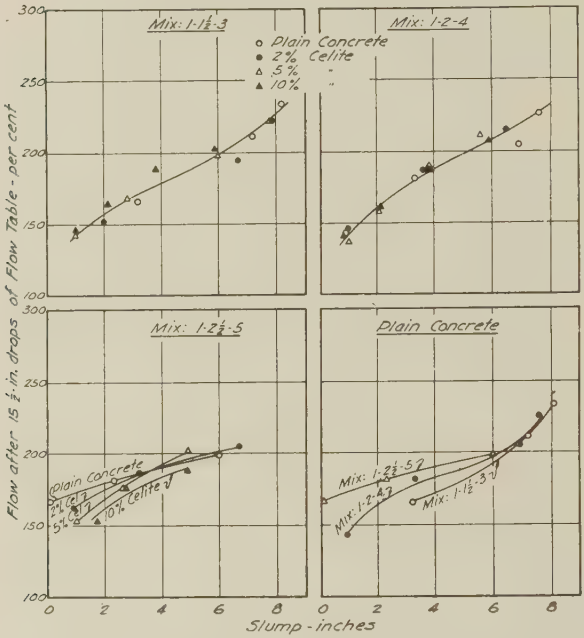

FIG. 6—RELATION BETWEEN STANDARD MEASURES OF SLUMP AND FLOW OF CONCRETE

of the flow table, which corresponds to the standard method of making the slump test.

The slumps measured with the flow cone, however, show a somewhat different behavior. The slumps on plastic mixes seem to increase with the increase in shaking just as fast and in some cases even faster than do the slumps for relatively stiff mixes. This difference in behavior is mostly due to the difference in shape of the concrete cone used, and indicates that for a flow cone the use of a large number of drops on the flow-table will not decrease the sensitivity of the slump materially.

The increase in number of drops of the flow-table seems to have little or no effect upon the sensitivity of the flow as measured either with the slump cone or flow cone. The curves remain

practically parallel to each other throughout the range used in this series so that no definite number of drops indicates any special advantage. It appears therefore of little importance at what number of drops the flow is taken; five drops seem to give just as sensitive a measure of the flowability of the concrete as the standardized 15 drops. Figs. 1 to 3 also show the effect of the water content on the consistency of concrete. In general the concretes of different water contents behaved similarly under increasing number of drops of the flow-table.

Slump Using Slump Cone and Flow Cone

The slump measured with the 12-in. slump cone of 8-in. base diameter is naturally much larger than the slump measured on the 5-in. flow cone of 10-in. base diameter. Figs. 1 to 3 show that the slump with the slump cone is usually several times as large as that with the flow cone for concrete of a given composition. The difference in slump for different water content is also correspondingly larger for the slump cone than for the flow cone. The slumps with the flow cone are actually so small that this method of test is practically useless for measuring plasticity of concrete. Just a glance at the curves in Figs. 1 to 3 shows the slump as measured on the standardized cone of the American Society for Testing Materials to be much more suitable than when measured on the flow cone.

Flow Using Slump Cone and Flow Cone

The flow with the slump cone is ordinarily much larger than with the flow cone for the same mix and number of drops. The difference in measured flow caused by changes in the water content is also considerably larger for the slump cone than for the flow cone. This is shown by Figs. 1 to 3 and leads to the conclusion that the slump cone provides a more sensitive test than the flow cone on the flow-table with ½-in. drops.

In Fig. 4 a direct comparison has been made between flows with the slump and flow cones using five ½-in. drops. The steep inclination of the curves indicates the much larger percentage of flow with the slump cone than with the flow cone. For the 1:1½:3 and 1:2:4 mixes which show an almost identical relation between flow with the two cones, a flow of 150 per cent on the flow cone corresponds to 190 per cent on the slump cone. This ratio re-

mains practically constant at all flows, indicating that the slump cone is a more sensitive measure of the changes in flowability of concrete than the flow cone. The addition of up to 10 per cent Celite by weight of cement does not seem to make any change in this relation. Neither of the two methods, therefore, shows any particular advantage over the other for measuring the smoothness of the mix produced by the addition of the Celite.

In the lower right hand corner of Fig. 4 each of the three plain concrete mixes is shown. It is noted that the 1:2½:5 mix has a considerably steeper inclination than the 1:1½:3 and 1:2:4 mixes. The relation between flow obtained with the flow cone and that obtained with the slump cone, therefore, varies somewhat with the richness of the mix. This affords a direct comparison between the suitability of each of these two methods as a measure of change in workability produced by changes in mix. For a given flow with the slump cone the leanest mix gives the lowest flow with the flow cone while for a given flow on the basis of the flow cone the richest mixes give the lowest flow with the slump cone. According to a general conception of workability of concrete a rich mix having the same flow on the standard flow test as a lean mix, will be the most workable of the two. Correspondingly, the flow cone will be selected as the one giving a better indication of real workability than the slump cone for use on the flow table. This fact partly offsets the advantage in the greater sensitivity of the slump cone found above.

Relation Between Standard Methods of Measuring Slump and Flow of Concrete

The relation between the two methods for measuring workability of concrete standardized by the American Society for Testing Materials is given in Figs. 5 to 9. Fig. 5 shows the relation for plain concrete mixes and concrete containing up to 20 per cent portland cement as an admixture. It is noted that the curve representing the relation between slump and flow changes somewhat with the richness of the mix. The addition of portland cement in the quantities used, however, is not large enough to make any material change in this relation. The two methods are therefore about equally suitable for measuring the effect of an

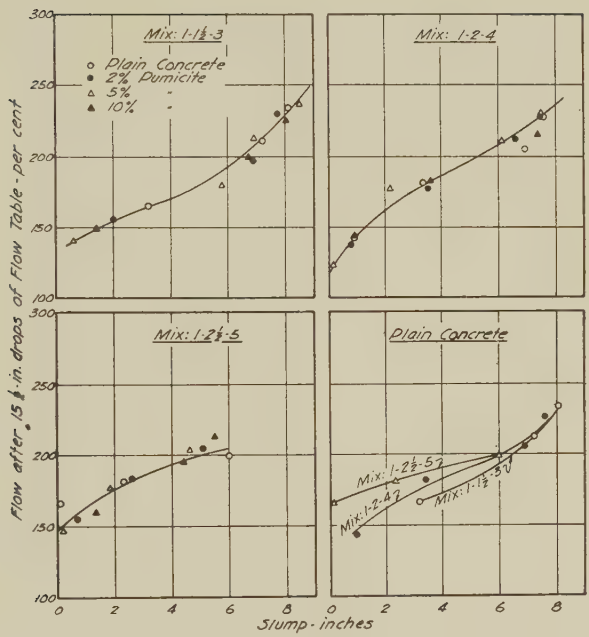

FIG. 7—RELATION BETWEEN STANDARD MEASURES OF SLUMP AND FLOW OF CONCRETE

addition of cement used as an admixture. For a mix as rich as 1:1½:3 the sensitivity of the flow as compared with the slump is not so large for dry consistencies as for wet consistencies. For leaner mixes, however, the relation is reversed and the sensitivity of the flow seems to be greatest for rather dry consistencies.

In the lower right hand corner of Fig. 5 the different mixes of plain concrete have been grouped together. This figure shows very clearly the variation in the relation between slump and flow caused by the richness of the concrete mix. It is generally considered that of two mixes having equal slump the richer mix is the more workable. A comparison between the 1:1½:3 mix and the 1:2½:5 mix shows that for the same slump the flow of the 1:1½:3 mix is considerably less than the flow of the 1:2½:5 mix. This is entirely contrary to a general conception of workability. If on

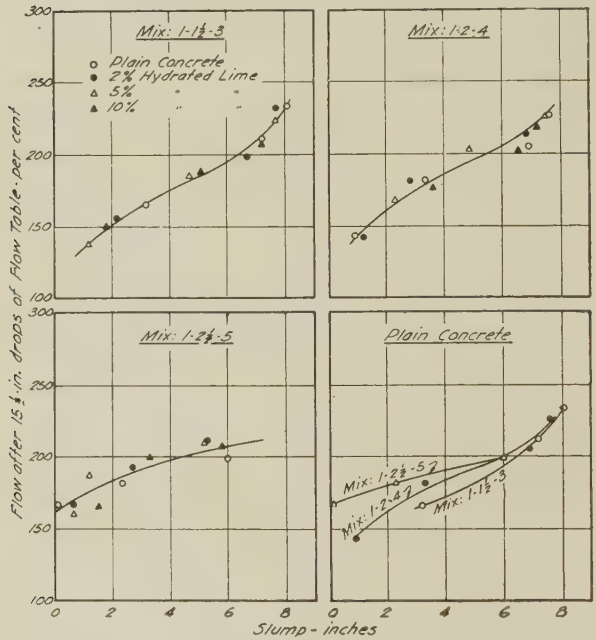

FIG. 8—RELATION BETWEEN STANDARD MEASURES OF SLUMP AND FLOW OF CONCRETE

the other hand a comparison is made on the basis of equal flow the richer mixes are seen to have the greatest slump. This strongly supports the conclusion that the slump is superior to the flow as an indication of the degree of workability of concrete mixes.

Fig. 6 shows the relation between the standard slump and flow when Celite is used as an admixture in amounts up to 10 per cent. The results indicate little or no change in the relation between slump and flow from the addition of Celite to 1:1½:3 and 1:2:4 mixes. The 1:2½:5 mix, however, was more affected by the Celite admixture; each increase in the amount of Celite gave a different relation between slump and flow. For a given flow the slump was increased with each addition of admixture. Thus the smoothing effect of the admixture changes the slump to a greater

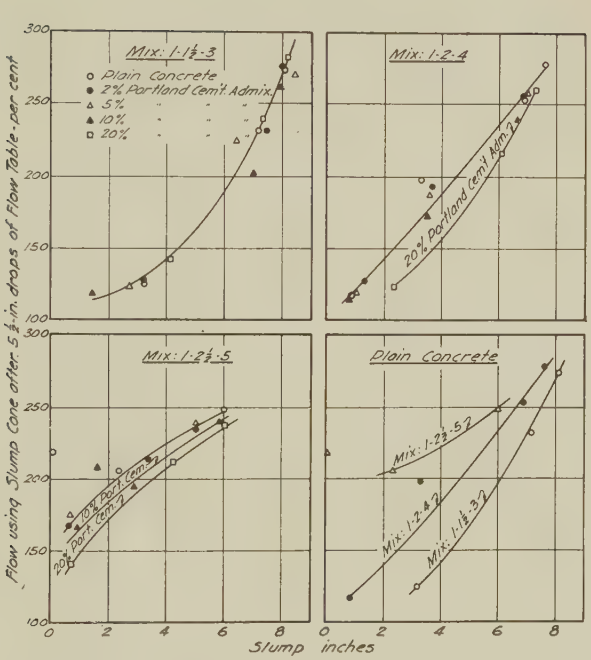

FIG. 9—RELATION BETWEEN SLUMP AND FLOW AS MEASURED WITH SLUMP CONE

extent than the flow so that the slump here also might be considered the more satisfactory measure of the workability of concrete.

Fig. 7 shows the relation between standard slump and flow for admixtures of Pumicite, and Fig. 8 for admixtures of hydrated lime. The effect of both these admixtures is seen to be very small for both the 1:1½:3 and 1:2:4 mixes, and even for the 1:2½:5mix the relation is practically unchanged. This indicates that either slump or flow is equally suitable for measuring the smoothing effect of these admixtures. This smoothing effect, therefore, appears to be less than that found by the Celite. This does not alter the conclusion drawn from other data obtained in

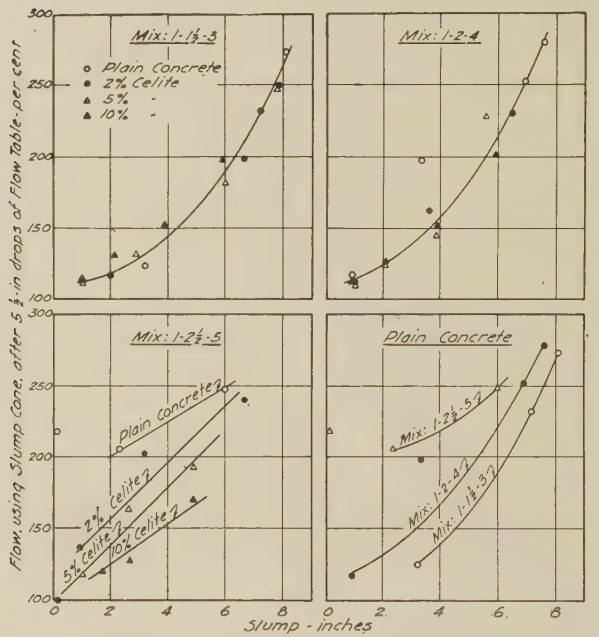

FIG. 10—RELATION BETWEEN SLUMP AND FLOW AS MEASURED WITH SLUMP CONE

this series of tests that the slump gives a more accurate indication of the real workability of a concrete mix than the flow.

Relation Between the Standard Slump Test and the Flow Using the Slump Cone After 5 Drops with Flow-Table

In the above discussion of the relation between flow measured with the flow and slump cones it was found that the slump cone gave the more sensitive measure, while the flow cone gave a somewhat better indication of real workability based on the richness of the mix. In view of the greater sensitivity shown by the flow when measured on the slump cone specimen, it was of interest to compare the results on this basis with those obtained by the standard slump test. This comparison is shown in Figs. 9 to 12 where the flow is based on 5 drops, using the slump cone specimen. These figures can be compared directly with Figs. 5 to 8 in which

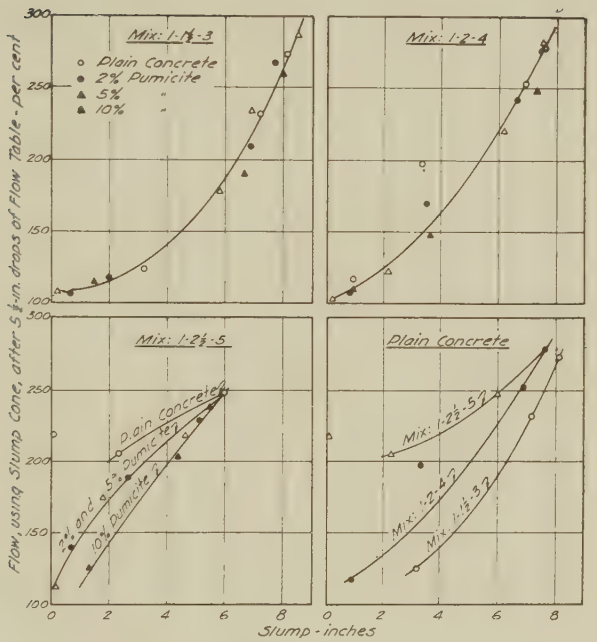

FIG. 11—RELATION BETWEEN SLUMP AND FLOW AS MEASURED WITH SLUMP CONE

the relation is based on the standard flow. In this comparison it will be seen that the curve in the pairs of figures: 5 and 9; 6 and 10; 7 and 11; and 8 and 12 are very similar in their general characteristics. They show two significant characteristics: First; for the rich mixes the flow is more sensitive than the slump in the case of the wet consistencies, but less sensitive in the case of the dry consistencies. Second; for the intermediate and lean mixes, the relationship is just reversed, the flow being less sensitive than the slump for the wetter mixes and more sensitive for the stiff mixes.

A further comparison of these pairs of figures brings out in an indirect way that the standard flow is a better measure of real workability than the flow using 5 drops with the slump cone specimen. This refers to improvement in workability, both by

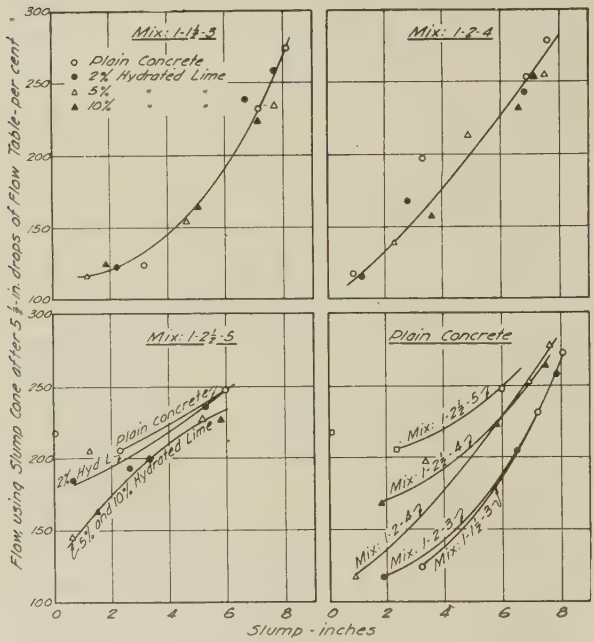

FIG. 12—RELATION BETWEEN SLUMP AND FLOW AS MEASURED WITH SLUMP CONE

increasing the cement content and by the use of some admixture which has a smoothing effect. In the discussion of Figs. 5 and 6, it was shown that for a given flow there was an increase in slump with an increase in richness for the plain concrete and an increase in slump with increasing percentages of Celite. This, it was pointed out, indicated the superiority of the slump as a measure of workability. In a study of Figs. 9 and 10 the same indication is seen in a much more marked degree, the slump being very plainly a better measure than the modified flow test of the increase in workability produced either by increasing the cement content or addition of Celite. Thus indirectly it is seen that in the flow test the standard flow cone gives a better indication of workability than the slump cone.

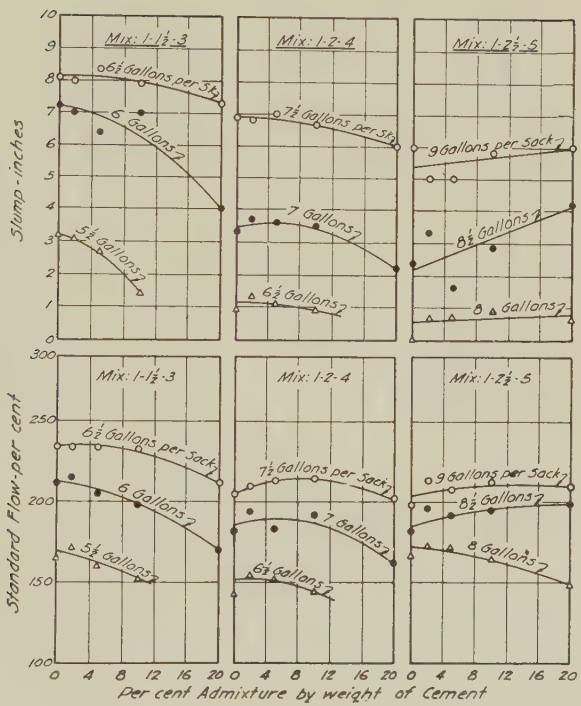

FIG. 13—EFFECT OF PORTLAND CEMENT AS AN ADMIXTURE ON SLUMP AND FLOW OF CONCRETE

In comparing Figs. 11 and 12 with Figs. 7 and 8, it is seen that in using the modified flow test, the relation between slump and flow is affected by additions of both Pumicite and hydrated lime, and also that the spread of the curves, representing the concretes without admixture, is very much greater. Both of these facts indicate the superiority of the slump test over the modified flow in bringing out the greater workability produced by enriching the mix or addition of admixture.

Effect of the Amount of Admixture on the Slump and Flow of Concrete

In the previous discussion it has been pointed out that the slump is a somewhat better measure than the flow of the improve-

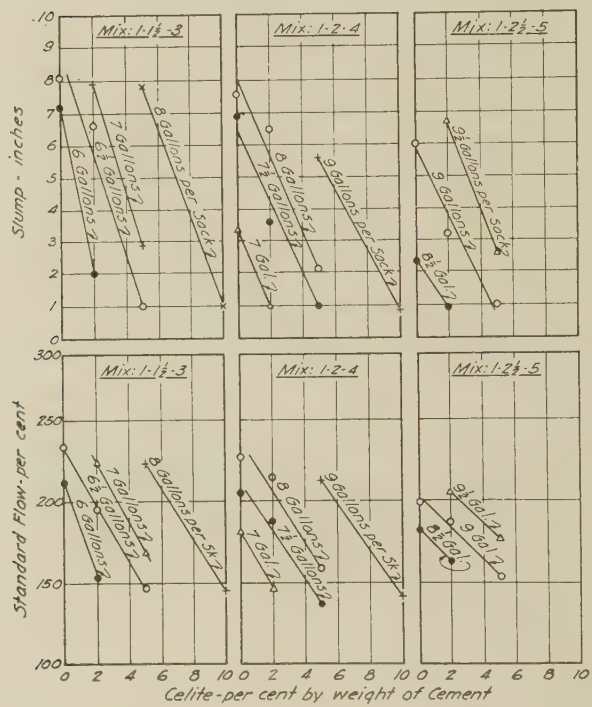

FIG. 14—EFFECT OF CELITE ON SLUMP AND FLOW OF CONCRETE

ment in smoothness resulting from the addition of admixtures to concrete. The actual effect of the amount of admixture on either the slump or flow, however, was not brought out. In Figs. 13 and 14 data are presented to show the effect of varying amounts of portland cement as an admixture and Celite on both the standard slump and standard flow for the several mixtures used in these tests. The data for the other admixtures are not shown as the curves for these lie between those for portland cement and Celite.

In Fig. 13 for portland cement as an admixture the upper diagrams contain the relations for the slump, and the lower ones those for the flow. It is noted that for a given water-cement ratio

(based on the original amount of cement) the slump is slightly decreased for the 1:1½:3 mix as the amount of cement is increased. A similar relation is seen to exist for the 1:2:4 mix but the decrease in slump is much less. The decrease in the slump for the 1:2:4 mix is negligible for additions of cement up to 10 per cent and only a slight decrease is noted for a 20 per cent addition. The 1:2½:5 mix, however, shows a different relation as the slump is somewhat increased with the increase in amount of cement. This indicates that the improvement on smoothness is not quite as great as the drying effect on rich mixes but greater than the drying effect on the lean mixes.

The results from the flow tests show a relation between the flow and amount of admixture for concrete of given water-cement ratio generally similar to that between the slump and amount of admixtures. The addition of cement decreases the flow of a rich concrete, but affects the leaner mixes to a lesser degree. For the 1:2½:5 mix the increase in flow with the addition of cement is slightly less than the increase in slump, indicating the previous finding that the slump is a more sensitive test than the flow for that smoother working which improves the workability of concrete.

In Fig. 14 the effect of Celite on a concrete mix of given water-cement ratio is shown. The slump as well as the flow is seen to decrease very sharply with the addition of the Celite. The upper diagram shows that for a 1:1½:3 mix of 6-gal. water ratio a slump of 7 in. in the plain concrete is reduced to 2 in. by the addition of 2 per cent Celite and an 8-in. slump in a 6½-gal. water ratio is reduced to 1 in. by adding 5 per cent Celite to the mix. To maintain a slump of about 7 in. in a 1:1½:3 mix the use of 2 per cent Celite requires the addition of ½ gal. of water per sack of cement and 6 per cent Celite requires an addition of 2 gal. over that required by concrete without admixture. The 1:2:4 and 1:2½:5 mixes show similar drops in slump with increase in percentage of Celite. The decrease in slump seems to be about proportional to the increase in percentage of admixture.

The relation between flow and per cent of Celite is shown in the lower diagrams of Fig. 14. Relations almost identical with those for the slump are found for the flow. The drying effect of

the admixture therefore affects both measures of consistency in a similar manner, and neither measure appears to be the better in comparing changes in consistency due to changes in water content. Fig. 6, however, showed the slump to be the more suitable measure of changes in workability due to admixtures, especially for the lean mixes. Fig. 5 (lower right hand diagram) also showed the slump test to be the better measure of increased workability due to increasing cement content.

The large difference between the curves in Figs. 13 and 14 is due to the kind of admixture used. While the addition of small percentages of cement did not change the consistency of a given mix to any important extent (water content unchanged) a very noticeable stiffening of the mix did result from the addition of corresponding percentages of Celite. Pumicite and hydrated lime did not show quite as great a drying effect as the Celite so that the relation between the slump and flow and the amount of these admixtures lies somewhere between the extremes represented in Figs. 13 and 14 for cement and Celite respectively.

SUMMARY

All data included in this series of tests show that the slump gives a more suitable indication than the flow of the increased workability of concrete produced either by enriching the mix or additions of admixtures. The results also indicate that the slump should be taken with no shaking of the concrete. The flow, however, remains about constant for the different number of drops on the flow-table so that any number is about equally suitable for the test. The use of five, ½-in. drops of the flow-table would seem to be as satisfactory as the use of 15, and would noticeably shorten the test.

The slump with the flow cone is not a sensitive test and is not suited to measuring consistency or workability.

The flow test is much more sensitive with the slump cone than with the standard flow cone for measuring changes in consistency due to changes in water content, also in showing the effect of increasing number of drops of the flow table. The use of the standard flow cone, however, seems to give a more accurate indication of increased smoothness resulting from richer mixes or the use of admixtures. This, therefore, partly offsets the ad-

vantage of the higher sensitivity obtained with the slump cone when used for measuring flow.

The relation between the flow and slump measured in accordance with the methods standardized by the American Society for Testing Materials changes with the richness of the concrete mix. For concrete of a given flow the slump increased as the richness increased, indicating that the slump is the better of the two methods for measuring improvement in workability obtained through increased cement content. The addition of admixtures also affects the slump to a greater extent than the flow, especially for lean mixes, which indicates further the superiority of the slump test over the flow test.

Modifying the flow test by using the slump cone instead of the standard flow cone increased the sensitivity of the test to changes in water content, but not to improvement in workability obtained through richer mixes or the use of admixtures.

While these tests have shown an increase in smoothness of concrete due to the use of admixtures they have also shown the stiffening of the mix which results from their use when no change is made in the water content.

Readers are referred to the JOURNAL *for May, 1931, for discussion of the two preceding papers, which may develop. Such discussion should reach the Secretary by April 1, 1931.*

A STUDY OF SLUMP AND FLOW OF CONCRETE

TABLE 1—DATA OF SLUMP AND FLOW TESTS USING SLUMP CONE

Mix by volume: sufficient material used to make one 6- by 12-in. cylinder.

Cement: a mixture of equal parts of 4 brands of portland cement purchased in Chicago.

Aggregate (room dry when used):

Fine: sand from Elgin, Ill., graded from 0 - No. 4 (F. M. = 3.00).

Coarse: pebbles from Elgin, Ill., graded from No. 4 - 1½ in. (F. M. = 7.00).

Flow and slump tests made immediately after mixing concrete. A 4- by 8- by 12-in. slump cone was filled in 3 layers on a 30-in. flow table, each layer being rodded 25 times. Immediately after filling the cone was removed, both slump and flow recorded and the table was then given five ½-in. drops in about 3 seconds and the slump and flow again recorded. This operation was repeated on the same sample using 10, 15 and 25 ½-in. drops.

Each value is the average of 3 tests made on different days.

A STUDY OF SLUMP AND FLOW OF CONCRETE

TABLE 2—DATA OF SLUMP AND FLOW TESTS USING FLOW CONE

Mix by volume: sufficient material used to make one 6-by- 12-in. cylinder.

Cement: a mixture of equal parts of 4 brands of portland cement purchased in Chicago.

Aggregate (room dry when used):

Fine: sand from Elgin, Ill., graded from 0 - No. 4 (F. M. = 3.00).

Coarse: pebbles from Elgin, Ill., graded from No. 4 - 1½ in. (F. M. = 7.00).

Flow and slump tests made immediately after mixing concrete. A 6¾- by- 10- by- 5-in. flow cone was filled in 2 layers on a 30-in. flow-table, each layer being rodded 25 times. Immediately after filling the cone was removed both flow and slump recorded and the table was then given five ½-in. drops in about 3 seconds and the slump and flow again recorded. This operation was repeated on the same sample using 10, 15 and 25 ½-in. drops.

Each value is the average of 3 tests made on different days.

Current Researches on Plain and Reinforced Concrete and Related Materials

Report of Committee 101, Survey of Current Research

H. F. GONNERMAN, CHAIRMAN

INTRODUCTION

With the reorganization of the standing committees of the American Concrete Institute, Committee E-3, Research, was replaced by Committee 101, Survey of Current Research. With the change in the committee's name, a change was also made in its function. Those members of the Institute who are familiar with the reports of the old committee will recall that about half of the report was devoted to brief abstracts on researches published in current American and foreign engineering journals. The interest shown in these brief abstracts was one of the considerations, when Journal publication was inaugurated, in the creation of a section of Abstracts, and the formation of the new Committee on Abstracts, whose efforts would be entirely devoted to this type of work, giving much greater scope to the undertaking. Committee 101 will no longer include bibliographies in its report, but will devote its time entirely to assembling and compiling information on researches received from various college, state and commercial laboratories throughout the country. To this end, the subject-matter of this report has been prepared and is arranged in the following sections:

1—*Researches on cement.* Most of the researches already carried out or now in progress on cement are concerned with the constitution of portland cement and means of improving it, as well as with tests on high early strength cements. In addition, reference is made to the development of a comparatively inexpensive damp closet for cement testing.

2—*Researches on aggregates.* This section includes tests on durability of aggregates, effect of size and shape of aggregate particles, effect of heating aggregates prior to their incorporation in the mix, effect of grading, and the development of a comparative strength test for sand.

3—*Researches on plain concrete.* In the field of plain concrete the trend of the investigations is toward comparative tests on methods of curing, durability of concrete under various conditions of natural exposure, effect of use of various admixtures, and factors affecting volume changes. In addition, short summaries are given on tests of bricklaying problems, fatigue, flow under sustained stress, jigging, mixer operation, modulus of elasticity and Poisson's ratio, pavements, permeability and methods of obtaining watertightness, cast stone, compressive and flexural strength, temperature effects, uniformity of concrete test methods, wear, and workability.

4—*Researches on reinforced concrete.* The work on reinforced concrete includes studies on bond resistance of reinforced concrete beams under continued load, tests on bridge arches, and studies on type of reinforcing. An important investigation on columns is being carried out under the auspices of Committee 105 of the American Concrete Institute.

5—*Suggested researches on concrete and related subjects.* The number of researches suggested as needed and of prime importance indicates that there is a never-ending source of problems requiring study in the efficient use of concrete. These will be of particular interest to laboratories seeking subjects on which to direct their efforts.

This report has been submitted to letter ballot of the Committee, which consists of 11 members, of whom seven have voted affirmatively, none negatively, and four have refrained from voting.

H. F. GONNERMAN, *Chairman.*
F. E. RICHART, *Secretary.*

(NOTE—Many of the researches listed have not been completed, and in general, reports giving data of the tests are not available. In a few instances reference is made to the publication of reports. The conclusions given for certain of the investigations are those of the investigator and do not necessarily represent the views of the Committee.)

1—Cement

Improvement of Portland Cement: (Board of Water Supply, New York City). Studies in progress since 1914 with a view to improving the quality of portland cement, have covered such subjects as: Solubility in sugar solutions, heat of setting, alkali content, resistance to sodium sulfate solutions, lime-silica ratios, tests of cements previously used, and effects of calcium chloride and other salts. Results from these investigations are published from time to time in various engineering journals.

Stabilization of Di-Calcium Silicate: (Ohio State University, Columbus). Studies were made in the Department of Mineralogy on the properties of di-calcium silicate, particularly as they relate to refractories, but also in their application to portland cement products in the question of dusting. The results will be published at an early date by the Engineering Experiment Station.

The Upper SO_3 Limit in Portland Cement: (Mellon Institute, University of Pittsburgh). Only enough SO_3 should be added to portland cement to control its initial set, owing to the crystallizing tendency of the sulfoaluminate formed. Compressive strengths of small specimens of 1:3 mix, made from high early strength cement flour and Ottawa standard sand were about 5500 pounds per square inch at 24 hours and then rose steadily to 9200 at one year. As the great bulk of the cement was hydrated within the first day the increase strength must be ascribed to the induration reactions occurring within the silica gel.

Specifications and Tests for High Early Strength Cements: (State of Washington, Department of Highways, Olympia). The purpose of this investigation is to develop suitable specifications for the use of high-early strength cements. Tests were made on various kinds of cements at various ages using 6 by 12-in. cylinders, beams, and small mortar specimens. The data obtained thus far indicate that standard Ottawa sand briquets are unsatisfactory test specimens.

Development of a Low-Priced Damp Closet for Cement Testing: (Lehigh Portland Cement Co., Allentown, Pa.). Urgent need of an efficient low-priced damp closet for cement testing has led to a rather extensive search for simple devices for control of temperature and humidity. The most promising combination so far developed consists of a household refrigerator of the "top-icer" type, modified as to interior construction to provide a storage tank and shelves for pats and briquets; a nozzle of the oil spray type for discharging a water spray to provide humidification close to saturation, temperature control, and continuous circulation of the air inside the closet; and a thermostatic element to control the temperature of the water supply to the spray. While the limitations of this combination are not yet fully established, the object in view is to provide a cabinet that will automatically insure the conditions prescribed by the cement specification at all seasons of the year at a cost not to exceed $200 for the complete installation.

Slide-Rule for Calculating Compounds in Portland Cement: (Lehigh Portland Cement Co., Allentown, Pa.). In an effort to simplify the computation

of compound composition of portland cement, it was found that the percentage of any compound can be calculated directly from the analysis without the previous calculation of the percentage of any other compound. The series of equations for direct computation have been used as a basis for the design of a slide-rule for calculating the compound composition of portland cement. The slide-rule is described and illustrated in an article by L. A. Dahl, "A Slide-Rule for Calculating Compounds in Portland Cement," *Rock Products*, November 9, 1929, p. 50.

High Early Strength Concrete: (Pennsylvania Department of Highways, Harrisburg). This investigation was undertaken to determine the efficiency of high early strength cement compared with blended standard portland cement. Cement-sand mortar and concrete beams and cylinders were molded for test at age of 1 day to 1 year. Tension and compression tests were made on the cement sand mortars, beams were tested for modulus of rupture, and cylinders were tested in compression. The special cement showed increased strength at ages of 1 to 28 days, but at the 3-month period the strengths were nearly equal in the mortar tests and in the modulus of rupture tests on concrete. The concrete compression tests showed the special cements to be slightly higher than the standard portland.

In another series of tests which has just been completed, a high-early strength cement showed a considerable gain in mortar tension and compression for the first 7 days. At the 28-day period and later periods, the strengths converged, and in some cases the standard cement showed slightly higher strengths. In the concrete tests the high early strength cement showed slightly higher strengths at the 1- and 2-day periods, but strengths thereafter were about equal to those of the standard portland cement.

Comparative Strength Tests of Cement: (Iowa State Highway Commission, Dept. of Materials and Tests, Ames). Tests were carried out in cooperation with Sub-Committee VII of A. S. T. M. Committee C-1 on Cement and the Special Committee on Cement of the American Society of Civil Engineers, and the results obtained were forwarded to the respective committees for comparison with the results obtained by the other cooperating laboratories.

Study of the Effect of Quality of Cement on Quality of Concrete: (U. S. Bureau of Public Roads, Washington, D. C.). 3-year tests have been completed and report will be issued shortly.

Researches on Cement: (Portland Cement Association Fellowship, National Bureau of Standards, Washington, D. C.) The investigations of this Fellowship are designed to explore the major chemical problems of the cement industry. Among the investigations now in progress are the following:

(1) A study, with pure materials, of the influence of composition on the volume constancy of specimens of the set cements. The compositions examined include the cement compounds, mixtures of compounds, laboratory cements of systematically varying composition prepared under definitely controlled conditions, and commercial cements. The specimens, 6 by 1 by 1-in. are stored (a) continuously in air, (b) continuously in water after the

first 24 hours, and (c) alternately in air and in water at 7-day intervals. Length measurements are made at definite time intervals, over a period of years, using a microscope comparator and a micrometer comparator.

(2) A comprehensive study of the set of cements which includes research on (1), the chemical phenomenon of set; (2), the influence of rate of set on the properties of the cement; (3) the measurement of rate of set; and (4) the control of set. During the past year some of the causes have been examined of the so-called "false" or "hesitating" set. Also, a study is under way on the heat of setting and a correlation of the heat evolved with the reactions taking place as determined by microscopic, chemical and physical tests.

(3) A fundamental investigation on the kinetics and thermodynamics of the hydration or setting process. The rate and degree of hydration are being measured by observations on the change in density of samples of the cement compounds of known specific surface, and by observations on the heat of hydration of the compounds. Likewise, a thermal analysis of the hydrated compounds is being made by the continuous weighing of samples undergoing dehydration under rigidly controlled conditions.

(4) Phase equilibria study of the cement systems. During the past year the system CaO-Al_2O_3-Na_2O has been studied. Soda is commonly present in cements in small amounts and it is important to have information on the compounds which it forms. Only then can a rational study be made of the influence of the soda under all conditions.

(5) The development of the x-ray method to a study of the constitution of portland cement. It often is not possible by microscopic or chemical means to identify the phases present in laboratory or commercial cements. The x-ray method has been developed to a point where it is of great value in the identification of compounds and in the following of reactions. Many of the problems which have long baffled investigators have yielded to the convincing criteria of the x-ray.

Recent publications of the Fellowship are as follows:

Paper No. 21—"Calculation of Compounds in Portland Cement," by R. H. Bogue, *Ind. Eng. Chem.* (Analytical Edition), I, (1929), 192; *Rock Products 32*, No. 23 (1929), p. 47.

Paper No. 22—"The Influence of Magnesia, Ferric Oxide and Soda upon the Temperature of Liquid Formation in Certain Portland Cement Mixtures," by W. C. Hansen. *Bureau of Standards J. of Research*, Jan., 1930, Research Paper No. 132.

Paper No. 23—"Revised Procedure for the Determination of Uncombined Lime in Portland Cement," by William Lerch and R. H. Bogue. *Ind. Eng. Chem.* (Analytical Edition) *2* (1930), 296; *Concrete, 37*, (1930), 88.

Paper No. 24—"The X-ray Method Applied to a Study of the Constitution of Portland Cement," by L. T. Brownmiller and R. H. Bogue. *Bureau of Standards J. of Research*, October (1930) R. P. No. 233, *Am. J. Sci.* (in press).

Researches in Cement: (A. S. T. M. Committee C-1 on Cement). At the meeting of Committee C-1 of the American Society for Testing Materials held in Washington, Sept. 6, 1930, the following sub-committees were formed:

"A"—Methods of Testing
"B"—Specifications for Portland Cement
"C"—Specifications for High Early Strength Cement
"D"—Specifications for Masonry Cement

These sub-committees are empowered to form technical committees for the purpose of studying specific problems. The technical committees are not to be considered as standing committees but are expected to complete their work and make a final report as early as possible.

Sub-Committee "A" will give its immediate attention to the rewriting of the Manual and will undertake to suggest such changes in present apparatus as may be necessary and also to develop better apparatus for cement testing than is available at present. The development of a moist closet which will maintain constant temperature and humidity is quite an urgent question as many laboratories are willing to install this equipment if a suitable one can be economically manufactured.

Sub-Committee B has appointed 3 technical committees to report on the following problems relating to portland cement:

1. Relation of Particle Size to Physical Properties,
2. Relation of Chemical Composition, particularly as Affected by Ratios, to Physical Properties,
3. Study of Accelerators and Retarders,
4. Effect of Temperatures at time of use,
5. Study of Accumulated Data on Plastic Mortar Strength Tests, and Recommendation as to Whether Work Shall be continued on this Subject,
6. Study of Tests Indicative of Durability,
7. Early-age Tests.
8. Factors Affecting Volume Change.

2—AGGREGATES

Effect of Mixing Coarse Screenings with Sand which Does Not Meet Specifications: (Kentucky State Highway Department and University of Kentucky, Lexington). This procedure has been in operation for two years, with excellent results. A complete report on the findings from this study will be published soon.

Durability of Concrete Made from Unsound Stone: (Kentucky State Highway Department and University of Kentucky, Lexington). This investigation included tests on concrete made with 50 and 100 per cent unsound fine and coarse aggregate. Concrete made with 100 per cent unsound aggregate and exposed to weather tested as follows: 3 per cent increase in strength from 28 days to 6 months, with no failures due to disintegration; 11 per cent decrease in strength from 6 months to 1 year, one specimen in three having failed through

disintegration; 44 per cent increase in strength from 1 year to 2 years, with two failures due to disintegration.

Concrete made with only 50 per cent unsound aggregate tested as follows: 36 per cent increase in strength from 28 days to 6 months; 13 per cent increase from 6 months to 1 year; 27 per cent increase from 1 to 2 years. In this group of tests there was some crazing but no disintegration. Tests will be made through the 5-year period.

Sandstone as Aggregate in Concrete: (Kentucky State Highway Department and University of Kentucky, Lexington). An extensive investigation has been in progress since 1920 to determine the suitability of sandstone as fine and coarse aggregate in the construction of concrete roads and structures. It was found that any sound sandstone having a percentage of wear of less than 7 can be used in concrete pavement under proper control methods. Sandstone with a percentage of wear as high as 15 can be used for structures. A report is being prepared for early publication.

Method of Testing Stability of Sandstone for First-Class Masonry Construction: (Kentucky State Highway Department and University of Kentucky, Lexington). Tests were made to determine the reliability of sodium sulfate soundness tests on sandstone common to Kentucky. Specimens which went to pieces under the accelerated test have not been affected after two years in the weather, and the same stone was not affected by twenty alternations of freezing and thawing. Complete chemical analyses are being made of the stone which passed the accelerated soundness test and on the samples which did not. Though indications are that this test is not suitable for this type of aggregate, no conclusions can be drawn until further tests are made.

Properties of Concrete Made with Light-Weight Aggregate: (T. & A. M. Dept., University of Illinois, Urbana). The purpose of this investigation was to determine the properties of a structural grade of Haydite concrete such as might be suitable for reinforced concrete buildings and other structures. Studies have been made thus far on the properties of the aggregate, as well as on compressive strength, weight, density, modulus of elasticity, and workability of concrete of varying proportions, richnesses, and consistencies. In addition, determinations are being made of the resistance to diagonal tension, bond and compressive stress in flexure of reinforced concrete beams. Data of the tests were given in paper on "Tests of Plain and Reinforced Haydite Concrete," by F. E. Richart and V. P. Jensen, Proceedings, American Society for Testing Materials, Vol. 29, 1930; also by the same authors, "Construction and Design Features of Haydite Concrete," this JOURNAL, A. C. I., Oct., 1930, p. 151; "Tests of Bonding Floor Finish to Slabs of Haydite and Sand Concrete," JOURNAL, A. C. I., Dec. 1930, p. 339.

Effect on Strength of Soft Particles of Coarse Aggregate on the Strength and Durability of Concrete. (Michigan State Highway Department Laboratory, Lansing). This investigation was undertaken to determine to what extent the strength of concrete is affected by the presence of shale, friable sandstone, ochre, etc. 6 by 12-in. cylinders and 6 by 6 by 40-in. beams were made from concrete in which an aggregate known to be sound was mixed with varying

percentages of soft and non-durable particles. In one group of tests, the specimens were broken after 28 days' moist curing, and in another group after 25 cycles of freezing and thawing following 28 days moist curing. The strength of concrete, both moist-cured and subjected to freezing and thawing, was reduced by the presence of these particles. Report on this investigation by W. J. Emmons published, Proceedings of the 16th Annual Conference on Highway Engineering, University of Michigan, p. 45.

Effect of Character of Fine Aggregate on Mortar Strength: (Minnesota Highway Department, St. Paul). Six sands from different pits in Minnesota were artificially graded and tested in mortar in compression, tension, and flexure. The results show that with grading and water-cement ratio constant, variation in shape and characteristics of the sands had practically no effect on the strength of the resultant mortar.

Effect of Heating Aggregates on Concrete Strength: (Minnesota Highway Department, St. Paul). Compression and transverse specimens made for test at 3, 7, 14, 28 and 180 days, 12, 18 and 24 mo., from sand, gravel, and water heated sufficiently to bring the temperature of the concrete to 70, 100 and 130 degrees F. when deposited in the molds. Time of set determined by flow. It appears from the data obtained thus far that: (1) heated concrete requires more water to produce a given workability, (2) there is a reduction in strength so great that the difference in water-cement ratio can hardly be the cause, (3) heated concrete sets more quickly than unheated, (4) concrete should be placed in forms at a temperature of not over 70 to 80 degrees F.

Joint Influence of Iron and Aluminum in Native Sands and Mortar Strengths: (Maine Technology Experiment Station, Orono). The status of this investigation was reported in the Proc. of National Acad. of Sciences, v. 15, p. 742, Sept., 1929, and reprinted as Paper 9 of the Maine Technology Experiment Station.

Influence of Aluminum on Mortar Strength: (Maine Technology Experiment Station, Orono). The status of this investigation was reported in the Proceedings of the National Academy of Sciences, v. 15, p. 740, Sept., 1929, and reprinted as Paper 8 of the Maine Technology Experiment Station.

Study of Hydrogen Ion Content of Maine Sands in Relation to Their Use in Concrete: (Maine Technology Experiment Station, Orono). It appears from the results obtained thus far that the hydrogen ion content will add much to the knowledge of strength-making qualities of sands.

Selection of Mortar and Plaster Sands: (Lehigh Portland Cement Company, Allentown, Pa.) Two comparatively new methods of test were employed in these studies, one of which is the so-called plastic mortar test which provides a means of judging sands from the point of view of economy, as well as a method for determining quantitatively the deleterious effects of organic matter in sands. The other was a simple titration method for determining the absorption of sand. The former test is under investigation by Committee C-1, of the American Society for Testing Materials as a possible specification test for portland cement and the latter test is useful in connection with all concrete tests in which the absorption of the fine aggregate is a factor. The

sand tests were described and discussed by J. C. Pearson in paper on "Fine Aggregate in Mortar and Plaster" (see Proc. A. S. T. M. 1929) and "A Simple Titration Method for Determining the Absorption of Fine Aggregate" (see *Rock Products*, p. 64, May 11, 1929).

The Laws of Grading Derived and Applied to Aggregates and Cement: (Mellon Institute, University of Pittsburgh and Bureau of Mines, Minneapolis Station). Fundamental laws have been derived by a mathematical analysis for maximum packing, giving two systems, one with an intermittent or gap grading and the other continuous. These have been applied to mortar, where noteworthy applications have been made to stucco, cast stone and masonry mortars, to concrete and to the proper distribution for the cement itself. The function of admixtures is analyzed.

Effect of Grading of Fine and Coarse Aggregate on Strength of Concrete: (National Sand and Gravel Association, Washington). This investigation was designed to furnish information on the effect of maximum size of sand and gravel on quality of concrete, and the effect of variations in grading within the usual specification limits. Tests were made in compression and flexure, using three different concrete mixes involving three gradings of fine aggregate and seven gradings of coarse aggregate.

Effect of Flat Particles on Concrete-Making Properties of Gravel: (National Sand and Gravel Association, Washington). The report on this investigation, which consisted of compressive and flexural tests of concrete of two different mixes using gravel free from flat particles and gravel containing 15 per cent flat particles, was published in the 1929 Proceedings of the American Society for Testing Materials, and in the July, 1929, issue of the National Sand and Gravel Bulletin.

Effect of Grading on Void Content: (National Sand and Gravel Association, Washington). This investigation supplements the work on this subject described in the 1928 Report of this Committee. The report on these tests, together with a report on the previous researches, has been published in the National Sand and Gravel Bulletin and as Circular 8 of the National Sand and Gravel Association, and includes data of tests on void content for all possible combinations of three sizes of sand—No. 14 to No. 4, No. 48 to 14, and 0 to No. 48—and for 57 combinations of four sizes of gravel—¾ to 1½-in., ⅜ to ¾-in., No. 4 to ⅜-in., and No. 8 to No. 4.

Effect of Mineral Composition and Shape of Particles in Coarse Aggregate on Strength of Concrete: (National Sand and Gravel Association, Washington, D. C.). This investigation is designed primarily to show what variations in quality of concrete may result from a difference in mineral composition of the coarse aggregate or from a difference in the shape of particle. It includes a large number of different aggregates from widely separated sources tested under comparable conditions. A feature of the tests is the attention paid to differences in the void contents of the different aggregates and the effect of this factor on the quantity of mortar required to produce workability. Both compression and flexural tests are being made.

Effect of a Amall Amount of Colloidal Clay in Sand on Its Usefulness as a Fine Aggregate. (University of Colorado, Boulder). A leading sand and gravel company of Denver has been having trouble in marketing the sand that is obtained in connection with their commercial gravel. The sand and gravel deposit underlies 2 or 3 feet of top soil and is very extensive and uniform. With nominal washing the gravel is entirely satisfactory, but although the sand makes concrete that is satisfactory from the standpoint of strength, contractors have objected that it is "dead" and does not work properly. It has been necessary, therefore, to waste most of the 0-4 material from this pit. After various tests it was found that the presence of a small amount of colloidal clay seemed to be the main source of the trouble. Some of this clay is so fine that water containing it will remain clouded for days. This slime is very tenacious and the adhesion is such as to impart a distinct crustiness to any dried surface of the unwashed sand. When the clay is washed out and dried it resembles hardened cement and has considerable strength in tension. A thorough washing removed all signs of the objectionable "deadness" and no crust formed upon drying. Special cone slime removers and washing equipment were installed as a result of these tests and the sand has apparently been rendered a satisfactory and marketable product. The washing also removed some indications of organic contamination as shown by the colorimetric test.

Effect of Briquet Molding Pressure on Strength Ratio of Sand Mortars: (National Sand and Gravel Association, Washington). This investigation was outlined for the purpose of obtaining information on the effect of different laboratory practices on results of tests of sands in mortar. Preliminary studies indicate that the pressure applied in molding briquets may affect the strength of concrete sand mortars differently from standard sand mortars, and hence may affect the strength-ratio.

Crushing and Abrasion Tests of Gravel: (National Sand and Gravel Association, Washington). In a study of quality of gravel particles, crushing tests and modified Deval abrasion tests of a large number of samples of gravel are being made. The crushing test is being made by applying a pressure of 3000 lb. per sq. in. on a 3 kg. sample of gravel, graded 50 per cent 1 to 1½-in., 25 per cent ¾ to 1-in., and 25 per cent ½ to ¾-in., confined in a cast iron cylinder 6 in. in diameter. The reduction in fineness modulus and in volume of voids due to application of load is being determined. The abrasion test is being made on a sample of the same grading, to which 6 cast iron balls 1⅞-in. in diameter are added as an abrasive charge, revolved 10,000 revolutions in a standard Deval cylinder at 33 r. p. m. These data are included in a progress report to Sub-Committee 2 of Committee 2 on Ballast of the American Railway Engineering Association (Bulletin No. 321, Vol. 31, Nov., 1929, p. 761).

Accelerated Soundness Tests of Gravel: (National Sand and Gravel Association, Washington). Preliminary tests have been carried out to determine whether the difference in abrasion test results of gravel before and after treatment with sodium sulfate, in accordance with the accelerated soundness test, may be used as an indication of the soundness of the material. Results

on gravels studied to date have been unsatisfactory, since a greater resistance to abrasion after treatment with sodium sulfate is shown sometimes than was obtained on the untreated samples.

Durability Studies of Aggregates for Concrete: (Research Laboratory, Portland Cement Association, Chicago). Comprehensive studies are being made of the variations in aggregate quality that may be encountered in pits and quarries and the effect of such variations on the durability of concrete in which the aggregates are used. The study embraces petrographic and geologic studies in the field and laboratory, sodium sulfate tests for soundness of aggregate, freezing and thawing tests of the aggregates and of concretes and mortars in which the aggregates are incorporated. A major objective of this study is the establishment of some physical test by which the suitability of aggregate for use in concrete can be determined.

Well-Graded Washed Sand Versus Crushed Granite Screenings as Fine Aggregate: (University of Colorado, Boulder). For the conditions of these tests the granite screenings gave concretes which were decidedly above those from the washed sand in strength and fully equal to them in workability. These tests were with identical coarse aggregates and water-cement ratios. Mixtures of sand and screenings gave strengths below those for the screenings alone but above those for the washed sand.

Limestone and Gravel Used as Coarse Aggregate: (Pennsylvania Department of Highways, Harrisburg). Tests were made to compare the relationship between strength of concrete in which limestone and gravel were used as coarse aggregate. Modulus of rupture tests were made on concrete beams and compression tests on concrete cylinders at ages of 1 day to 1 year. At all ages the crushed limestone gave higher strengths than the gravel. The modulus of rupture of the limestone concrete at various ages ranged from 10 to 20 per cent higher than that of the gravel concrete. In compression, the limestone concrete was between 20 and 35 per cent higher than the gravel concrete.

Use of Soft Limestone in Concrete: (Iowa State Highway Commission, Ames.) Tests were made to determine the effect on strength and durability of concrete of the use of relatively soft limestone as coarse aggregate. Six by 6 by 30-in. beams and 6 by 12-in. cylinders were made using normal limestone in one group, and a very soft limestone in companion specimens. Strength tests indicate a slight decrease in both flexural and compressive strengths particularly for soft limestone which was found to be unsound in the sodium sulfate soundness test.

Development of a New Strength Test for Sand: (Iowa State Highway Commission, Ames). The purpose of this investigation was twofold: (1) to develop a strength test for sand which will accurately and consistently evaluate the concrete-making ability of different sands, (2) to develop a method of designing concrete mixes on the basis of this test. At various periods for the past 9 years work has been undertaken on these problems using different phases, different approaches, and different ideas. Of all the methods tried, the mortar-

voids method of Talbot and Richart seems to be the most dependable, the nearest approach to the realization of the basic laws which govern the strength of concrete. During the past year, several thousand 2 by 4-in. and 6 by 12-in. cylinders and 6 by 6 by 30 and 2 by 2 by 14-in. beams were made and tested. The method of Talbot and Richart of designing mixes was tried out in the field and used in the construction of about 200 miles of pavement. Tests were made on core specimens from this pavement and on beams made during the construction of the pavement. The technique of Talbot and Richart has been improved upon to such an extent that some of the difficulties they met with have been eliminated, as well as new difficulties which arose during these tests. The technique has now reached the point where the effect of such variables as amount of water required to wet the surface of coarse aggregate variations in manner of mixing and placing, and workability as distinguished from consistency are factors of prime importance. When these factors have been evaluated, it will be possible to design concrete mixes for a definite strength and attain values within a range of considerably less than 10 per cent of the desired result. In addition, it will be possible to estimate accurately quantities of all materials after a few hours' work with the sand and cement to be used in the concrete. The attainment of this is, of course, based on the assumption that the curing condition will be the same, and that the coarse aggregate is structurally sound and of the quality normally used.

Short-Time Strength Tests for Concrete Sands: (Kansas State Agricultural College, Manhattan). This investigation was undertaken in 1925 to determine the relation between the strength-ratios of various natural and commercially available sands in the State, using a high early strength cement and those obtained using portland cement in the ordinary 7 and 28-day strength tests.

The procedure is to test a number of sets of three briquets and three 2 by 4-in. cylinders made with each sand and each high early strength cement at 24 and 48 hours, for comparison with corresponding sets of briquets and cylinders made on the same day from standard Ottawa sand and the same high early strength cements. Similarly 7 and 28-day strength ratios will be obtained for each of the sands with ordinary portland cement. It should be possible to secure certain coefficients for interpreting 24 and 48-hour strength ratios in terms of 7 and 28-day strength ratios. Also, it is possible that curves may be obtained which will show directly the relationship between strength ratios of early strength cements and those of ordinary portland cement with the various sands available in Kansas.

Study of Effect of Character of Fine Aggregate on Flexural Strength of Mortars: (U. S. Bureau of Public Roads, Washington). This investigation has been undertaken to determine the importance of character of fine aggregate on resultant strength of mortar in flexure.

Study of Methods of Determining Absorption and Free Water Content of Fine Aggregates: (U. S. Bureau of Public Roads, Washington). This group of tests is being made to develop, if possible, efficient methods for determining absorption and free water content of fine aggregates.

Study of Methods of Making Abrasion Tests on Fine Aggregates and Hardness Tests of Mortars: (U. S. Bureau of Public Roads, Washington). This is a continuing investigation to study the relation between abrasion tests on fine aggregates and hardness tests of mortars.

Studies of Effect of Type of Aggregate on Resistance of Concrete to Frost Action: (U. S. Bureau of Public Roads, Washington). This investigation has been completed, and a report on the results obtained will be published shortly.

Study of Relation between Coarse Aggregate Content and Quality of Pavement Concrete: (U. S. Bureau of Public Roads, Washington). The object of this investigation was to determine the effect of variations in the amount of coarse aggregate on workability and quality of portland cement concrete in pavement slabs constructed with standard equipment. The study involves the construction of approximately one-half mile of concrete pavement 9 feet wide and 7 inches thick, constructed in 9-ft. sections. Both crushed stone and gravel were used as coarse aggregate and the proportions varied from a distinctly over-sanded mix (1:2:3½) to mixes containing as high as 4¾ parts of crushed stone and 5¼ parts of gravel. Observations were made on the relative workability of the various concretes when finished with both of the standard finishing machines now on the market. The quality of the concrete was determined by flexural tests on concrete beams 27 in. wide and 5 ft. long taken from the test sections. Other tests for quality, such as compression tests on cores drilled from the slabs, and freezing and thawing tests of concrete specimens taken from the beams, were also made.

Investigation on the Quality of Concrete for Bridge Floor Slabs with Special Reference to Use of Light-weight Aggregates: (U. S. Bureau of Public Roads, Washington). This investigation is under way in cooperation with the Port of New York Authority.

3—Plain concrete

The researches under way on plain concrete which are described below have been listed under the following classifications:

Admixtures
Bricklaying
Crazing
Curing
Dams
Durability
Fatigue
Fire Resistance
Flow under Load
Jigging
Mixers and Mixing
Modulus of Elasticity and Poisson's Ratio
Pavements
Permeability
Pipe
Products
Strength—compressive, flexural
Temperature Effects
Tests and Test Methods
Volume Changes
Wear
Workability

ADMIXTURES

Effect of Sugar on Strength of Concrete: (Kentucky State Highway Department and University of Kentucky, Lexington). Tests were made on sand, cement, and coarse aggregate which were sent to the Laboratory in sugar containers, such as sacks and syrup buckets. It was found that very small amounts of sugar reduce the strength of mortar to almost nothing, and that very unreliable results are obtained on material shipped in such containers. Fine and coarse aggregate shipped in this manner, however, tested satisfactorily after being thoroughly washed. Results of this investigation were published in Kentucky Highways, v. 3, No. 3, Sept., 1928.

Tests of Admixtures: (California Division of Highways, Sacramento). Tests are under way to determine the effect of additions of various commercial powders on the properties of cement mortars and concretes. Laboratory compression tests are being made on 2 by 4-in. mortar specimens and on cores drilled from pavements. Results not yet available.

Celite as an Admixture: (University of Colorado, Boulder). The strengths of concretes and mortars with 1:2 and 1:3 cement-sand ratios were increased appreciably by additions of Celite of 3, 5 or 10 per cent of the weight of the cement. The mixtures were stiffened by the Celite and at constant workability the required increase in water-cement ratio offset the effect of the Celite. Both fine and coarse aggregates were crushed granite of excellent quality. While the mixtures were not harsh prior to the addition of Celite there was apparent the usual softening or "fine sand" effect. (In some former tests with different cement and aggregates, there was no apparent strength difference between concretes and mortars with and without Celite at constant water-cement ratio). Celite had no measurable effect on yield in either series.

Permeability Tests of Concrete with and without Admixtures of Celite: (Pierce Testing Laboratories, Denver, Colorado, for Johns-Manville Corp.). Permeability tests were made on 1:2:4 concrete mixtures, with and without admixtures of Celite, subjected to water and oil at pressures up to 200 lb. per sq. in. In a 1:2:4 mix with a water-cement ratio of 0.85, the slump for concrete without Celite was 4 in., and that with the admixture in amounts of 3 lb. per bag of cement, the slump was 1.75 in. The compressive strength at 7 days was 2645 and 2910 lb. per sq. in., and at 28 days was 4017 and 4652, for untreated and treated concrete, respectively.

The concretes were cast into 14 by 14-in. concrete cylinders, with a pipe projecting from the center, at the bottom of which was left a cavity 1½ by 1½ in. thus leaving a wall of concrete 6 in. thick in every direction, on which the pressure was applied. These specimens were connected with the apparatus, each having a reservoir equipped with a water or oil gage, thus making it possible to read the amount of water or oil forced into or through each specimen at any time. These reservoirs in turn were connected to an air tank equipped with pressure gage, air compressor, and motor by means of which the pressure was raised to and maintained at the desired amounts. On total

loss of oil, Celite concrete showed a permeability 15.4 with plain concrete considered as 100; on total loss of water, Celite concrete showed a permeability of 29.5 on this same basis.

Effect of Calcium Chloride on Hydration of Minerals: (Ohio State University) This investigation was conducted in the Department of Mineralogy in cooperation with the Calcium Chloride Association. The results obtained will be published by the Engineering Experiment Station.

Effect of Various Powdered Admixtures on Workability of Concrete: (Missouri State Highway Department, Jefferson City). These tests were made to determine the efficacy of various powdered admixtures for improving the workability of concrete. Laboratory tests were made with the Smith-Conahey workability apparatus on concrete containing different admixtures in varying amounts, all batches being gaged with enough water to give a constant flow. The basic mixture used was 1:2:3½ at a flow of 125 (15⅛-in. drops). Two sands were included, one a rounded-grain quartz river sand, and the other an angular-grained crushed flint sand. Field tests and observations were also made of the use of these admixtures in actual construction. Though the investigation has been completed, no report is available for publication.

Effect of Crusher Dust on the Strength and Other Properties of Mortars and Concretes Made from Crushed Granite: (Univ. of Colorado, Boulder). Crusher dust (of the same material as the aggregates 0-100 grading) was added to mortars and concretes as a check on the extent to which accidental concentrations of dust might be harmful to the quality of the concrete. At a constant water-cement ratio the dust strengthened the concrete but stiffened it materially. At constant slump the increase in strength from adding dust was about equal to the decrease from increasing the water-cement ratio up to an amount of dust equal to 15 or 20 per cent of the total fine aggregate. The conclusion from these tests and materials is that no ordinary concentration should be injurious but it may complicate the control of mixing water and workability. The results from these tests should not be extended to other conditions and materials without experimental verification, however.

Use of Diatomaceous Earth in Concrete. (Pennsylvania Department of Highways, Harrisburg). This investigation was undertaken to determine the effect of admixtures of diatomaceous earth on the properties of concrete. Concrete cylinders and beams were molded using the same water-cement ratio and same materials, except that diatomaceous earth was added to one group of specimens in amount of 3 lb. per bag of cement. Concrete containing the admixture was found to be more plastic, and the surface of the specimens smoother, while the plain concrete had a higher modulus of rupture and higher compressive strength. The admixture did not reduce the absorption of the concrete.

Use of Calcium Chloride in Concrete: (Iowa State Highway Commission, Ames). The purpose of this investigation was to determine the effect of calcium chloride used as an admixture in concrete. Two series of 6 by 6 by

30-in. beam specimens were prepared, one set during the construction of a paving project which was started in 1926, and the other set in the laboratory. For the field series the principal variables were curing condition and type of aggregate. For the laboratory specimens a number of variables was introduced, such as different brands of cement, various types of coarse aggregates, and different consistencies. A final report will be prepared supplementing the progress reports of January and August, 1927.

Use of Admixtures in Concrete: (Iowa State Highway Commission, Ames). These tests were undertaken to determine the effect of various inert admixtures in concrete, including pumicite, hydrated lime, Celite, Morrisite, and portland cement. Specimens tested were 6 by 6 by 30-in. beams and 6 by 12-in. concrete cylinders containing varying amounts of the admixtures. The strength tests obtained to date indicate little or no advantage in using admixtures in the amounts recommended by the producers. Some of them, particularly Celite, increase the yield slightly, and somewhat out of proportion to the absolute volume of the material added. This appears to be due to the additional water required. Workability, the talking point of the producers, is as yet unmeasured by any means which affords a common measure for concrete made with different admixtures.

Tests of Cements and Admixtures: (Delaware, Lackawanna, and Western Railway Co., Hoboken, N. J.). 6 by 12-in. cylinders were made for test at 7, 28, 60, 180, and 360 days from concrete with and without 5 per cent admixtures by weight of cement of Celite, Cal, Dowflake, Colloy and Fluresit, using two standard portland cements as well as Lumnite and trass cements. Two water-cement ratios were used for each group—6.25 and 6.75 gal. per sack—the aggregates were dry, and the slump was 3 in. in all tests. In tests planned for future work Incor cement will be included to determine its early strength quality and its strength up to one year.

BRICKLAYING

Investigation on Bricklaying Problems: (Mellon Institute, University of Pittsburgh, Pittsburgh). This series of tests was undertaken by Mellon Institute, in collaboration with the Eastern Face Brick Manufacturers' Association, to study those combinations of variables representing the probable range of practical application. About 400 experimental walls and panels were erected in the grounds of Mellon Institute Building. Since the most obvious point of attack are studies of the characteristics of different kinds of brick and mortar, the brick and mortar problems under investigation include the absorption and surface characteristics of brick, and differences in mortars due to varying the cementing materials, sand, and pigments. Properties of mortars being studied are workability, compressive and transverse strength, absorption and permeability, shrinkage, durability, staining and efflorescence, and elasticity. Information is also being collected to determine whether the 10 per cent lime often specified by architects, or the 25 per cent or more usually employed by brick masons, gives better results.

The problems in backing include a study of hollow tile of different sizes, of brick, of cinder or concrete block, of brick tile, and of metal or other lath on

steel frame. Variations in workmanship are most apparent in regard to tapping, pointing, and the filling of head-joints. Tapping is being studied not only with relation to the effect of excessive downward tapping into place, but also with relation to plumbing both before and after initial set.

Special mention should be made of weather problems. The experiments are planned for the purpose of investigating the behavior of mortar with reference to the other variables in all types of climatic conditions. Summarized recommendations as well as the complete report are being published by the American Face Brick Association.

CRAZING

Development of Hair Cracks into Structural Cracks: (University of Michigan, Ann Arbor). This investigation was started in 1926 to determine whether hair cracks develop into structural cracks on alternate wetting and drying of neat cements and rich mortars. Though the data are being obtained very slowly, it appears that hair cracks become larger and deeper with alternations of volume change.

CURING

Rates of Evaporation and Absorption of Mortar and Concrete Specimens of Different Sizes and Shapes: (University of Colorado, Boulder, in cooperation with the U. S. Bureau of Reclamation and the Arch Dam Committee of Engineering Foundation). By frequently weighing large numbers of specimens of different sizes and shapes as they were exposed to the air after different periods of curing in water a very large quantity of data on the rates of moisture loss have been collected. Among the sizes and shapes of specimens were cylinders (2 by 4-in., 3 by 6-in., 3 by 12-in., 3 by 18-in., 4 by 14-in., and 6 by 12-in.) and beams (3 by 3 by 40-in., and 4 by 6 by 38-in.). It is reasonable to expect the rate of moisture loss to be more or less proportional to the surface volume ratio for a given mixture, period of moist curing, and type of exposure. This presumption was borne out in part. Other tests were made to ascertain the absorption rates upon re-immersion. The absorption rate is much higher than the rate of moisture loss, very substantial quantities of water being taken up by dry concrete during the first few seconds of immersion. These data are in process of preparation for publication.

Curing Concrete Pavements: (Kentucky State Highway Department and University of Kentucky, Lexington). The purpose of this investigation was to determine whether pavement protected with wet burlap for 24 hours is as satisfactory as that covered on the surface with calcium chloride following the 24-hour wet burlap curing. The concrete used was a 1:2:3.5 mix by volume field condition, with an average cement factor of 1.52. Washed bank sand and gravel of satisfactory gradation were used with standard portland cement averaging about 300 lb. in tensile strength at 7 days. Two 7 by 7 by 30-in. beams were made each day for 20 days; both were covered with wet burlap for the first 24 hours, after which one beam of each pair was surface-treated with calcium chloride. The specimens were tested in flexure and compression

at 7, 14, 21 and 28 days. During the construction of the pavement the concrete was covered over with wet burlap for the first 24 hours, after which every alternate 50-ft. section was treated with calcium chloride. Two cores were taken from each treated and untreated section. The results obtained from these tests indicate that there is no advantage in using calcium chloride, since almost equal strengths were obtained for both treated and untreated concrete, and the untreated concrete developed sufficient strength at 7 days both in flexure and compression to permit opening the pavement. A study of cracking of the pavement did not show any advantage of the treated over the untreated concrete.

When the project was nearing completion it was found that the supply of calcium chloride was exhausted. It was decided to omit calcium chloride from the last 3000 ft. of pavement, but to treat 2000 ft. of concrete with silicate of soda. The small amount of work done in this connection indicated that there is nothing to be gained by using this material.

Imperial Valley Curing Investigation: (California Division of Highways, Sacramento.) An extensive investigation is under way to determine the efficacy of various methods of curing concrete pavements. Bending tests are being made on beams cast in pavement and on cores drilled from the concrete. Tests made up to and including 28 days on all curing methods showed lower strengths than standard water curing. At 3 months, three of the methods gave slightly higher strengths.

Effect of Methods of Curing on Strength and Wear Resistance of Concrete: (Texas A. & M. College, College Station). Tests are being made to determine the strength and resistance to wear of 250 beams and 500 cylinders cured by means of calcium chloride, Hunt process, curcrete, silicate of soda, wet earth, regulated sprinkling, and no curing.

Curing of Concrete: (Ohio State University, Columbus). Researches were made to determine the effect of calcium chloride as a curing agent for portland cement concrete. These studies were made as a part of a graduate thesis, in cooperation with the Calcium Chloride Association, and will be published by the Engineering Experiment Station.

Comparison of Methods of Curing Concrete Pavements: (Wisconsin Highway Commission, Madison). This investigation covered comparative tests of various methods of curing, using wet earth curing as the criterion. The tests were run in 3 series of five 400-ft. curing sections. One-half the slab was cured with wet earth, and a wood header was placed down the center joint and tarred thereto to prevent seepage. The other half was treated with the various methods included in these studies. Three sets of beams of two each, one earth-cured and the other with special curing, were cast within road forms, and hand-finished composite specimens were made outside road forms. In addition, cores were taken at various ages.

Loss of Moisture from Concrete Cured by Various Methods: (Missouri State Highway Department, Jefferson City). The purpose of these tests was to

determine the relative efficiency of various curing methods in keeping concrete moist during the curing period. Weighed samples of concrete were placed in enameled pans 12 in. in diameter and 4 in. deep. Two samples were cured by each of the following methods:

(1) Wet burlap for eighteen hours followed by
    (a) Calcium chloride
    (b) Sodium silicate
(2) Curcrete applied immediately after molding.
(3) Hunt Process applied immediately after molding.
(4) Calcium chloride used integrally.

Though these tests have been completed, no report has yet been prepared for publication.

Effect of Different Methods of Curing on Strength of Concrete: (Pennsylvania Department of Highways, Harrisburg). This investigation covered a comparison of the value of wet straw, calcium chloride used integrally, and asphaltic emulsion sprayed on the surface as curing agents. Sections of a state highway were cured by these methods. Specimens were molded for strength determinations at various ages, and cores were taken from the road at the six-month and one-year periods. The strength of beams, cylinders, and cores was about equal. At the six-month period the calicum chloride and straw-cured cores gave a strength of 4100 lb. while those cured with the asphaltic emulsion were slightly lower. The beams and cylinders cured with calcium chloride were slightly higher at 7 and 10 days than either of the others, but at the 14 and 28-day periods the strengths were about equal.

Methods of Curing Concrete: (Iowa State Highway Commission, Ames). This problem was concerned particularly with curing of concrete pavement slabs. The investigation was conducted in four groups, each of which consisted of tests on slabs 10 ft. by 10 ft. by 6 in., made in a manner approximating ideal field conditions, and including from four to fifteen methods of curing. In the construction of the slabs longitudinal divider boards were spaced two and one-half feet apart, thus dividing the slabs into four strips 2½ ft. wide and 11 ft. long. These strips were removed one day before testing at ages of 7, 28, 90 and 360 days. Each strip was sawed transversely into 6 by 6 by 30-in. beams on which flexural tests were made. Compression tests were made on specimens prepared from the beams. The results indicate that the wet burlap moist earth method of curing is the most efficient method available; that other methods afford strength results of varying percentages of the results obtained for this method; that asphaltic coatings such as Curcrete and Hunt Process are 90 and 95 per cent as effective as this method; that calcium chloride on the surface is about the same; and that the original water content of the concrete must be maintained or even augmented for the most efficient curing.

A laboratory study has been undertaken to investigate the latter point, and to determine the effect of different methods of curing on cracking, scaling, and

volume changes of the concrete. The work on volume changes is well under way and the data obtained indicate greater daily volume changes for asphaltic coatings than for the other methods, especially the standard earth and water method.

Comparative Study of Wet Earth, Calcium Chloride, and Sodium Silicate for Curing Concrete Pavements: (U. S. Bureau of Public Roads, Washington, in cooperation with the Maryland State Roads Commission). A description of this project as well as the results of tests made up to one year was published in the September, 1928, issue of Public Roads. Observation of service behavior is made from time to time.

DAMS

Temperature Studies in an Arch Dam: (University of Alabama, University, Ala.). The purpose of this investigation was to determine the maximum temperature occurring in concrete after placing, the temperature at time of closure of the dam, and the annual range in temperature. Thermocouples were set in the concrete at time of construction, and readings have been taken each month for the past year. This investigation will probably be continued for another year.

Investigation of Models of Arch Dams: (University of Colorado, Boulder, in cooperation with U. S. Bureau of Reclamation and Engineering Foundation). This extensive study was undertaken to add to existing knowledge of stress distribution for design purposes, and is a part of the preliminary investigation of the Boulder Canyon Dam. The report of this Committee for 1928 (see page 444, Proceedings, A. C. I.), carried a complete outline of tests to be made on a model of the Stevenson Creek Dam, which have since been completed. Experimental work of similar nature was carried out on a model of the Gibson Dam, with auxiliary tests in flexure, tension, torsion, compression, volume changes, etc., somewhat less elaborate than those carried out on the Stevenson Creek model. It appears from the results obtained to date that models have great possibilities as aids to structural analysis of dams, as have also the auxiliary findings.

Model Tests on Hoover Dam: (U. S. Bureau of Reclamation at the University of Colorado, Boulder, in conjunction with Arch Dam Committee of Engineering Foundation). A model of plaster of Paris diluted with Celite to reduce the modulus of elasticity sufficiently to give measurable deformations is under construction. Young's modulus will be between 100,000 and 300,000 lb. per sq. in. and the model will be to a scale of about 1:200. Very extensive tests on cylinders (2 by 4-in., 3 by 6-in., and 6 by 12-in., on 3 by 3 by 40-in. and 4 by 6 by 38-in. beams) have been made on a great variety of mixtures and materials in finally selecting the materials and proportions to be used in the model. Extensive tests on the rate of drying out have been made, since plaster of Paris is plastic when moist and must therefore be in a dry condition at test. The methods of test will be similar to those used for the Stevenson Creek and Gibson models.

DURABILITY

Durability of Concrete: (Hydro-Electric Power Commission, Toronto, Canada). During the past year most of the work done in this investigation was a field study of the behavior of concrete structures under different conditions of service, with a total inspection of about seventy-five structures. In addition, laboratory studies are being made of different natural waters to determine their corrosive effect on concrete. The monthly variation in composition is being obtained of fifteen different waters ranging in type from a very pure, soft water, originating from swamps to a relatively hard water. The products resulting from the seepage of these various waters through the concrete are being determined, and an attempt is being made to duplicate in the laboratory the action of corrosive water on concrete as observed in the field.

A 3-yr. study of the efficacy of colorless waterproofing treatments for concrete surfaces, which forms a part of this investigation, has been completed. The results indicate that few of these treatments have any permanent waterproofing or protective value when applied to concrete surfaces.

Methods of Rendering Concrete Drain Tile Resistant to Alkali Attack: (Iowa State College, Ames). This project covers long-time observations of concrete samples which were treated with various chemicals and inert materials before immersion in alkali solutions. A report of this investigation will be published during 1930.

Resistance of Concrete to Waters of Acid Reaction: (State of Washington Department of Highways, Olympia). The purpose of this extensive investigation, which was started in 1927 and which will probably not be completed before 1931, is to determine the nature and extent of attack by waters having an acid reaction, and to study means of making concrete resistant to such attack. One series of tests has already been completed, and another is under way on tests of specimens exposed to artificially acidified slowly running water in the laboratory, and to natural waters of acid reaction. It is intended that the second series will cover such points as (1) relationship between volume of concrete and surface exposed, (2) depth of attack from the surface, (3) protection afforded by coatings and admixtures, and (4) comparison between artificially acidified water in the laboratory and a naturally acid stream.

Durability of Concrete: (Kansas State Agricultural College, Manhattan). The purpose of this investigation was to determine the resistance of concrete and concrete aggregates to alternate freezing and thawing and to exposure to alkali water, as well as to determine the effect of porosity on durability. Freezing and thawing tests were made on 300 concrete specimens of various water-cement ratios and mixes, and on 200 aggregate samples.

Field specimens were placed in 4 locations in Kansas streams known to contain alkali. The following are some of the results obtained:

(1) Field specimens of 1:5 or leaner mix show continued disintegration. Specimens of mixes richer than 1:5 are unaffected.

(2) From tests of specimens exposed to freezing and thawing it appears that:

(a) Alternate freezing of saturated concrete at low temperatures and thawing at room temperatures are a valuable means of determining durability of concrete.

(b) Variations in water-cement ratio of plastic, workable concrete have a very marked effect on its durability. A water-cement ratio of 1.0 is near the maximum permissible to obtain desirable durability of concrete under conditions of exposure.

(c) Use of unsound aggregate results in unsound concrete the resistance of the mortar to distintegration being only slightly effective in protecting the aggregate.

Deterioration of Concrete Silos: (Kansas State Agricultural College, Manhattan). The purpose of this investigation was to determine the causes of deterioration of portland cement concrete when exposed to action of ensilage liquors, and to develop methods of overcoming and preventing such deterioration. The tests were undertaken as the direct result of numerous requests received during the past five years for information on means of protecting the interior surfaces of silos from deterioration by the ensilage juices.

In carrying out this investigation, portland cement concrete specimens were prepared with varying mixtures and varying types of surface treatments, and tested for permeability before and after exposure to the silage juices. Synthetic solutions of ensilage liquors were prepared and the specimens were exposed to the action of these solutions under varying conditions of submergence, air exposure, temperature and concentration of solution. The interiors of five silos in the vicinity of Manhattan were treated with ten different protective coatings. The interior of each silo was divided into equal areas (usually 6 or 8), extending the full length of the silo, each area being treated with a different material. These treated silos are being examined periodically to determine the effectiveness of the surface coatings.

Protective Treatments for Concrete against the Action of Salt Waters: (U. S. Bureau of Public Roads, Washington). Mortar specimens treated in various ways are installed in the alkali water of Medicine Lake, South Dakota, and their condition noted from time to time.

FATIGUE

Fatigue Tests on Concrete: (Iowa State Highway Commission, Ames). Studies are under way to determine the effect of repetition of stresses on concrete. Tests were made on 6 by 12-in. and 4½ by 9-in. cylinders to determine effect of repeated loadings on modulus of elasticity and strength in compression. Some work was also done on the number of repetitions at different percentages of the ultimate loading. Apparently a relatively small number of repetitions of 62.5 and 75.0 per cent of the ultimate stress will cause failure.

FIRE RESISTANCE

Fire Resistance of Walls of Concrete Masonry Units: (Research Laboratory of the Portland Cement Association, Chicago). In this investigation the

various factors bearing on the performance of walls of concrete masonry units when subjected to standard fire exposure are being studied. The investigation was started in June, 1928 with the design and construction of suitable equipment for the conduct of standard fire tests and the installation of a block machine and mixer for the manufacture of the units. To date fire tests have been conducted on more than 80 wall panels 5½ by 6 ft. in size representing approximately two thirds of the test work scheduled for the investigation.

The test program is arranged to determine the influence of such factors as grading of aggregate, cement content, character of aggregate, design of masonry units, type of mortar, workmanship in laying up the walls, and application of plaster. In general, the tests are scheduled in groups or series to bring out the effects of each factor over a wide range. As the work progressed it was found desirable to include several miscellaneous tests. Valuable information is being obtained regarding the stability and safety of walls of concrete masonry both before and after severe fire exposure.

JIGGING

Effect of Jigging during Setting Period on Compressive Strength of Concrete: (University of California, Berkeley, Calif.). Tests were made on 1:4 concrete having a ¼-in. slump. For one group, the aggregate had an appreciable excess of fines, and in another group the proportion of fine aggregate was the minimum which would produce a workable mix. After molding, the specimens were subjected to jigging, which varied from one-half to 1½ hours and from 33 to 154 vibrations per minute, in accordance with methods described in the 1927 report of this Committee.

The maximum increase in strength of the jigged over corresponding unjigged specimens was 40 per cent. The average increase for Group 1 was 13 per cent and for Group 2, 19 per cent. The highest rate of jigging gave the best results for each group. For this condition, the average increase in strength for Group 1 was 31 per cent, and for Group 2, 23 per cent.

A second series of tests was conducted using two water-cement ratios, two gradations of aggregates, and two diatomaceous earths in varying proportions. The compressive strength was increased by jigging for all mixes used, and increased with time of jigging up to the maximum of one hour used in this series. Concrete made from an aggregate with an excess of fine material was benefited less than that made from a properly proportioned aggregate.

FLOW UNDER LOAD

Flow of Concrete under Continuous Compressive Stress: (University of California, Berkeley.) This investigation is being conducted in 3 series, the first of which includes tests on 4 by 14-in. cylinders subjected to constant compressive stress at 70 degrees F. as previously described in the 1928 report of this Committee.

The second series of flow tests has been started to determine the effect of type of aggregate and the effect of moisture conditions upon flow. All specimens were loaded at 28 days to 800 lb. per sq. in. The net flows (after cor-

recting for the changes in unloaded control specimens) at age of 90 days were as follows:

Type of Aggregate	*Flow in Millionths of Inches per Inch*
Sandstone	710
Basalt	680
Gravel	565
Granite	465
Quartz	387
Limestone	313

The third series of tests to determine the relative longitudinal and lateral flow of plain and reinforced concrete cylinders is now in progress. The cylinders are 10 in. in diameter and 20 in. long, two of them being reinforced with six ½-in. square bars enclosed within an 8-in. spiral. One reinforced cylinder and 1 plain cylinder were loaded to produce a stress of 800 lb. per sq. in. in the concrete. Test observations up to the age of 90 days show that the deformation due to load in the reinforced specimen is approximately ⅔ the deformation of the plain specimen at all ages. For the unloaded specimens the shrinkage deformation of the reinforced specimen is approximately ¾ that of the plain.

Flow of Concrete under Continuous Compressive, Flexural, and Tensile Stress: (University of Colorado, Boulder, in cooperation with U. S. Bureau of Reclamation and Arch Dam Committee of Engineering Foundation. See Proc. A. C. I., 1929, p. 444 for outline). Data have been obtained for loadings at various ages under air and water curing and the results are being worked up for publication. In general the findings accord with the published results of Davis and others in so far as the tests are parallel.

Plastic Flow of Concrete: (Ohio State University, Columbus). A correlation is contemplated of all work carried out on this subject to date for the purpose of publishing it, together with methods of application to engineering design computations.

MIXERS AND MIXING

Investigation of Concrete Paver Operation: (Minnesota Highway Department, St. Paul). The purpose of this experiment was to check the water supply equipment in use and the amount of concrete remaining in mixer drums from one batch to the next, and to make a time study of the mixer cycle on Minnesota paving jobs. Stop watch studies of the mixer cycle, water measuring tanks were calibrated, and the water supply equipment was inspected. The latter was usually found to be adequate, though the valves on water measuring tanks were inefficient in several cases. There was considerable variation in different mixers in time of charging, discharging, and entrance of water into the drum, which resulted in a variation in the time interval necessary for mixing and for complete cycle.

MODULUS OF ELASTICITY AND POISSON'S RATIO

Effect of Moisture on Strength and Modulus of Elasticity of Concrete: (University of California, Berkeley). Tests were made at ages of 35 and 142 days

on 6 and 12-in. cylinders of three water-cement ratios. Half the specimens were left in water until the time of test, and the remainder removed from the water and stored in dry air at 130 degrees F. for 7 days prior to test. All were tested at 70 degrees F. The results are given below:

Mix	*Strength, lb. per sq. in.*				*Secant Modulus at 800 lb. per sq. in.*			
	35 Days		*142 Days*		*35 Days*		*142 Days*	
	Dry	*Wet*	*Dry*	*Wet*	*Dry*	*Wet*	*Dry*	*Wet*
1:1⅔:3	3740	3150	5940	5400	2,770,000	3,270,000	4,060,000	4,640,000
1:2½:3	3120	2470	4870	3840	2,510,000	2,940,000	2,960,000	3,520,000
1:3¾:4½	1590	1400	2520	1695	2,020,000	2,740,000	2,100,000	2,800,000

It is evident that the effect of moisture is to lower the strength and to increase the modulus of elasticity, the strength range being relatively greater for rich mixes than for lean ones, and the modulus of elasticity range being relatively greater for lean mixes than for rich ones.

Modulus of Elasticity of Concrete (State College of Washington, Pullman). Data have been collected from the results of routine testing of concrete cylinders in the field as well as in the laboratory to determine whether concrete can be considered elastic, and if so, to determine the relation between the proportional limit and ultimate strength, as well as to determine the modulus of elasticity. The results of these tests were published in Bulletin 30 of the Engineering Experiment Station, in April, 1930.

Modulus of Elasticity and Poisson's Ratio of Concrete: (University of Colorado, Boulder, in cooperation with U. S. Bureau of Reclamation and Arch Dam Committee of Engineering Foundation). In connection with all compression tests now made in this laboratory both lateral and longitudinal strains are measured continuously to failure. A semi-autographic apparatus is used in connection with dial extensometers and compressometers. Hundreds of tests have been conducted in this manner and quantities of data have been obtained from 2 by 4-in., 3 by 6-in. and 6 by 12-in. compressive specimens for many different mixtures, aggregates, ages, and curing conditions. Some of these data are in preparation for publication.

Modulus of Elasticity and Poisson's Ratio (National Bureau of Standards, Washington). Tests have just been started on 24 by 48-in. cylinders made at the site of the Calderwood Dam in Tennessee from concrete containing crushed stone fragments ranging in size from five to six inches in diameter, to determine the deformations under load. Longitudinal deformations are being measured during the loading over 32-in. gage lengths along 6 lines equally spaced around the periphery, and also in 2-in. gage lengths at five different elevations. In addition, transverse deformations are being measured in five diameters at different elevations. It is hoped that the data obtained will be sufficient for a satisfactory determination of the modulus of elasticity and Poisson's ratio of the concrete.

Elastic Properties of Concrete: (Kansas State Agricultural College, Manhattan). This investigation has just been undertaken to determine the

modulus of elasticity and Poisson's ratio for concrete, particularly for that made from sand and gravel. At present the extent of the investigation is the trial of several different types of measuring instruments and the development of a new type.

Modulus of Elasticity in Tension, Torsion, and Flexure: (University of Colorado, Boulder, in cooperation with U. S. Bureau of Reclamation and Arch Dam Committee of Engineering Foundation). Many tests have been made on 3 by 12-in. tensile and torsion specimens, and on 3 by 3 by 40-in., and 4 by 6 by 38-in. beams for different ages and curings for the mixtures of the Stevenson Creek and Gibson models. Loads and elongations were taken for tensile specimens; loads and detrusions for torsional specimens; and loads and deflections for flexural specimens. The increment method was used since semi-autographic facilities for continuous testing are not available for these tests. Results are in preparation for publication.

PAVEMENTS

Stresses in Concrete Pavement Slabs under Concentrated Static Loads: (Iowa State College, Ames). This project was started in the spring of 1929 and complete data have been assembled on tests of one small slab, a report on which will be available at an early date.

Correlation of Pavement Condition and Soil Survey: (Michigan State Highway Department, Lansing). Tests were started in 1925 to determine and evaluate those factors which influence the condition of pavements. Three thousand miles of pavement have been studied, including field sketches of pavement condition summarized slab by slab, and correlation of the condition with slab characteristics, such as design, age, traffic, material, curing, reinforcement, character of subgrade, old road beds, and drainage. No definite conclusions are available at the present time.

Study of Methods Commonly Used for Removing Ice from Concrete Pavement Surfaces: Michigan State Highway Department, Lansing). This investigation is being made to determine the most economical and efficient material for removing ice with no detrimental effect on the concrete. Laboratory beams were made, frozen a number of times, and the surface film of ice removed with an application of sodium chloride, calcium chloride, or hot sand. Subsequent observations will be made of the surface condition when exposed to drying atmosphere.

High Early Strength Concrete in Pavements: (Pennsylvania Department of Highways, Harrisburg). A service test road was constructed to determine the relative efficiency of high early strength concrete obtained by (a) high early strength cement, and (b) a special mix. Sections of the road were built using high early strength cement in a 1:2:3¾ mix, standard portland cement in the same proportions and standard portland cement in a 1:1½:2½ mix. The project included four traffic lanes, two of which contained high early strength cement, and the other two the standard portland cement used in the 1:2:3¾ and 1:1½:2½ mixes. After approximately one year of traffic the road sections are all in excellent condition. The special mix and the mix using high

early strength cement were opened at one and two-day periods, depending on the beam strength of the concrete.

Effect of Variable Subgrade Conditions, Various Construction Practices, and the Use of Joints of Various Types on the Service Behavior of Concrete Roads: (U. S. Bureau of Public Roads, Washington, in cooperation with the Virginia State Highway Commission). A description of the various test sections of the Virginia Demonstration Road was published in the June, 1928, issue of Public Roads. Observations of the behavior test sections are being made from time to time.

PERMEABILITY

Permeability Tests of Concrete: (Kansas State Agricultural College, Manhattan). Permeability tests were made on 440 mortar specimens of various mixes and water-cement ratios at pressures varying from 10 to 100 lb. per sq. in. In these tests 3 by ¾ in. cylinders were cured in the moist closet for 24 hours and stored until test in stone jars containing distilled water. The water coming through the specimens was timed for rate of flow, and then titrated with N/20 HCl, using phenophthalein and methyl orange as indicators to determine the amount of lime which was dissolved. In another group of tests 1½-in. discs were sawed from 6 by 24-in. concrete cylinders made from portland cement and Quikard cement in the following mixes: Cement, sand from the Kansas River with a fineness modulus of 2.94, and crushed sandstone in the proportions of 1:1¾:3½, cement and total aggregate in the proportions of 1:3½, the water-cement ratio in each case being 0.7.

The results thus far show that a 1:2 mix was watertight at any pressure up to and including 100 lb. per sq. in. if enough water was used to make a good workable mix, but not so much that the mix is sloppy. That is, a water-ratio of 0.6 to 1.0 may be used, but 0.65 to 0.8 would be better. A 1:3 mix was watertight between the water-ratios of 0.6 and 1.0 and a 1:4 mix between the water-ratios of 0.7 and 1.0 at all pressures up to 100 lb. per sq. in. A 1:5 mix with a water-cement ratio of 0.8 was watertight up to 60 lb. pressure, but water flowed through when more pressure was applied, or if a higher or lower water-cement ratio was used.

Permeability of Concrete: (University of California, Berkeley). An investigation has been outlined to determine the effect of water-cement ratio on permeability of 2 by 6-in. discs.

Permeability Studies: (Portland Cement Association Research Laboratory, Chicago). Studies were inaugurated in the spring of 1928 to determine the influence of various factors on the watertightness of concrete. Apparatus was developed which permitted the making of simultaneous tests on a large number of specimens. The apparatus is so constructed as to permit measurement of the water passing through the specimens which consist of 6-in. diameter discs of varying thickness. The specimens may either be cast in special molds or cut from standard 6 by 12-in. cylinders.

Thus far tests have been made to determine the effect of the following factors on the permeability of concrete: Quality and quantity of cement paste, quantity and type of cement, duration of moist and air-curing, age at test, duration of the test period, thickness of specimen, amount of pressure applied, type of unit, method of molding, direction of application of pressure, uniformity of results, and influence of powdered and liquid admixtures. Results of some of the early tests are reported in the December, 1929, JOURNAL of the Institute.

Oilproofing Concrete (Detroit Edison Co., Detroit, Michigan). The purpose of this investigation was to develop a concrete, or a surface treatment for concrete, which would prevent the absorption of oil from transformers. Seven commercial surface coatings, 3 special cements, 2 integral compounds, and 10 concrete toppings of various mixes, aggregates, and methods of application were investigated. The concrete was molded into saucers 22 by 22 by 6-in. with a 2-in. depression in the top to hold the oil. These specimens were cured for 7 days, dried out for 14 days, treated with various coatings, and filled with light oil of the type used in transformers, the oil being left in the depression for various periods between 9 and 28 days. The specimens were then broken and a careful study made of the cross sections. The results obtained show that concrete can be made or surface treated in such a manner that it will shed oil without any absorption.

Waterproofing Concrete: (Iowa State Highway Commission, Ames). In this investigation tests were made to determine the efficacy of various methods of waterproofing concrete by surface treatments. A number of specimens were coated or painted and immersed in water, after which they were removed and weighed at fixed intervals. From the results obtained it appears that several relatively cheap asphaltic coatings would be quite satisfactory as waterproofers for concrete.

PIPE

Study of Loads on Concrete Pipe in Embankments: (Iowa State College, Ames). This study was continued with the collection of special data on the correlation of laboratory strength of pipe with field strength, and additional studies were made to determine the settlement, changes in diameter, and other phenomena necessary to correct interpretation of the loads caused by embankments.

Strength of Concrete-Encased Clay Sewer Pipe: (Iowa State College, Ames). The results of this investigation were published in the autumn of 1929 in Bulletin 93 of the Iowa Engineering Experiment Station. In addition to the results of strength tests of encased clay pipe, the bulletin includes data on the effect of temperature on strength of concrete.

PRODUCTS

Physical Properties of Cast Stone: (National Bureau of Standards, Washington). This study was undertaken with a view to establishing a federal specification for cast stone. Compression tests were made on 2 by 2-in. cylinders and the modulus of rupture was determined on 1 by 1-in. prisms using a 6-in. span.

In addition, rate of absorption tests were made, and weathering effect was determined by freezing at a temperature of 10 degrees F.

STRENGTH, COMPRESSIVE

Strength of Cement Mortar and Concrete: (Iowa State Highway Commission, Ames). The purpose of this study was to determine the relationship between the strength of cement mortar and the strength of concrete. Particular attention was given to comparison of values obtained in tensile tests of standard mortar briquets and compression tests of field specimens made during the construction of paving projects. The mortar strength tests were made as a part of the routine tests conducted for the acceptance of cement shipped to each paving project. Correlation of these tests with strength tests on field specimens was found to be practically impossible because of the number of variables encountered and the complexity of their relationships. Though work has been temporarily discontinued, these studies will be resumed when the effect of the variables can be more accurately evaluated.

Effect of Adding One-Half to Three-Quarters Inch Gravel and Also One-Half to Three-Quarters Crushed Quartzite Particles to a Neat Cement Paste: (University of Colorado, Boulder). These were miniature "plum or cobble" concretes (specimens about 3¼ inches in diameter). They were cast in watertight molds and only such an amount of stone as could be accommodated easily was added. The "cobble" specimens had compressive strengths about half those of the same paste without any "cobbles." The water-cement ratio was 42 per cent by weight. The weakening was probably due in part to lack of homogeneity (stone bearing on stone, splitting and wedging action) but may also have been traceable to bond failures between stone particles and paste.

STRENGTH, FLEXURAL

Relationship between Transverse and Compressive Strength of Concrete: (Kentucky State Highway Department and University of Kentucky, Lexington). A compilation was made of all available results obtained since 1925 in an effort to determine whether transverse or compressive strength results should be considered the fairer criterion of the quality of a concrete. Transverse tests were made using third point loading, and compression tests were made either on 6 by 12-in. cylinders or on pieces cut from broken beams. Below is a brief tabulation of the more important results:

Age in Days	*Strength, lb. per sq. in.*		*Factor*	*Number of Tests*
	Transverse	*Compressive*		
28	1010	3833	3.82	12
21	934	3737	3.99	12
14	936	3596	3.83	12
7	752	2833	3.76	4
28	616	3761	6.08	30

In addition, 23 tests at 28 days showed from 440 to 1141 lb. transverse strength and from 2250 to 5386 lb. in compression with a factor of from 3.84

to 7.03. It is evident that the aggregate is a factor affecting the transverse and compressive strength of concrete, and the results indicate that the compression test is the more likely to reflect the true value of the material. It seems feasible to state that concrete giving satisfactory compressive strength will also give satisfactory strength in flexure, and the resultant concrete will function properly in a pavement.

Comparison of Compressive Strength and Modulus of Rupture: (University of California, Berkeley). For the mixes tested, giving compressive strengths of 2000 to 4000 lb. per sq. in. at 28 days, the modulus of rupture was found to be approximately

$$(S_C - 2000)\ .11 + 450$$

where S_C is the compressive strength of the concrete.
The actual modulus may vary from the computed value by as much as 90 lb. per sq. in.

Masonry Flexure Tests: (University of California, Berkeley). Tests are in progress to determine the flexural strength of brick and tile masonry beams using a variety of cement-lime mortars, the beams varying in size from 8 by 4 by 24-in. to 24 by 12 by 54-in. Nearly 500 specimens are to be tested, including a group of adhesion and bond specimens.

Flexural Tests of Plain Concrete Beams: (New Hampshire University, Durham). This study was undertaken to determine the relation in modulus of rupture between the standard Olsen Laboratory Machine and certain field testing machines, thereby determining the exact stress in beams broken in the field. One hundred sixteen beams were made from water-cement ratio concrete designed for strengths of 2000, 2500, 3000, 4000, and 5000 lb. per sq. in. Such variable factors as curing, time of mixing, size of aggregate, etc., were carefully controlled to insure uniformity in concrete. Companion specimens for each batch were tested on each type of machine, the beams tested in laboratory on the Olsen machine being loaded at the third points of the span.

Standardization of Method for Determining Flexural Strength of Plain Concrete: (American Association of State Highway Officials). The purpose of this investigation was to design and adopt a standard apparatus and method of molding specimens for the determination of the flexural strength of plain concrete. Special apparatus has been designed and built, which is to be used in conjunction with a power testing machine. It is so designed that all forces applied to the specimen are coplanar and perpendicular to its axis, and the deformation due to applied load is entirely unrestrained.

Standardization of Methods of Making Flexural Tests of Concrete: (U. S. Bureau of Public Roads, Washington). These tests are being made in cooperation with A. S. T. M. Committee C-9 on "Concrete and Concrete Aggregates."

TEMPERATURE EFFECTS

Effect of Temperature at Time of Test on Strength of Concrete: (University of California, Berkeley). Tests were conducted on 6 by 12-in. concrete cylin-

ders of 1:2:4 and 1:3:6 mixes at ages of 28 and 135 days. All specimens were wet-cured, but a few days prior to test various groups were subjected to temperatures ranging from 25 degrees F. to 130 degrees F.; some were dried while others were kept wet. In general, the test results show a progressive decrease in strength with an increase in temperature at time of test. The maximum effect developed in the 1:2:4 wet specimens tested at 135 days, the strength ranging from 140 per cent to 85 per cent of the strength at 70 degrees F. The leaner mixes were not affected so markedly as the 1:2:4 mixes, nor the dry specimens so much as the wet.

Effect of High Curing Temperature on Strength of Concrete: (University of California, Berkeley). Tests were made on 2 by 4-in. mortar cylinders of 1:2½ and 1:5 mixes by volume. The curing temperatures were 70, 100, 140 and 180 degrees F.; the time of curing 18, 24, and 36 hours for each temperature, a fog being maintained during this period by means of an atomizer. Some of the specimens were stored dry at 50 per cent relative humidity, and some were stored wet until time of test at various ages. High temperatures increased the early strength of cement mortars, the maximum effect being produced by a temperature of 140 degrees F. maintained for from 24 to 36 hours. In general, at ages of 7 days or more, a curing temperature of 180 degrees F. produced lower strengths than a temperature of 100 degrees F. After the age of 7 days, specimens cured at normal temperatures and stored in water exhibited higher compressive strengths then did similar specimens cured at high temperatures and stored in water.

Further tests are in progress on 3-ft. cubes of concrete insulated on all sides, which indicate to date that mass concrete develops a temperature of about 155 degrees F. within 20 hours when using 9 sacks of cement per cubic yard. The 1-day strength of the mass concrete is much greater than the strength of corresponding 6 by 12-in. cylinders cured at 70 degrees F.

Thermal Expansion of Concrete: (University of California, Berkeley). Tests are in progress to determine variations in coefficient of thermal expansion in which variables are water-cement ratio, richness of mix, type of aggregate, curing condition, and age of specimen. Tests on 3 by 3 by 40-in. bars for temperatures between 15 and 130 degrees F. indicate the following results:

(1) The coefficient of thermal expansion varies with the richness of the mix, the value for a 1:3 mix being about 6 per cent higher than for a 1:6 mix of similar materials.

(2) The coefficient is about 5 per cent higher for water-soaked specimens than for air-dry concrete.

(3) There is no appreciable variation in the coefficient for ordinary ranges of temperature.

(4) The variation in the coefficient for mixes of various consistencies is negligible.

(5) The type of aggregate has a marked influence on the coefficient, the actual values for 1:4½ mixes of aggregates of identical gradations being as follows:

Quartz	0.0000066	per 1 degree F.
Sandstone	0.0000065	" "
Gravel	0.0000060	" "
Granite	0.0000053	" "
Basalt	0.0000048	" "
Limestone	0.0000038	" "

(6) The coefficient of expansion for air-dry concrete cured normally for 2 months and then subjected to 100 alternations of temperature between 15 and 130 degrees F. was decreased about 14 per cent from the value obtained for concrete not subjected to alternations of high and low temperatures, but stored at a constant temperature of 70 degrees F.

Variations in Temperature in Plain Concrete Slabs as Affected by Type of Curing: (Texas A. and M. College, College Station). Investigations have been started to determine variations in temperature within concrete slabs. Tests are to be made in the field, and temperature records taken with resistance wires. Laboratory tests will be made to parallel the field investigation, using the same materials in 6 by 6 by 32-in. beams and 6 by 12-in. cylinders.

TESTS AND TEST METHODS

Effect of Removing the Water that Gathers at the Top of Mortar or Concrete Soon After Placing: (University of Colorado, Boulder). Comparison specimens were made in water-tight molds. As the water gathered it was carefully removed by blotters from some of these. The amount removed was determined by weighing the specimens at intervals. Except in the case of very rich mixtures and a great excess of mixing water, the water that gathered at the tops of the specimens that were not blotted returned within the mass after a few hours. All specimens were stored in water after one or two days. Those which had been blotted absorbed more water during the early storage period but the strengths of the two classes were practically identical. The shrinkages were equal and it is evident that the removal of the water did not add to the amount of settlement (decrease the voids) and that the effective water-cement ratio was not changed from what it was for the specimens from which no water was removed. These results would indicate that it is incorrect to use a corrected water-cement as a measure of leakage effect unless added compaction results from the loss or removal of the water. It has been demonstrated that any method of water removal that does cause the particles to move closer together will lower the water-cement ratio and increase the strength and density.

Variations in Strength of Concrete Cylinders Due to Rodding: (Kentucky State Highway Department and University of Kentucky, Lexington). The purpose of these tests was to determine variations in strength of cylinders not rodded in accordance with standard methods. The only variables permitted in the investigation were the methods of rodding and placing, which consisted of: (a) use of standard rod with 4-in. layers of concrete varying the number of roddings; (b) use of standard rod with 25 roddings varying the thickness of the layers; (c) 4-in. layers rodded 25 times with a variation in size of rod from

¼-in. round to a 2 by 4-in. wooden rod; and (d) placing without rodding or tamping, but pushing down with trowel. It was found that (1) standard rodding produced satisfactory results both as to strength and density, while (2) concrete thoroughly rodded with a ⅝-in. or larger rod, total roddings being as many as 75 in some cases, gave satisfactory strength, but was less dense than concrete rodded in accordance with standard methods. It may be concluded that if reasonable care is used in tamping concrete into the mold and sufficient tamping is done, use of a standard rod is not important.

Relationship between End Condition and Strength of Concrete Cylinders: (Kentucky State Highway Department and University of Kentucky, Lexington). Studies were made to determine the value of true end condition and the most effective way of obtaining it. Tests were made at 28 days on specimens essentially alike except for end conditions, which varied from true to $\frac{3}{16}$-in. concave and $\frac{3}{16}$-in. convex, in addition to one set which had 14 per cent end area chipped off. Cement mortar and sand bearings were used. The following are the outstanding conclusions drawn from the results: (1) the end condition of a cylinder should be carefully noted upon its arrival at the Laboratory, and if convex should be rubbed to a plane surface or capped with a suitable cap. In no case of this type should sand bearing be used; (2) if the end is concave, it can be rectified by rubbing down, or a thin sand bearing of confined sand, not to exceed ⅛ in. can be used; (3) if the specimen is slightly irregular, as in the case of finishing with a trowel, it should preferably be rubbed down to a smooth surface, though a thin sand bearing can be used; (4) reduction of 14 per cent in end area has no effect on strength obtained; (5) if the true value of a concrete is to be obtained from the cylinder it must be made with perfect bearings on each end. Fair to good results may be obtained with the sand bearing or added cap, but neither of these methods are reliable, and it is important that the ends of the cylinders be correctly finished. This laboratory has recently built and installed a cup grinding machine for finishing cylinders, but results from the use of this machine are not yet available.

Effect of Size of Cylinder on Strength of Concrete: (University of California, Berkeley). Cylinders varying from 2 to 12 inches in diameter and two diameters in length were made from an identical mix, using ½-in. maximum size of aggregate. One group of specimens was stored in air, while a second group was coated with Inertol and stored in a continual fog. Variations in moisture content of test specimens of various sizes were the cause of considerable variations in strength. The strength was not materially influenced by size of test cylinder if all other conditions, including the percentage of moisture in the specimen at time of test, were maintained constant, and if the maximum size of aggregate was small with respect to the diameter of the cylinder. With ½-in. aggregate the strength was not influenced, provided the diameter of the cylinder was not less than 3 inches (6 times the maximum size of aggregate).

Effect of Size of Cylinder on Strength of Concrete and Mortars: (University of Colorado, Boulder). Several hundred of comparative tests have been made

on 2 by 4-in., 3 by 6-in., and 6 by 12-in. cylinders of mortars and concretes in which the aggregates did not exceed ¾ in. (¼ diameter of 2-in. cylinder).

For similar curing and test conditions, the variations between specimens of different sizes is no greater than between companion specimens of the same size. Lateral extensometers and longitudinal compressometers and semi-autographic recording devices have been developed and used in the majority of these tests. The stress-strain curves, both lateral and longitudinal, are similar throughout. Recognition of this as fact opens up a fruitful field for research by smaller laboratories in the realm of one and two-man projects in which studies can be made on results from the smaller sizes of specimens. These tests included varied curings and test conditions and for these cases the agreement is much less perfect because of the differences in the rates of drying out, etc. for the different sizes of specimens. A number of tests were made on 2 by 4-in. specimens in which the ¾-in. maximum size of coarse aggregate particle was exceeded, particles up to nearly 2-in. being included in some cases. For such specimens the strengths were much more erratic but the maximum strengths attained were about the same as those from the same concrete in larger specimens. The minimum strengths were much lower, however, depending upon how much such large particles lay in the specimen. The least strengths were obtained when large particles lay on a bias. Failure then occurred by sliding along the inclined bedding plane. Many of these results are in process of preparation for publication.

Study of Methods for Determining the Height of Cores Drilled from Concrete Structures: (U. S. Bureau of Public Roads, Washington). These tests are being made in cooperation with A. S. T. M. Committee C-9 on "Concrete and Concrete Aggregates" to develop a standard way of determining height of cored cylinders.

VOLUME CHANGES

Volume Changes in Concrete Due to Changes in Moisture Conditions: (University of California, Berkeley). This is a continuing investigation, the earlier results of which are presented in the 1928 report. A series of specimens was made using various types of aggregate but for which all other factors such as gradation, cement factor, etc. were constant. Tests show that volume changes are approximately the same for concrete having limestone, quartz and granite as aggregates. Gravel and sandstone concretes exhibit volume changes about twice as great as for the aggregates just mentioned.

A second series of tests of gravel concrete, using 1:4 and 1:6 mixes and water-cement ratios of 0.98, 1.07, and 1.16 for each mix show:

(1) Contraction in air is greater for mixes of high water cement ratio than for those of low water cement ratio, the effect being most pronounced for the rich mixes,

(2) In general the expansion in water is greater for the mixes of low-water cement ratio, but the difference is not marked.

Volume Changes in Concrete Due to Changes in Moisture Conditions: (University of Colorado, Boulder, in cooperation with U. S. Bureau of Reclamation

and Arch Dam Committee of Engineering Foundation). These tests consisted in length measurements taken at intervals on 3 by 3 by 40-in. beams (similar to those used by Davis) and were obtained for the mixtures of both the Stevenson Creek and Gibson models for various combinations of air and water curing. In general the results accord with previously reported findings by Davis and others.

Volume Changes in Concrete: (University of Michigan, Ann Arbor). This investigation was started in 1902 to determine the changes of volume occurring in neat cement and rich mortar bars at various ages under different conditions. Results obtained at various periods have been published in current engineering literature.

Volume Changes of Neat Cements: (Lehigh Portland Cement Co., Allentown, Pa.). This is a continuation of a project reported in 1928 in which data are continually being obtained on the behavior of test bars under various conditions of exposure. Numerous interesting relations have been disclosed or indicated between behavior of bars under normal and accelerated tests and the constitution of the cements used. In this connection, it may be mentioned that a small conditioning room maintained constantly at a temperature of 70 degrees F. and 50 per cent relative humidity affords a means of comparing shrinkage of bars under definite storage conditions. The indications thus far are that the majority of "normal" cements are much alike in their shrinkage characteristics, but enough exceptions are found to warrant extensive studies into the causes and possible control.

Volume Change of Concrete: (Kansas State Agricultural College, Manhattan). The purpose of this investigation was to determine the reason for the relatively greater number of shrinkage cracks which appear in sand or sand-gravel concretes as compared with those in concrete in which both fine and coarse aggregates are used. Readings are being taken at definite periods on 151 specimens (4 by 6 by 24-in. beams), 86 of which are over one year old, and only 30 of which are less than 100 days old, to determine the effect of the following factors on volume changes:

(1) Type of coarse aggregate,
(2) Variation of material used as total aggregate,
(3) Type of sand in mortar mix,
(4) Type of sand in concrete mix,
(5) Quantity and type of cement,
(6) Variation in water-cement ratio,
(7) Use of various admixtures.

Data from this investigation were published in a paper by Scholer and Dawley on "Volume Change of Concrete," in the Proceedings of the American Society for Testing Materials for 1930.

Study of Volume Changes: (Research Laboratory, Portland Cement Association, Chicago). Various factors affecting volume change of concrete are being investigated. These include effect of regaging and remixing, size and shape

of specimen, absorptive form, curing, coatings, admixtures, fineness, type and storage of cement, cement content, paste ratio, water-cement ratio, type and kind of aggregates, ratio of fine to coarse aggregate, moisture loss and vibration during mixing. The studies to date have brought out the inter-relation of some of the principal factors involved in these changes and a method has been evolved for estimating the relative shrinkage of various concrete mixtures.

WEAR

Relationship between Cement Factor and Wear and Strength of Concrete: (Kentucky State Highway Department and University of Kentucky, Lexington). The purpose of this investigation was to establish an economical cement factor as a basis of control for pavement concrete. A concrete mix was used in which the fine aggregate was 1.2 times the voids in the coarse aggregate, with a cement factor varying from 1.5 to 1.7 bbl. per cu yd. Comparisons were made of different aggregates in beams, cylinders, and 9-in. balls. Below is a summary of the tests made using stone and gravel:

Cement bbl. per cu. yd.	*Coarse Aggregate*	*Water-Cement Ratio*	*Wear Concrete Balls* %	*28-Day Strength*		*Strength Comp. Specimen at 42 Days*	
				Compressive	*Transverse*	*Cylinders*	*Cores*
1.5	Stone	0.74	19.4	3606	860	5061	4888
	Gravel	0.70	19.4	3206	643	3732	3300
1.6	Stone	0.70	17.5	3273	817	4465	4690
	Gravel	0.63	15.9	3899	712	3856	4300
1.7	Stone	0.68	15.0	4361	912	4521	4725
	Gravel	0.60	11.7	3585	692	3990	3990

The above data indicate that 1.5 bbl. of cement per cu. yd. of concrete with 5¾ gal. of water using aggregate that passed a standard specification will give sufficient strength both in tension and compression to insure good concrete pavement.

There seems to be no good reason why concrete made with crushed stone should require from 0.1 to 0.2 bbl. more cement than that made with gravel as is the case with the 1:2:3.5 mix commonly used.

Workability of Concrete: (Ohio State University, Columbus). As a means of standardizing concrete from central mixing plants, tests are being made to develop a satisfactory workability meter, after which a thorough study will be made in an effort to determine why some mixtures of the same proportions are harsh and others are smooth.

Workability of Portland Cement Mortars: (National Bureau of Standards, Washington). This is a continuation of the study described in the paper on "Cement as a Factor in the Workability of Concrete," which appeared in the 1928 Proceedings of the A. C. I. in which the effect of various portland cements on the workability of mortars is described, as well as a discussion of a means of measuring this workability. Further tests have been made for measurement

of workability as described in the foregoing paper, but at present full attention is being given a modified McMichaels viscosimeter, using various mixes with various water content, as well as various gradings of sand.

4—Reinforced Concrete

BOND

Bond Resistance of Reinforced Concrete Beams under Continued Load: (T. & A. M. Dept., University of Illinois, Urbana). A group of 24 beams were loaded continuously over a period of several months by means of jacks and heavy, calibrated spiral springs to determine the effect of continued loading of various intensities on bond-slip relations. Slips and strains were measured at various points in the beams at regular intervals of time. There was a total of 40 beams in all, together with auxiliary compression and pull-out specimens.

BRIDGES

Study of Behavior of Reinforced Concrete Arches During and Immediately Following Construction: (State Highway Board of Georgia, East Point). This investigation was conducted on an arch bridge near Eatonton, Georgia. Measurements were taken to determine the initial behavior of an open-spandrel reinforced concrete arch rib. Readings were first taken during placing of the concrete in the arch ribs and continued throughout the construction of the bridge and for a month thereafter, a total period of about 4 months. The work included measurement of strain in steel and concrete, beginning with zero strain while the concrete was being placed; determination of the compressive strength, modulus of rupture, and modulus of elasticity of the concrete used in the arch rib at various ages; measurement of the vertical movement of the arch rib at the crown, beginning just after the last section of the rib had been completed; measurement of the movement of abutments; measurement of temperatures at various points in the arch rib; and measurements of movements in expansion joints in the decks. Full details of this investigation were reported in the Proceedings of the American Society of Civil Engineers, page 2279, November, 1929.

Tests on Arlington Memorial Bridge: (National Bureau of Standards, Washington). Tests on one of the arches of the Arlington Memorial Bridge are being made by the National Bureau of Standards in conjunction with the Arlington Memorial Bridge Commission to obtain data on the structural behavior of the arch during and after its construction. Arch span No. 7 selected for testing purposes is 177 ft. 4 in. in clear span, and has a rise from springing line to crown intrados of 26 ft. 8 in. Construction of the arch was begun in October, 1928, and it is now completed, with the exception of the roadway and sidewalk paving surfaces.

The temperature of the concrete in the arch barrel has been measured at intervals since the concrete was placed. Other measurements include the deflections and strains of the arch barrel caused by different temperature and load conditions. The concrete temperature has been measured with resistance thermometers and thermocouples, the thermometers being connected to a

potentiometer recorder for sixteen stations. Deflection observations are obtained by means of clinometers which are used on a continuous line of 5-ft. stations extending over the back of the arch and a portion of each supporting pier.

Strain measurements are made at selected points, strain gages being used on the extrados, and electric telemeters buried in the concrete are used at the intrados. The measurements will be continued until data have been obtained on the effects of temperature changes on the deformations of the arch.

Stress Reduction in Concrete Arches by Means of Hydraulic Jacks During Construction for Adjusting the Axis to its Most Favorable Position: (U. S. Bureau of Public Roads, Washington, in cooperation with the Oregon State Highway Commission). Studies are being made in accordance with Freyssinet's method of reducing stress in concrete arches by means of hydraulic jacks.

Investigation of Reinforced Concrete Columns: (American Concrete Institute Committee 105). An extensive investigation on reinforced concrete columns is being carried out at Lehigh University and at the University of Illinois by Committee 105 of the American Concrete Institute. The purpose of this study is to establish the fundamental relationships between load, elastic properties and ultimate strength of reinforced concrete columns as influenced by variations in size, quality of concrete, curing of concrete, amount, arrangement and quality of reinforcement, fireproofing, rate and method of loading and the effect of continuous loading over long periods of time.

The original program includes a total of 531 reinforced specimens and 64 unreinforced specimens. To this number an additional series of 24 specimens has recently been added.

The size of specimens ranges from 8 in. in diameter by 5 ft. long to 32 in. in diameter by 17 ft. 6 in. long. Most of the specimens, however, are of the smaller size. Concrete strengths vary from 2000 to 8000 pounds. per square inch. Sixty are being held under design loadings over a period of one year during which time periodical strain gage measurements are being made to determine the amount and rate of time yield. Measurements are made on companion specimens not under load at corresponding intervals to determine shrinkage effects.

In 4 out of a total of 6 series comprising the original program the work of the two laboratories is intended to be identical. The larger columns are all being tested at University of Illinois where a 3,000,000 pound hydraulic testing machine has recently been installed. Some of the specimens will utilize this machine to practically its full capacity.

Effect of Stressing Steel Encased in Concrete Above Its Yield Point: (University of Colorado, Boulder). Plain and spirally reinforced 6 by 12-in. concrete cylinders were cast each with a single ½-in. square structural steel bar along its axis. The bars had milled ends and projected about ⅛-in. from each end of the cylinders. This required that a bar be stressed to the yield point of the steel before any load bore directly on the concrete. In some specimens the bars were greased and in others not. There were also controls of plain concrete, and spirally reinforced specimens with no bar. Still other

specimens had the bar ground flush and in others the bar did not extend quite to the ends of the specimens. Both lateral and longitudinal strains were measured. While the findings are not all decisive, two facts were demonstrated in so far as the conditions of these tests are concerned.

(1) The plain concrete specimen with bar projecting, but without spiral, split about the time that the yield point of the steel was reached.

(2) The spirally reinforced cylinders with projecting bars did not split. The bar shortened and became flush with the specimen within its yield point range and without visible damage to the concrete. Finally the bars buckled within the specimen after the maximum load was passed and the concrete badly punished.

These tests were run as a reconnaissance of what might be expected in a concrete column if the yield point of the steel is exceeded due to shrinkage, flow, or other cause. The tentative conclusion is that the result should not be serious in a well-spiralled column but it is to be expected that splitting would occur at the yield point, if not earlier in a tied column or a block of plain concrete, in which similar steel was imbedded.

REINFORCING STEEL

Design of New Type of Steel Reinforcing for Large Concrete Conduits: (Iowa State College, Ames). This investigation has been under way for some time and a patent has been secured on a new steel reinforcing. Tests were made at the Indianapolis plant of the Independent Pipe Company on several sections of concrete pipe reinforced with this special steel. The results of the tests will be available soon.

Investigation of Hooks as Anchorage in Reinforced Concrete: (Washington University, St. Louis, Mo.). The purpose of this investigation is (1) to determine the effect of varying strength of concrete, (2) effect of radius of hook bend, (3) effect of kind of bar (plain or deformed) on hook resistance, (4) effect of shape of hook on anchorage resistance, semi-circular hooks compared with hooks of changing radius, and (4) to develop a more efficient hook than the Joint Committee 8d. hook. Sixty anchorage specimens 8 by 8 by 16-in. blocks have been tested to date, including load-slip studies on two grades of concrete for both plain and deformed straight bars, two sizes of semi-circular hooks, and compound-circular hooks. Slip is measured internally, at 2 points on straight rods, and at 2 points of tangency on all hooks, by means of Ames dials attached to indicator rods which are welded to the reinforcing bars. The results obtained thus far indicate that (1) the carrying capacity of hooks tested varies directly with compressive strength of concrete; (2) amount of slip varies inversely with compressive strength of concrete; and (3) compound-circular hooks are more efficient than semi-circular hooks. It is proposed to make an experimental analysis of the load-slip relation, including such factors as stiffness of hooks, sliding friction, and distribution of steel stress. Tests are also planned in which the above forms of anchorage will be used in beams.

5—SUGGESTED RESEARCHES

CEMENT

Development of satisfactory method for making accurate particle size separations of relatively large quantities of cement.

A satisfactory method for determining the actual diameter of finely divided particles.

Determination of particle size and size distribution of finely divided materials including cement. Should include study of air analyzer, Noebel elutriator, microscopic projection, or other methods.

Effect of hot cement on temperature and behavior of fresh cement on properties of hardened concrete.

Use of high strength cement in tests of sand.

Review and comparison of foreign and American methods of testing cement.

AGGREGATES

Development of a reliable test for absorption of fine aggregates.

Effect of organic material in fine aggregates on resistance of mortar and concrete to freezing and thawing.

Effect of surface texture or mineral composition of aggregates on transverse, tensile, and compressive strength of concrete.

Effect of heating aggregates and water on strength of concrete.

Volume change of different types of aggregate when subjected to wide ranges in moisture content and in temperature.

Investigation of properties of cinder concrete; influence of cinder aggregate on corrosion of reinforcing.

Methods of determining durability of fine and coarse aggregates.

Methods for testing the quality of sands for use in concrete (shale content, strength, and resistance to weathering and abrasion, etc.)

Effect of coatings on coarse aggregate on strength of concrete.

Effect of grading of fine aggregate on properties other than strength of mortar and concrete.

Effect of aggregate size upon strength, Young's modulus, Poisson's ratio and other properties, with special reference to the larger gradings such as those which result when cobbles are used in mass concrete.

PLAIN CONCRETE

Effect of vibration during setting on strength of concrete.

Effect of temperature at time of test on strength of concrete.

Effect of calcium chloride and sodium chloride on hardened concrete and methods of protection against their action.

Effect of long-continued mixing on strength of concrete.

Influence of high pressure steam curing on strength, volume change, and resistance of concrete to corrosion in sulfate solutions.

Study of fatigue of concrete under (a) slowly applied loads, (b) impact, (c) high frequency vibration.

Effect of high and low temperatures on strength of concrete at different ages.

Investigation of the uniformity of concrete in deep sections when wet mixtures are used.

Study of the influence of moisture content at time of test on flexural, compressive, and tensile strength of specimens of different size.

Strength relations for different types, shapes, and sizes of mortar and concrete specimens at different ages.

Development of methods of making absorption tests of concrete products.

Study of the durability of finish coat stucco mixtures.

Effect of admixtures such as inorganic silt or clays, diatomaceous earth, etc., on strength, bond, permeability, workability, yield and resistance to weathering of concrete.

Temperature in concrete slabs as influenced by curing methods.

Effect of various factors on volume changes due to (a) temperature, and (b) moisture changes.

Study of deformation or flow of concrete under sustained load.

Tests to determine workability of concrete.

Study of effect of admixtures on workability of concrete.

Simple method of designing concrete mixtures which will recognize that the "character" as well as the grading of the aggregate affect the strength of the concrete.

Laboratory tests for determining the resistance of concrete to weathering.

Effect of percolating water on hydraulic structures.

Study of maximum temperatures attained near centers of concrete masses.

Extent and effect of shrinkage cracks in arch dams.

Air deterioration of concrete in different humidities.

Moisture gradient through masses of concrete.

Magnitude of segregation encountered when concrete is discharged from paving mixer.

Study of internal friction in concrete.

Development of a practical consistency regulator.

Study of causes of scaling of concrete.

Field study of joints in road slabs to determine types least susceptible to spalling due to curing. Particular attention to be given to behavior of dummy joints.

Study of methods of controlling movement of slabs—similar to rail creep.

Determination of that grading of sand and gravel which when used as concrete aggregates and designed by the water-cement ratio method will give the least cost per cu. yd. of concrete.

REINFORCED CONCRETE

Study of the effect of coatings and admixtures on the bond resistance of concrete.

Investigation of the initial stresses developed in steel and concrete due to shrinkage, and their effect on the stresses in flexure.

Study of shearing stresses in webs of shallow beams and methods of web reinforcement.

Effect of mortar coating on reinforcing bars on bond resistance.

Effect of repeated and continued loads at high stresses (1) on bond, and (2) on direct compression.

Bond tests of high early strength concrete.

Initial stress developed in steel and in concrete due to setting.

Effect of curing water on reinforcing steel and depth to which such water permeates reinforced concrete members.

Study of column splices, tied, spiralled, combination, and composite.

Bond—hooks vs. straight bars, radius of hook, etc.

Study of behavior of reinforced concrete arches during and immediately following construction.

Shearing stresses due to concentrated loads on floor slabs.

Effect of concentrated load on a cantilever slab with particular application to most economical design of bridge of width just sufficient to permit passing of two vehicles.

Readers are referred to the JOURNAL *for May, 1931, for discussion which may develop. Such discussion should reach the Secretary by April 1, 1931.*

Discussion of Paper by Lars Jorgensen

Memorandum on Arch Dam Developments*

BY FREDRIK VOGT†

The author is to be congratulated for his pioneer work on the development of arch dam construction.

As to the safety of single span arch dams, the records are rather convincing: No one has failed, while a great number of dams of other types have failed for different reasons. It may be objected that the Moyie River and the Lanier Lake arch dams failed,[1] but what the records really tell, is, that the proper arch dams did not fail in spite of the failure of a gravity abutment wing in one case and of a faulty rock abutment in the other case. The lesson is therefore not that the arched structure was weak, but, on the contrary, that in this case it was strong enough to carry the water-load even though the regular support suddenly broke away for half the height at one side.[2] In addition, the failure repeats the old lesson, that a gravity dam on a faulty foundation is a dangerous structure.

Some problems in dam construction are common for all types of dams, which is especially true for the problem of how to make permanent and impermeable concrete. It may in this connection be worth while to refer to the comprehensive investigations carried out by the Norwegian Engineering Society on disintegration of concrete in dams, particularly when exposed to water with small silt content, but high acidity, as very often is found in high mountain and sub-arctic climates.[3] The self-tightening of the concrete referred to by the author, and well known for dams

*A. C. I. *Journal*, Sept., 1930; *Proceedings*, V. 27, p. 1.

in southern climates, can not be counted upon when it is exposed to this type of water. On the contrary, all seepages are then slowly increasing and the cement correspondingly dissolved, if seepages exist.

In addition to this problem, the arch dams have their own problems, namely the analysis of stresses and the design of the dam according to this analysis. Not many special problems in civil engineering have been so much discussed during the later years, as the analysis of stresses in single span arch dams. Most of the investigations, however, have been merely mathematical analyses, and the problem goes deeper than to a clever application of mathematics. A mathematical analysis is indispensable, but it can only give the consequences of certain assumptions, and positive information on what assumptions have to be made is still more indispensable. It is a well known fact that tensile cracks can be observed in structures where the usual theory calls for compressive stresses, and also that some of the earlier mathematical studies on arch dams indicated unavoidable horizontal cracking due to vertical tension at places where no cracks or indication of cracks are observed. If something is wrong, it is hardly the mathematics in itself, but the assumptions on which it is based.

Two main problems, which can not be said to be conclusively solved at present, are: (1) What is the time effect in continuously stressed concrete, and, (2) What are the shrinkage and swelling (volumetric changes) in concrete of dams, including volumetric changes due to chemical changes, temperature changes, and moisture changes, and how are these volumetric changes distributed over the section.

As to the time effect, or flow, much basic information is obtained particularly by Professor R. E. Davis[4], and his results are confirmed by tests at the University of Colorado.[5] The main result seems to be that the flow of concrete under continuous load is about proportional to the stresses, at least up to twice the working stresses. Hence the flow does not change materially the distribution or magnitude of the stresses due to load, but it

[4]"Modulus of Elasticity and Poisson's Ratio for Concrete," *Proc.* Am. Soc. Test. Mat., 1929, Part II.

[5]Gilkey and Vogt, discussion on this paper, loc. cit.

reduces the magnitude of the stresses due to volumetric changes.[6] For wet concrete this reduction seems to be about 40 per cent for slow changes, for dry concrete the reduction is much greater. These results, however, need to be confirmed, and the tests need to be extended to different kinds of concrete and stone under different conditions. Also the effect of variable loads should be investigated, before the problem can be characterized as solved.

Laboratory tests have given information on the volumetric changes which can be expected under certain conditions, but before these results can be used in the analysis of large dams, it is necessary to know the conditions in the interior of the mass. The temperature changes in the interior can be estimated with fair accuracy, but the moisture changes differ considerably from one case to another, hence also the actual magnitude of the shrinkage is variable. In a great number of dams the writer has found variations in shrinkage from 0 to 0.02 per cent according to type of concrete, method in concreting, and climate. Before a stress-analysis can be claimed to be fairly accurate, this matter has to be investigated very carefully. The writer has tried to compile information on this subject,[7] but a cooperative work by all interested parties is needed before the matter can be solved.

The author has introduced grouting of the joints in order to eliminate at least partly the effect of the volumetric changes. If the reservoir is filled before grouting, the dam is exposed to shrinkage stresses, and if the joints are grouted too early, the subsequent shrinkage will produce shrinkage stresses in the final state of the dam. For large dams the radiation of the initial heat demands several years, and if the dam must be put in use before the radiation is completed, the choice of a proper time for grouting is a problem which only can be solved by means of intimate knowledge of the volumetric changes. Furthermore, changes in temperature and moisture content, and in the distribution of these, go on with the times, and cause volumetric changes, which can not be counteracted by grouting. The problem of volumetric changes should therefore not be neglected because of the grouting.

[6]Gilkey and Vogt, discussion "Plastic Flow in Concrete Arches," *Proc.* A. S. C. E., 1930, p. 1440.

[7]F. Vogt "Shrinkage and Cracks in Concrete of Dams" to be printed in English this winter in *Det Kgl. Norske Videnskabers Selskab*, Skrifter, Nidaros, Norway. See also F. Vogt "Fundamental Views in the Analysis of Arch Dams," World Power Conference, Berlin, 1930, paper No. 159.

In the later years the Bureau of Reclamation has provided for grouting of the joints in their arch dams. Also the writer has tried to develop the grouting one step farther by introduction of a "multiple pressure grouting system," by which initial stresses in the structure can be introduced in such a way that they partly counteract the stresses from dead load, water load and shrinkage, thus reducing the final resulting stresses[8].

If the arch elements can carry the total water load without being overstressed, an arch dam must be considered as very safe against failure due to loading. However, in many cases the vertical stresses are higher than the horizontal arch stresses, and vertical tension may develop horizontal cracks, which invite the water to attack the concrete chemically and mechanically. Also the investigation of these vertical stresses is therefore of importance.

For dams in narrow canyons the vertical stresses are usually not the limiting factor. For instance, for a preliminary design for Diablo Canyon dam, the writer in 1927, then employed by the author, computed the vertical stresses at the base of the maximum section as 201 — 135 = 66 lb. per sq. in. upstream, and 247 + 291 = 538 downstream compression due to dead load and water load. The final design will show slightly smaller stresses. Assumed that the joints are grouted at low temperature after the major part of the shrinkage has taken place, the volumetric changes will not aggravate the result enough to make these stresses dangerous.

For dams in wide canyons the ratio of radius to height will be larger, and then a vertical tension at the upstream face is harder to avoid. The Stevenson Creek Test Dam is one example of this. The dam cracked horizontally at the base with water level between half and two thirds of the height. Later on it cracked vertically and horizontally at other places. This test dam has exceptionally daring dimensions in order to obtain large deflections and eventually get a test to failure, and a direct comparison with commercial dams is therefore difficult. Some of the most daring dams may be assumed cracked in a similar manner at the base, but for a number of arch dams, conclusions about

[8]See "Hydraulic Engineering," Los Angeles, Dec., 1928.

such cracks made from mathematical analysis are not checked by any positive indications of cracks in the actual structure. This discrepancy between observation and analysis may be due to wrong assumptions with respect to shrinkage and swelling, or due to incomplete analysis, or both. A number of factors, which formerly were neglected in the analysis, have proved to reduce the vertical tension which otherwise could have been expected, and a complete analysis must take into account not only the deformation of arch and cantilever elements due to thrust and bending, but also shear deformation, elastic yielding of the foundation, lateral deformation, and stiffness against tangential displacements.[9] In some cases perhaps also the stiffness against twisting of the elements may be of importance.

The author has several times also pointed at the release in the vertical bending stresses due to swelling at the upstream wet face and the following warping of the dam. This factor will undoubtedly sometimes be of importance, but as a result of observations on dams, the writer has received the impression that this factor has sometimes been overemphasized, and that no release worth mentioning can be counted upon except for the very skin.

The maximum distance, which can be used between the joints if interjacent cracks should be avoided, must necessarily be dependent on the type of the dam, and the author can hardly expect to find "any spacing which he thinks is the best in general" given by a certain number of feet. If the shrinkage were the same and distributed in the same way for a large dam, and for a model of this in scale $1:n$, the stresses would also be the same in dam and model. As an example, may be mentioned that the shrinkage cracks at both abutment joints in Stevenson Creek dam were truly repeated in a mortar model in scale 1:12. If cracks can be avoided in the dam by a maximum spacing a of the joints, then the spacing in the model should be maximum $a:n$. If dams with similar shaped cross-sections were divided in sections by joints with spacing given as a certain fraction of the height for each block, each block would be a model of all the other blocks, and the same shrinkage in all dams would give the same stresses,

[9] "Fundamental Views, Etc.," loc. cit.

i. e., the proper spacing should be a certain fraction of the height. To some extent this rule may be correct, the writer has, for instance, noticed cracks in all sections midway between joints with spacing 30 to 40 ft. on a small arch dam at Twin Lake, Cal., while large dams usually do not crack if the spacing is 50 ft.

The volumetric changes are, in general, greater for small thin-sectioned structures than for thick-sectioned due to more complete drying, and the spacing of the joints should then possibly be increased for large dams more than in proportion to the height. This, however, is in disagreement with the experience. The reason may be that for large thick dams the volumetric changes in the interior mass is much smaller than for concrete near the face, and that cracks are started at the face due to this difference more than due to the restraining from the foundation. Regardless of the size of the dam, a certain maximum spacing should therefore not be exceeded, but this limit will necessarily be dependent on type of concrete and on climatic conditions at the dam-site, and no simple rule will hold for all locations.

One experience is very frequently repeated, namely that contraction joints are continued down to the very foundation by irregular cracks, if the joints initially stopped at a higher elevation. As a rule all joints should therefore be continued directly down to the very base at once, in order to avoid this cracking.

BY W. NIMMO*

Since there is much truth in the old adage that "an ounce of practice is worth a pound of theory," this paper, in which the author sets forth the results of his long experience in the design and construction of arch dams, is of particular value. Little real progress in the determination of stresses in an arched dam was made until Professor Cain published well known equations which have become the basis for much subsequent work. Numerous attempts have been made to analyze the stresses in an arch dam by equating the deflections of arch slices and cantilevers at one or more points, and, while many elegant mathematical treatments have been evolved, few of them are of real practical use.

The trial load method,[1] developed by practical designers, has

*Designing Engineer, Main Roads Commission, Brisbane, Queensland, Australia.

[1] "Analysis of Arch Dams by the Trial Load Method" by C. H. Howell and A. C. Jaquith, *Trans.* Am. Soc. C. E., V. 93, 1929.

been used to a considerable extent for the design of large dams and the method appears to the writer to be the most suitable of the theoretical treatments, and some arch dams in Europe have been successfully designed by somewhat similar methods. The experimental results obtained from models and from the Stevenson Creek dam show that, at least for the conditions obtained during such experiments, the trial load method yields results which are in close agreement with observation. Most of the published deflection curves for actual dams, including those recently obtained from a number of Swiss dams,[2] exhibit the same general characteristics as those derived from the experimental work.

Notwithstanding these results such an experienced designer as the author, while admitting the existence of cantilever action, considers that its effect is so uncertain that he prefers to neglect it in his analysis of stresses and assumes that all the water load is carried by arch action or in the lower portion of the dam by shear. In the Stevenson Creek and Swiss experiments the variation of water level was so rapid that the effects of water soaking and plastic flow are practically eliminated, but this is not so for a dam in ordinary use. Expansion of the upstream face due to water soaking will appreciably lessen the load supported by the cantilevers, but the effect of plastic flow is less certain. Deformation of the foundation, including movement downstream and tilting at the base and spreading of the abutments at the higher levels and also cracking due to shrinkage was clearly in evidence at Stevenson Creek but their extent in a large dam is still a matter upon which reliable data is lacking. The effect of deformation of the foundation will be to diminish the load carried by the cantilever while shrinkage, if it be excessive, may crack the cantilevers and almost destroy their capacity to carry load. Moreover the dams dealt with by the author have been pressure grouted after shrinkage has taken place and, since the full water load on them usually occurs during the summer, the deflections under load will be less than in the case of those dams which have not been pressure grouted, and this will further decrease the proportion of load that can be carried by the cantilevers.

[2] "Deformationsmessungen an Staumauern nach den Methoden der Geodäsie" by W. Lang *Service Topographique*, Berne, 1929.

The dams that have been designed by the trial load method have not, so far as is known to the writer, been pressure grouted and therefore cantilever action may be expected to play a large part necessitating its inclusion in the analysis. The fact that grouting throws more of the work upon the arch is, in the opinion of the writer, a great advantage. In the southern portion of Australia dams are usually filled during the colder portion of the year so that the maximum downstream deflection due to temperature occurs at the same time as that due to load and under these conditions to minimize cantilever action it would be necessary to employ a sufficient pressure in grouting to force the empty dam somewhat upstream.

It would be of great value if deflection measurements extending over several seasons were available for a large arch dam that has been pressure grouted and one of similar type that has not been so treated. It is remarkable that although computation indicates the existence of tension amounting to 289 lb. per sq. in. in the Lake Spaulding dam, no harmful result has been observed.

The author's satisfactory experience with a mat of rocks as an energy dissipator under high overfalls is of interest, but in this country where masonry dams are usually built in sandstone formations, the method would probably not give sufficient protection against wear.

AUTHOR'S CLOSURE

It has been well stated by both W. Nimmo and Fredrik Vogt, that certain difficulties exist, when it comes to deciding upon proper values to use for modulus of elasticity, shrinkage and water soaking effect when designing arch dams.

More tests have been made to find values for the modulus of elasticity and shrinkage than for the water soaking effect. The main reason may be that the distribution of this effect is much more difficult to find than the other properties of the concrete, but it is at least as important, if one desires to attempt to distribute the waterload between arch and cantilever.

If the design has been based upon a certain calculated distribution of the load between arch and cantilever and this distribution is wrong, "It is hardly the mathematics itself, but the assumptions on which it is based" that is wrong, to quote from Dr. Vogt.

The writer prefers to use higher arch stresses and assume that no load goes on the cantilever, except near the bottom. There have been no tests made on commercial arch dams, as far as the writer knows, where it could be shown, that the cantilever took a certain definite part of the load relieving the arch of just that much. The Stevenson Creek tests may show a certain division of load, but the load in this case came on almost instantaneously and besides the proportions of this dam are not comparable with those of a good commercial arch dam.

Not alone is the sustained modulus of elasticity only about half of the instantaneous (at about 600-lb. compression per sq. inch in air), but the E for sustained load is from 60 per cent to 63 per cent higher for wet than for dry concrete according to tests made by Professor R. E. Davis in connection with the concrete in the Stevenson Creek dam (page 213 *Proc.* Am. Soc. of Civil Engineers, May, 1928, Part 3).

An important item for an arch dam is the grouting of the vertical contraction joints at the right time. The writer prefers to wait until the dam has taken load at least once and has cooled off. Unfortunately the owner will often not wait that long, and on a diversion dam very often grouting can not be put off that long. In such cases grouting will only be say 50 per cent effective and some cantilever action undoubtedly will develop.

It is not intended to grout the Diablo Dam until the Spring of 1932. After that time a power plant will utilize the head behind the dam and the water can not be drawn low enough to relieve the load on the structure sufficient for grouting purposes. By that time the heat should be out of the dam body and the structure should have taken its permanent set. Before grouting has taken place, there will undoubtedly be some cantilever action during the winter with reservoir full, this however, the structure will easily take care of.

The spacing of the contraction joints on the Diablo Dam was approximately 75 ft. This has been shown to be too large, since shrinkage cracks have appeared in the four middle blocks, between the artificial joints, extending from near the bottom to within 80 ft. of the crest. One shrinkage crack goes through the

dam body, the others appear, so far, on the down stream face only. Grouting the artificial joints later is expected to practically close these cracks and the load may do the rest.

For overfall dams on somewhat soft rock as mentioned by Mr. Nimmo it will be the best practice for arch dams to create a lake below the main dam and concentrate the overfall as much as possible into this lake.

In conclusion the writer desires to correct a misprint on page 62 line 17 from below. It should say: T. H. Carver was the principal assistant engineer in charge, etc.

The following is a list of Constant Angle Arch Dams built so far with their principal dimensions given. It can be seen, that there is nothing new and untried about arch dams any more, since some of the highest dams in the world are in this list and have so far given good satisfaction.

CONSTANT ANGLE ARCH DAMS BUILT IN THE PAST

1. Lake Spaulding Dam, South Yuba River, built 1912-13; 295 ft. high above foundation; 275 ft. high above river level; 770 ft. span; 192,000 cu. yd. of concrete; upstream radius at crest 440 ft., at bottom, 250 ft.

2. Salmon Creek Dam, Alaska near Juneau, built 1912-13; 168 ft. above river level; 545 ft. span; 52,000 cu. yd. of concrete; upstream radius at crest 331 ft., at bottom 147.5 ft.; thickness at crest, 6 ft., at bottom 47.5 ft.

3. Kerckhoff Dam, San Joaquin River, California, 1919; 108 ft. high; 450 ft. span; 23,000 cu. yd. of concrete; dam designed for 100,000 sec. ft. free overfall.

4. Carmel River Dam near Monterey, California, 1920; 90 ft. high; 270 ft. span; radius at crest 135 ft., at bottom 80 ft. long; thickness of dam 5 ft. at crest, 16 ft. at bottom; 10,000 sec. ft. free overfall.

5. Bullards Bar Dam, Yuba River, California, 1923; 183 ft. high; 440 ft. span; in connection with power plant. Upstream radius at crest 240 ft. long, at bottom 94 ft.; thickness at crest 6 ft., at bottom 43 ft.; 47,000 cu. yd.; 65,000 sec. ft. free overfall.

6. Lost Creek Dam, Lost Creek, California, 1923; 112 ft. high; 380 ft. span; radius upstream crest 200 ft., at bottom 90 ft. long; thickness at crest 4 ft., at bottom 23.5 ft.; 11,000 cu. yd. Spillway free overfall 15,000 sec. ft.

7. Concow Dam, Concow Creek, Calif., Thermolite Irrigation District, 1924; height 90 ft. above stream bed; span 275 ft.; upstream radius at crest 180.6 ft., at bottom 78 ft.; thickness at top 3.75 ft., at bottom 18.9 ft; 1:3:6 concrete; 63,000 cu. yd. of concrete. Spillway 10,000 sec. ft. free overfall.

8. East Canyon Creek Dam, Utah, 1917; 140 ft. high above river level; 190 ft. high above foundation; about 400 ft. span including tangents; upstream radius at crest 98.8 ft. long, at bottom 70 ft. long; crest thickness 5 ft.; bottom thickness 26.25 ft.; 15,888 cu. yd. of concrete. Total overall cost $8.62 per cu. yd.

9. Sun River Dam, Idaho, 1917; 100 ft. high; 250 ft. span.

10. Clear Creek Dam, Washington, 1914-18; 90 ft. high; 180 ft. span; approx. 5,000 sec. ft. free overfall.

11. Manila Dam, Philippine Islands, 1913; 98.4 ft. high; 100 ft. span.

12. La Jogne Dam, Switzerland, 1920; 186 ft. high; upstream crest radius 126 ft.; 250 ft. span.

13. Crocodile River Dam, South Africa Union Irrigation District, 1922; 198 ft. high; 450 ft. crest length; upstream radius at crest, 225 ft.

14. Amsteg Dam, Switzerland, 1921; 105 ft. high; upstream crest radius 62 ft.; 102 ft. span.

15. Gide River Dam, Sweden, 1919; 85 ft. high; 131 ft. span; upstream radius at crest 98 ft; and 72 ft. at an elevation 43 ft. lower down; spillway free overfall.

16. Butte Creek Dam, Calif., 1915; 45 ft. high; 85 ft. span; spillway free overfall..

17. Mormon Flat Dam Salt River, Arizona, 1923-24; height 229 ft. above bedrock; span 326 plus 90 ft. gravity tangent; upstream radius at crest 193 ft. at river level 100 ft.; thickness 8 ft. at top and varies from 20 to 29 ft. at bottom; 43,000 cu. yd. of concrete; 150,000 sec. ft. spillway on gravity section. Total cost of concrete $473,000; 63,000 acre ft. of storage.

18. Gerber Dam, Klamath Project, Oregon; U. S. Reclamation Service, 1923-24; height 70 ft. above river bed, and 82.5 ft. above lowest foundation; span 375 ft.; length of crest along curve 478 ft.; upstream radius at crest 197 ft.; at bottom 155 ft.; thickness 5 ft. at top, and 15 ft. at streambed; 11,880 cu. yd.; 1:2½:5 concrete; 31½ tons of reinforcement; spillway free overfall.

19. Upper Hubbart Dam, Flathead Project, Montana; U. S. Reclamation Service, 1923; height 92.5 ft., above river bed, 113.5 ft. above foundation; span 400 ft.; length of crest along curve 503 ft.; upstream radius at crest 200 ft., at bottom 194 ft.; thickness 5 ft. at top, 22 ft. at bottom; 1:2½:5 concrete; 17,000 cu. yd. of concrete; spillway free overfall.

20. Montejaque Dam, Caduares River, Spain, 1923-24; height 210 ft. above river level, and 273 ft. above foundations; span 208 ft.; length of center line at crest 256 ft.; upstream radius 123 ft. at crest, 72 ft. at base; thickness at crest 10 ft., at base 55 ft.; 35,000 cu. yd. of concrete.

21. Emigrant Creek Dam, Oregon; Talent Irrigation District, 1924; height 100 ft. above stream level; 115 ft. above foundation; span 360 ft.; upstream

radius at crest 165, at base 132 ft.; thickness 5 ft. at crest, and 19.3 ft. at base; 14,000 cu. yd. concrete; spillway partly free overfall.

22. Balch Diversion Dam, Kings River, California, 1926; 100 ft. high above foundation (initial height), ultimate 150 ft.; 300 ft. span; 9,300 cu. yd. of concrete; upstream radius at crest 184 ft. (initial) at bottom 90 ft.; spillway free overfall 40,000 sec. ft.

23. Glines Canyon Dam, Port Angeles, Washington, 1927; 200 ft. high from bottom of foundation to the crest; radius of upstream face at crest 128 ft., at bottom 62 ft.; dam is 28 ft. thick at the base, and 4 ft. thick at top; arch between two gravity tangents 152 ft. long; 16,630 yards concrete in arch; 20,000 cu. yd. total.

24. Big Santa Anita Dam, near Los Angeles; 225 ft. high; 515.0 ft. span; upstream radius at crest 301.5, and 129 ft. long at bottom; thickness at crest 7 ft., at bottom 48 ft.; 76,000 cu. yd. of concrete. Cost $1,211,000, 1927.

25. Urayama River Dam, location near Tokio, Japan, 1921; height 45 ft.; thickness at crest 4 ft., at bottom 9 ft.; radius at crest 48 ft.

26. Lake Cushman Dam, Washington, City of Tacoma; 280 ft. high; upstream radius at crest 200 ft., and 131 ft.; 150 ft. below crest to bottom; span of arch proper 340 ft.; thickness at crest 8 ft., at bottom 45.5 ft.; 85,000 cu. yd. of concrete; finished 1926.

27. Horse Mesa Dam, Arizona; 305 ft. high from foundation to parapet; top upstream radius at crest 251.4 ft., at bottom 82 ft.; thickness at top 8 ft.; thickness at bottom varies from 43 ft. to 57 ft.; stores 245,000 acre ft.; arch span 450 ft.; total span 784 ft.; contains 150,000 cu. yd., 1927. Cost $1,500,000; spillway capacity 150,000 sec. ft.

28. Bucks Creek Diversion Dam, Plumas County, Calif.; 96 ft. high; 420 ft. span; upstream radius at crest 213 ft., at bottom 156 ft.; thickness of dam at crest 6 ft., at bottom 27 ft.; 19,200 cubic yards of concrete; has two gravity tangents, 1927.

29. Canadea Dam, New York; 130 ft. high above river bottom; one gravity abutment arch span 480 ft.; upstream radius at crest 265 ft.; upstream radius at bottom 200 ft., and thickness at crest 5 ft.; at bottom 44 ft.; 50,000 cu. yd. of concrete, 1928.

30. Santeetlah Dam, Tallasse, North Carolina, Aluminum Co. of America; 202 ft. high above foundation; two overflow gravity tangents; arch span 340 ft.; upstream radius at crest 300 ft., at bottom 207 ft.; thickness 10 ft. at crest, and 48 ft. at bottom; 75,000 cu. yd. of concrete in arch portion; 217,000 yards total; total length of dam 1,120 ft., 1927.

31. Pacoima Dam, for Los Angeles County Flood Control; 365 ft. high above river bed; 375 ft. high above foundation; span 560 ft.; upstream radius at crest 340 ft., at bottom 171.34 ft.; thickness of dam at crest 8 ft., at bottom 96 ft.; 215,000 cu. yd. of concrete.

32. Grizzly Creek Diversion Dam, Plumas County, Calif.; 90 ft. high; 420 ft. span; upstream radius at crest 205 ft., at bottom 140 ft.; thickness of dam at crest 6 ft., at bottom 22 ft.; 18,000 cu. yd. of concrete, has gravity tangent; spillway partly overfall.

33. Von Geisen Diversion Dam on Bear River, California; Nevada Irrigation District; 100 ft. high; 365 ft. arch span between two tangents; upstream radius at crest 205 ft., at bottom 184 ft.; minimum thickness 5 ft.; thickness at bottom 22 ft., in the middle of arch. Contract price $157,000, 1928; spillway free, overfall 10,000 sec. ft.

34. Deer Creek Diversion Dam, Nevada Irrigation District; 97 ft. high; 270 ft. span; upstream radius at crest 136 ft., at bottom 98 ft.; minimum thickness 4 ft.; thickness at bottom 12 ft., in the middle of arch. Contract price $52,000, 1928; spillway free, overfall 7,500 sec. ft.

35. Pigeon River Dam, North Carolina; 190 ft. high, plus 10 ft. overflow; 600 ft. span; upstream radius at crest 320 ft., at bottom 244 ft.; minimum thickness 16 ft., just below overflow crest; thickness at bottom 38.5 ft.; Waterville Hydro-Electric Development of Carolina Power and Light Company; 120,000 cu. yd., 1929.

36. Canyon Diablo Dam on Skagit River, City of Seattle; 372 ft. high; span of arch 540 ft., arch butting against gravity tangents; total span approximately 950 ft.; upstream radius at crest 390 ft., at bottom 163 ft.; thickness at crest 16 ft.; thickness at bottom 98 ft.; 316,000 yards of concrete, 1930; overflow on tangents 100,000 sec. ft.

37. The Reeder Gulch Dam for the City of Ashland; 110 ft. high; overflow 415 ft. span; upstream radius at crest 230 ft.; at bottom 150 ft.; thickness at top 7 ft., at the bottom 19.5 ft.; 15,000 cu. yd. of concrete, 1928.

38. Yellow Creek Dam No. 1, Tuscaloosa, Alabama, 1929; 65 ft. high. This dam has horizontal sections of elliptical shape and is symmetrical about the major axis. Semi-major axis 179.5 ft. at crest; 166.5 ft. at base; semi-minor axis 149.26 ft. at crest; 130.62 ft. at base; thickness at crest 5 ft., at base 20 ft.; approximately 7,000 cu. yd. of concrete.

39. The Calles Dam, Mexico, River Santiago, 1929; height of dam 217 ft.; arch with gravity tangents; length of crest 985 ft.; overhang on downstream side at crown 6.66 ft.; radius variable in the same horizontal plane.

40. The Calderwood Dam, Tennessee, 1930; height of dam 230 ft. above foundation; length of upstream radius at spillway level 337.5 ft., 281 ft. at bottom; designed for 200,000 sec. ft. overflow; thickness at top 25 ft., at bottom 48 ft.

41. The Calaveras Dam near Stockton, Calif., 1930; height of dam 160 ft.; arch with gravity tangents; length of crest 1400 ft.; dam 50 ft. thick at base, and 7 ft. thick at top; upstream radius at crest 365.2 ft., at the bottom 204.8 ft.; lowest bid $838,715; 105,000 cu. yd. of concrete; dam overhangs in the middle on the downstream side and at the abutments on the upstream side.

42. The Juncal Dam, Montecito Water District, Santa Barbara County; height of dam 160 ft.; length of upstream radius at crest 196 ft., at bottom 132 ft.; thickness at the crest 6 ft., at the bottom 64 ft., 1930; span 350 ft.; crest length 440 ft.; 34,400 cu. yd. of concrete.

43. Upper Hansen Dam, Los Angeles Flood Control; height of dam 245 ft.; length of upstream radius at crest 190 ft., at bottom 132 ft.; thickness at crest 8 ft., at bottom 62 ft.; arch with two gravity tangents; right tangent spillway 150 ft. long; span of arch portion 265 ft.; left tangent 170 ft. long; 90,000 cu. yds. of concrete; 90,000 cu. yd. of excavation.

44. Dam near Safford, Arizona; 110 ft. high; 130 ft. span; central angle held at about 130 degrees; upstream radius at top 80 ft., at the bottom 14 ft.; dam 2 ft. thick at the crest, and 3 ft. thick at the base at the crown, thicker at the abutments; spillway capacity 1000 sec. ft.

45. Stewart Mountain Dam, Salt River, Arizona; height of dam 212 ft. above bedrock; 1200 ft. long; 117,000 cu. yd. of concrete; radius at top 273 ft.; at the bottom, face is irregular; thickness at top 8 ft., at bottom 33 ft. minimum.

46. Dam at Sautet on the Drag River near Grenoble, Switzerland; 443 ft. high, with secondary dam 180 ft. high below. Dam is designed for unbalanced pressure of 430 ft. (130 meters) head. Crest length 246 ft. Subtended angle held substantially at 90 degrees. Upstream radius at bottom 76.6 ft.; thickness at the bottom 54 ft. Dam contains 74,500 cu. yd. of concrete. Under construction.

47. Ariel Dam on the Lewis River, Wash. 300 ft. above lowest bedrock. Upstream radius at crest 400 ft.; at bottom 50 ft. Dam 93.5 ft. thick at base and 18 ft. thick at crest. Spillway on gravity abutment; capacity 120,000 second feet of water. Arch part of dam 760 ft. long at crest. Approx. 300,000 cu. yd. of concrete in complete dam. Under construction at present.

Discussion of Report of Committee 506

Proposed "Construction Specifications for Concrete Work on the Small Job"

BY H. N. WALSH*

I SUGGEST the insertion of a paragraph to the following effect immediately after the descriptions of the three classes of concrete on page 81:

Where rapid hardening portland cement is to be used, compression tests shall be made in an approved laboratory, to determine the water-cement ratio that will give concrete of the required strength at the age at which the concrete is to be put into use.

My experience has been that the relation strength to water-cement ratio may vary considerably for rapid hardening portlands, even for different shipments of the same brand. Further, as concrete made with these cements is generally put into service after 7 to 10 days curing, and as the strengths at the early ages are most affected by excess water, there is more necessity for careful determination of the proper water-cement ratio when rapid hardening cements are being used.

In the paragraph on page 81 dealing with water carried by sand, a warning might be added that if fine sand is used (being possibly the only fine aggregate economically available), then the job test for water content should be made obligatory. A fine sand may carry as much a 0.5 gallons of water per cu. ft., when appearing to be only slightly damp.

Many architects and engineers might like more detailed description of the consistency than that given on page 85; they would probably welcome reference to the slump test to indicate the approximate consistencies suitable for different classes of work. I, therefore, suggest consideration of the inclusion of a table on the following lines:

If the slump test is used, the concrete for different classes of work shall have the following slumps:

*Professor of Civil Engineering, University College, Cork, Ireland.

Mass concrete, Decking with little reinforcement, Heavy sections of reinforced concrete	2 in.-4 in.
Thin vertical members	5 in.-7 in.
Thin horizontal members	7 in.-9 in.
Roads	1 in.-3 in.

or as otherwise specified by the Architect or Engineer.

I am aware of the dangers attendant on the inclusion of such a list of slumps. Very probably it has been considered and decided against by the Author. Nevertheless I would like to have the matter discussed.

The amounts of the slumps stated above are merely tentative.

BY A. R. ELLIS*

The author of the specifications, so far as I can see, does not define the "small job." Some small jobs are quite important, and in some of them the quality of the materials involved are consequently of greater importance than the quality of materials on some large jobs.

On Page 71, under Article 4, the author provides that the cement shall be "certified by the dealer to comply with all requirements of the standard specifications, etc." Dealer certification in some instances is apt to be influenced by the desire to make a sale.

Frequently, it is the small job contractor who is imposed upon by dealers with cement that has been in storage sufficiently long to cause its deterioration. Some dealers do not know when deterioration, due to age, begins, and again the desire to make a sale is likely to influence covering up this fact, even if it is known.

Considerable stress is laid on fine and coarse aggregate and even that water from the usual drinking supply shall be used and then the door left pretty wide open when it comes to cement.

I would like to see this reference to dealer's certification of the cement omitted from this specification.

BY J. D. STODDARD†

Article 4 provides that cement shall be "certified by the dealer to comply with all requirements of the Standard Specifications of the A. S. T. M." We consider this to be a dangerous clause and

*Vice-president, Pittsburgh Testing Laboratory, Pittsburgh.
†Vice-president and treasurer, The Detroit Testing Laboratory.

one which should not be permitted to appear in any specification or building code. While it is intended to apply to "small" jobs only, the word "small" is a very flexible one and depends largely upon the opinion of the individual or possibly the viewpoint of the individual as to whether it should be considered small or large. Our experience with "dealers" has been such that we do not believe any great amount of value should be attached to any certification of the quality of portland cement purchased from them. Very few dealers have more than a smattering of knowledge regarding the nature of portland cement or the conditions under which its integrity is preserved or under which it deteriorates, and certainly the certification of quality should not be placed in the hands of such individuals.

Outside of the commercial phases of our activities which we are of necessity compelled constantly to recognize we are interested in the development of the construction industry along wise and safe lines. We trust you will appreciate our interest in the clause referred to, and hope the language will be changed and no such specification be adopted or recommended for use.

Readers are referred to the JOURNAL *for May, 1931, for discussion which may develop. Such discussion should reach the Secretary by April 1, 1931. The proposed specification will be open for discussion at the 27th Annual Convention when the committee will move its tentative adoption.*

Design and Control of Concrete for Diablo Dam*

BY H. F. FAULKNER† AND R. R. HUBBARD‡

DESIGN

The Diablo dam is in a very rugged section of the Cascade Mountains on the Skagit River about 100 miles northeast of Seattle, Wash. It is the second major unit to be completed in the comprehensive development of that river to furnish hydro-electric power for the City of Seattle.

The first unit completed was the Gorge Creek tunnel and power plant, several miles down stream from Diablo. This consists of a 21-ft. diameter concrete lined tunnel driven 11,000 ft. through solid rock, terminating in three penstocks which lead to the three generators in the power house. A temporary crib dam and intake at the upper portal supplies water to this tunnel, which has a fall of 265 ft. in its 11,000 ft.

Diablo Dam is the first permanent dam to be constructed, and is the middle dam of three to be located on 14 miles of the river. Ruby Dam, much larger and higher than Diablo, will be next to be built, 7 miles up stream from Diablo; and later a permanent dam at Gorge Creek, 6 miles down stream, will complete the 1,000,000 H. P. development.

The base of Diablo Dam is in a narrow gorge which the river has cut through a dyke of hard granitic rock lying across the main valley floor. At the dam site the walls of this gorge rise almost perpendicularly to a height of 200 ft., above which elevation the slopes flatten. The average width of the gorge is 150 ft. at the dam site.

The central portion of the dam is of the constant angle arch type, terminating at each end in gravity abutment sections in

*For presentation and discussion 27th Annual Convention, Milwaukee, Feb. 24-26, 1931.
†Assistant Engineer, City of Seattle.
‡Superintendent of Construction, City of Seattle.

which are the spillways. The dam is 390 ft. high, with a crest length of 1170 ft.; has an extreme thickness of 140 ft. at the base and 16 ft. at the crest; and contains 320,000 cu. yds. of concrete. The arch portion of the dam contains 8 sections, each 73 ft. between contraction joints, having keys 6 ft. by 12 in. Three beaded copper water stops are placed vertically in each joint, connecting the adjacent sections. Two of these copper water stops are near the upstream face of the dam, on either side of a 6-in. block or prism of asphalt which was built vertically into the joint during construction and which was melted by electricity when the dam was completed, to effect a final sealing. The third copper water stop was placed near the down stream face of the dam. Perfection grout pipes were provided vertically in each key-way. These will be grouted after the dam has taken its final settlement under load.

At a large bend in the river about one-half mile below the dam site was an extensive sand and gravel deposit known as Reflector bar. Investigations disclosed that this bar would furnish an ample supply of aggregates for the dam and an excellent level site for the large construction camp of the contractors and engineers.

The concrete was designed and specified with particular recognition of the facts that the hydrostatic pressures would be very great, that permeability is in direct ratio to pressure, that any dissolving of the cement by percolating water is proportional to the quantity of percolating water, that it was necessary to obtain concrete of low permeability and that the arch type of dam, of relatively thin section, logically requires a stronger, more nearly impermeable concrete than does one of gravity section.

Samples of pit run material from various parts of Reflector bar were sent to the city laboratory at Seattle for preliminary studies. Tests indicated that there might be insufficient sand and a deficiency of finer particles in the sand available; that there would be plenty of intermediate gravel from ¼ in. to 3 in., with an excess of pea gravel, ¼ in. to ¾ in.; that there was plenty of large gravel and oversized boulders to supply any deficiencies in the aggregate if this larger material were crushed.

It was decided early not to use plums or very large aggregate, since we believe that such aggregate detracts from the work-

FIG. 1—GORGE OF SKAGIT AT DAM SITE

FIG. 2—REFLECTOR BAR—SOURCE OF AGGREGATE

ability or mobility of the fresh concrete mass and does not readily permit uniform placement and the impermeable structure necessary to secure watertight concrete. In the depositing and subsequent plastic settlement of concrete, water, the lightest ingredient, tends to rise. Coming in contact with the undersurface of large aggregate or plums, it can rise no farther but collects there as a film and through it the cement particles that may have been in contact with the aggregate surface, settle or disperse. Such water films create corresponding voids in the hardened concrete and afford ready passage to percolating water. In concrete of fairly stiff consistency such voids may be so thin as merely to cause a weakening of bond, but in wet concrete they may be so large as to be readily visible. It appears to be desirable to eliminate them.

For uniformity of mix it was decided to separate the coarse aggregate into two sizes, and to do all proportioning by weight. It was also decided to fix the maximum diameter of aggregate at 4 in., although permitting the use of elongated particles whose third dimension did in some cases run as high as 8 inches. After screening the samples and giving due consideration to the economic production of the bar, the following grading was specified:

Fine Aggregate: 0 to No. 4 with from 20 to 40 per cent passing a No. 28 sieve		
Medium Aggregate:	Per cent passing 2″	95 to 100
	1½″	55 to 80
	1″	30 to 60
	½″	10 to 25
	¼″	0 to 5
Coarse Aggregate:	Per cent passing 4″	87 to 100
	3″	30 to 70
	2″	0 to 5

With the above grading of aggregates, the concrete mixture finally specified and used in the construction of the dam was determined by trial: various mixes containing various quantities of the different classes of aggregate were made and were compared as to their yield, strength, permeability, and (insofar as the elusive quality can be determined by both slump and by effort required to place properly in a test form) as to workability. Batches containing 20 lbs. of cement furnished sufficient con-

crete for the other tests and finally to make strength cylinders and permeability discs, which latter were 12 in. in diameter and 6 in. thick. The various aggregate proportions were tabulated in terms of their screen sizes and fineness moduli, but it was on the basis of the results obtained with the *trial mixes* that the final decision was made.

After making and testing specimens from the various trial mixtures, one using 20 lbs. cement to 160 lbs. of combined aggregate was decided upon as being most suitable. Making certain allowances for the rather coarse sand (F. M. 3.46) and the elongated shape of the coarse aggregate, and on the basis of the fineness modulus table, the selected mix had the following proportions, by weight:

1.0 parts cement
2.3 parts sand
3.5 parts medium aggregate
2.2 parts coarse aggregate

This mix produced a concrete which with a w/c of 0.75, 87.7 per cent solids and cement content of 1.19 barrels per cubic yard, could be readily placed, had a slump of 3½ in. when the aggregate over 2 in. in diameter was removed, and developed a compressive strength of 3,200 lbs. per sq. in. at 28 days. Best of all, the permeability discs, 6 in. thick, subjected to a pressure of 100 lbs. per sq. in. for 72 hours, remained dry on their unexposed faces for the entire period, such moisture as did penetrate through them being immediately removed by evaporation.

It was thought possible that the contractor might decide to crush the rock excavated from the dam foundations for use as aggregate. Since crushed aggregates do not produce as workable concrete for equal w/c, their use in the amount specified for gravel aggregate, i. e., 1.0 parts cement to 8.0 parts of graded aggregates, by weight, would require the use of more mixing water for equal plasticities, with a resulting loss of strength and increase of permeability. Therefore, it was specified that if crushed coarse aggregate were used, the mix should be 1.0 parts cement to 7.5 parts of combined aggregates, while if both fine and coarse

aggregates were crushed the mix should be 1.0 parts cement to 7.25 parts of combined aggregate.

The above is the "Class A" concrete which was specified for the main body of the dam.

In the upstream face of the dam to a depth of 3 ft. "Class B" concrete was placed integral with the "Class A" concrete. In this, the same gradation and relative proportion of aggregates was used, but the ratio of cement to aggregate was specified as one part cement to 5½ parts aggregate, by weight. This concrete required 1.60 barrels cement per cu. yd., and a w/c of .65 to produce the proper consistency. This richer mixture in the upstream face of the dam is an additional safeguard to a structure which is expected to serve for many centuries. The possibility of differential stresses between the two classes of concrete was considered, but it is believed that any such stresses will be minimized in that the gradation of the aggregate was the same in both classes of concrete.

Some of the principal requirements of the specifications were:

1. A mix of uniform fineness modulus, to be obtained by varying the quantities of the different aggregates.
2. Mixing time of 1½ minutes.
3. Concrete to be as dry as could be properly handled, but not to have more than 3-in. slump.
4. No chuting of concrete to be allowed.
5. No concrete to be dropped more than 3 ft.
6. Concrete to be spread over sections in layers not to exceed 6 in. thick.
7. Concrete not to be deposited in any section to a depth of more than 5 ft. at any one pour.

Some of these requirements were modified as the work progressed and as conditions appeared to warrant.

FIELD OPERATION AND CONTROL

A Telsmith screening and washing plant was installed by the contractor near the lower end of Reflector bar and river aggregate was used for the entire work. Sand and gravel were excavated by a Monoghan dredge and conveyed by a belt to the screening plant. This dredge could not furnish sufficient material at all times and a Sauerman drag line was installed to supplement the supply. The revolving screens at the plant had openings as follows for the production of the required sizes of aggregate:

For sand	⅛ in. by ¾ in.
For medium aggregate	2¼ in. square opening screens
For coarse aggregate	4½ in. square opening screens

Considerable difficulty was experienced at times in obtaining sand which contained the necessary amount of finer particles. The sand grading in the bar varied greatly in different locations. Usually if the dredge were working in coarse sand the Sauerman was placed where finer sand was known to be and vice versa.

Controlling the sand grading was something of a problem. Eight samples were taken at the screening plant from the stream of sand while it was filling a 38 yd. car in which the sand was conveyed from the bar to the storage bins at the damsite. These samples were mixed to form a composite sample, which was dried and screened. Certain tables and rules were worked out governing the acceptance of each car as follows:

If the percentage of sand retained on a No. 28 sieve was under 75, the fineness modulus could go as high as 3.60.

If the percentage retained was 76 to 80, the finess modulus must be 3.40 or under.

If the percentage was above 80, the car was rejected, or, as was the usual case, was held until the cars of finer sand were produced, which, on going into the storage bins at the same time, would bring the average grading within the specified limits.

Medium aggregate was comparatively easy to control. Pea gravel under ½ in. was almost entirely removed into a separate compartment at the plant. A sample from each car was screened and if the fineness modulus was found to be 7.90 to 8.00, 7 cu. yds. of pea gravel were added to the 38 yd. car:

If from 7.80 to 7.90	5.5 yards were added
If from 7.70 to 7.80	4.0 yards were added
If from 7.60 to 7.70	3.0 yards were added
If under 7.60 no pea gravel was added.	

There was no adjustment of the coarse aggregate except by the screens. All material brought to the plant between the 4½ in. and 8 in. sizes was put through a gyratory crusher, which was supposed to produce the 4 in. size, but for two reasons produced more medium than coarse material. These reasons were: first, the opening in the crusher was too small; second, the nature of the rock which, although having a compressive strength of 25,000 lbs. per sq. in. when tested in 3-in. cubes, was nevertheless

brittle, causing it to break into small pieces. The sizes produced with this crushed material, coupled with the plentiful supply of medium aggregate as it occurred in the natural deposit, developed an excess of the medium sized aggregate. Some of this excess was wasted, but much of it was stored and was either used for the reinforced sections of the dam or was sold to another contractor who used it for lining the tunnel between the dam and power house, for setting the penstock, and for building the surge chamber.

An average gradation of material produced is as follows:

	Fine Per Cent	Medium Per Cent	Coarse Per Cent
Ret. on 4″			12.8
3″			61.8
2″		4.1	91.1
1½″		20.0	95.2
1″		36.6	100
¾″		53.0	
⅜″		84.5	
No. 3	0.0	94	
4	2.5	100	
8	12.5		
14	41.5		
28	72.5		
48	93.5		
100	98.5		

The aggregates were loaded into 38 cu. yd. standard gauge cars and were taken to storage bins near the dam. These bins were cribs built on a steep hillside and held about 4,000 yards each of the three grades of aggregate, making the total storage 12,000 cu. yd. The material was drawn off through gates at the bottom of these cribs onto belts which conveyed it to small bins over the weighing hoppers at the mixing plant. Some difficulty was experienced with segregation of the coarse aggregate in the side hill bins, as, on drawing off, the coarser sizes would roll to the bottom, leaving the finer sizes on the slopes. This difficulty was overcome by putting back haul scrapers into the bins, which pulled the aggregate to the bottom with very little segregation.

Bulk cement was delivered to the job in 250 bbl. cars. This was scraped from the cars onto belts which conveyed it to silos

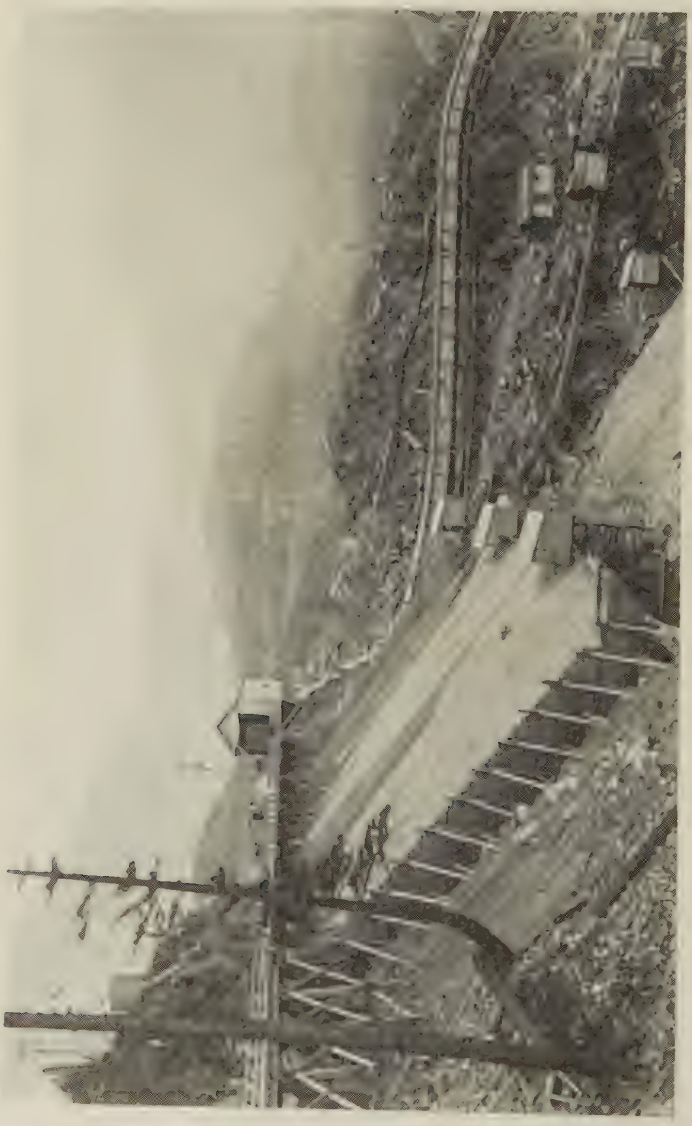

FIG. 3—AGGREGATE STORAGE AT DAM SITE AND BULK CEMENT CONVEYOR

at the mixing plant, from which a screw conveyor delivered it to the cement weighing hopper. Concrete was mixed by two 2-yd. Ransome mixers. Fine, medium and coarse aggregates were weighed in one hopper, three settings of the scale being necessary for each batch.

A typical mix for "Class A" concrete where none of the aggregate was crushed was: 940 lbs. cement, 2260 lbs. fine aggregate, 3142 medium aggregate, and 2090 coarse aggregate. Where a large percentage of both medium and coarse aggregate was crushed, as was frequently the case, a typical mix was 1003 lbs. cement, 2186 lbs. sand less 120 lbs. water, 3200 lbs. medium aggregate, and 2257 lbs. coarse aggregate. Moisture determinations of the sand were made and the entrained water was deducted from the quantity necessary for the proper consistency of the batch. A w/c of from .70-.75 was all that was required to produce a slump of 2½ to 3½ in. The water additional to that in the sand was measured very accurately by two 2-in. Neptune meters. These were accurate throughout the job to the nearest ¼ gal.

For the "Class B" or face concrete the aggregate mix remained the same, the only difference being that the cement content was increaesd to secure the ratio of 1 part cement to 5½ parts aggregate. From the mixing plant on the north rim of the gorge and about 100 feet downstream from the dam, the concrete was discharged into a hopper and thence was chuted down to the base of the dam, where two tall hoisting towers elevated it in skips to other hoppers on the towers located at the zone of construction operations. At the commencement of the concreting operations the concrete was discharged from the skips into 2-yd. bottom dump buckets which were handled by derricks. With the long cables necessary, this process was very slow and unsatisfactory, as it was difficult to position the heavy swinging buckets of concrete properly or to empty them without having the concrete pyramid and pile up in a manner requiring a great deal of shoveling and spreading to secure proper placement.

Later the contractors installed a belt conveyor system on the towers, which worked most efficiently. This installation con-

sisted of two 24-in. belts, the inner one being slung directly from the tower, while the outer one was suspended from a trolley on a steel boom. These belts were adjustable vertically on both tower and discharge ends, as the elevation of placement required. Each belt was driven independently by a small motor. Concrete discharged from the tower hopper onto the inner belt was conveyed outward and was discharged onto the outer belt through a short vertical pipe section which formed the hinge or elbow connecting the two belts. From this elbow the outer belt carried the concrete to its discharge into the "elephant trunk," suspended at the end of the outer belt. These belts were supported in a manner which allowed them to be jack-knifed through an arc of almost 360 deg. By proper jack-knifing of these belts a layer of the required thickness was spread rapidly and uniformly over the entire area of the section being placed, without segregation and requiring very little handling for placement. This conveyor handled as much as 1500 yds, in a 24-hour day. Our specifications required that concrete should be dropped not more than 3 ft., but it was found that better results could be obtained by dropping from 10 to 20 ft. with this "elephant trunk" method of depositing, and it was consequently permitted.

The concrete was of such consistency that ordinarily a man would sink about ankle deep in the fresh mass. During hot weather it was necessary to run the concrete somewhat wetter than a 3-in. slump, and during heavy rains which prevail at the damsite during the winter the consistency was reduced below a 3-in. slump, as water gains would occur as the pour progressed if not guarded against.

After a 5-ft. lift had been made, no more concrete was placed on that section until the concrete had hardened sufficiently to withstand the applied load without injury. Horizontal surfaces were prepared for succeeding pours by vigorous brushing with a stiff brush as soon as the concrete had stiffened sufficiently so that the sweepings were crumbly. The brushing removed the glaze and also any small amount of laitance which might have formed in low spots. Before fresh concrete was deposited the surface was picked where necessary, was hosed off under a high pressure water jet, and was then air blown. Upon this surface a

FIG. 4—UPSTREAM VIEW OF DAM DURING CONSTRUCTION

FIG. 5—DOWNSTREAM VIEW OF DAM UNDER CONSTRUCTION

layer of 1:1½ grout was thoroughly brushed in immediately preceding the concrete deposit.

On each 5-ft. lift a raised key 5 ft. wide and 15 in. high was placed 5 ft. back from the upstream face of the dam. About one foot back from the upstream face a strip of 26 gauge copper 8 in. wide was imbedded 4 in. in the surface of each 5-ft. lift, leaving 4 in. projecting to be imbedded in the next lift. This formed a water stop in the horizontal construction joints.

Concrete was cured by covering and sprinkling horizontal surfaces for 10 days, or until a fresh deposit was placed. The up and down stream faces of the dam were sprayed through perforated pipe hung along the top of the concrete. The ends of sections at the radial contraction joints were painted with asphalt as soon as the forms were removed.

No attempt was made to place concrete when the temperature was below 25 deg. F., as these occasions were rare and the plant was not provided with sufficient steam for protection in cold weather.

A few cracks developed in the dam during construction. They are entirely confined to the lower portion, where the sections are thick, and they occur on radial planes almost midway between contraction joints. None of these cracks has been traced through the dam, and they cease entirely at an elevation where the dam becomes about 40 ft. thick. Since the dam has been completed and filled no evidence has been observed of any leakage through the concrete itself. A few slight leaks have been found which come through the horizontal construction joints. Most of these are in proximity to the abutments and apparently come through cracks in the rock of the gorge wall, the water getting into the construction joints back of the keys and water stops. If keys and stops had been placed along the ends near the abutment walls, this condition would probably not have developed.

About 600 test cylinders of the various classes of concrete were made on this job. These were made by many different inspectors and were cured at the job laboratory in wet sand which was kept at a temperature of from 60 to 70 deg. F. until two days before test date, when they were packed in wet sawdust and shipped to the laboratory in Seattle. From the 6 by 12-in.

FIG. 6—CONCRETE BEING DEPOSITED THROUGH "ELEPHANT TRUNK"

cylinders aggregate coarser than 2 in. was removed; aggregate as large as 3 in. to 3½ in. was allowed in 8 by 16-in. cylinders. Of 350 "Class A" cylinders tested at 28 days:

2	failed under	2500 lbs. per sq. in.
11	failed between	2500 and 2800 lbs. per sq. in.
20	failed between	2800 and 3000 lbs. per sq. in.
53	failed between	3000 and 3500 lbs. per sq. in.
191	failed between	3500 and 5000 lbs. per sq. in.
52	failed between	5000 and 5500 lbs. per sq. in.
20	failed between	5500 and 6000 lbs. per sq. in.
1	failed over	6000

Average	7 day	"Class A" 6 x 12 in.	2662 lbs. per sq. in.
Average	28 day	"Class A" 6 x 12 in.	4297 lbs. per sq. in.
Average	6 mo.	"Class A" 6 x 12 in.	5709 lbs. per sq. in.
Average	1 yr.	"Class A" 6 x 12 in.	5907 lbs. per sq. in.
Average	28 day	"Class A" 8 x 16 in.	3817 lbs. per sq. in.
Average	7 day	"Class B" 6 x 12 in.	3377 lbs. per sq. in.
Average	28 day	"Class B" 6 x 12 in.	5100 lbs. per sq. in.
Average	6 mo.	"Class B" 6 x 12 in.	6350 lbs. per sq. in.
Average	1 yr.	"Class B" 6 x 12 in.	7250 lbs. per sq. in.

Permeability cylinders 8 by 9 in. were made from concrete as used at the dam and were taken to Prof. I. L. Collier at the University of Washington. These were subjected to 170 lbs. per sq. in. pressure and were found to be water tight.

The design and construction of this dam was under the direction of the City Engineer; T. H. Carver, Assistant City Engineer having direct charge. The Constant Angle Arch Dam Co., of San Francisco were consultants; E. D. Alexander was Resident Engineer; and Winston Bros., Minneapolis, Minn., Contractors.

Readers are referred to the JOURNAL *for June, 1931, for discussion which may develop. Such discussion should reach the Secretary by May 1, 1931.*

Some Long Time Tests of Concrete*

by M. O. Withey†

INTRODUCTION

Two programs of experiments to ascertain the age-strength relationship for concrete cured under common conditions are in progress at The University of Wisconsin. The older test program, herein called Series A,[1] was begun in 1910 and includes crushing tests on 450 6 x 18-in. concrete cylinders of 1:2:4 and 1:3:6 proportions together with auxiliary tests on neat cement and standard sand mortars. Only one set of materials was used in these tests. The three curing conditions in Series A are: 1, storage in a water tank; 2, storage in a cage out of doors; and 3, storage in a cellar. Originally the program was planned to extend over a 10-year period but changes have been made in the test ages to extend the breaking periods to 50 years. Results of tests after 20 years storage are recorded in this report.

In the summer of 1923 a more comprehensive test program, Series B, was initiated. In this, four brands of cement, three coarse aggregates, three proportions, two consistencies, and two curing conditions were used. The total program included 1600 6 x 12-in. concrete cylinders for compression tests, 120 for absorption tests, and 30 for alternate freezing and thawing tests; 96 4 x 6 x 24-in. concrete slabs for expansion tests; 960 2 x 4-in. mortar cylinders, and 1080 briquettes. The curing conditions for this series are: 1. Out of doors as in Series A; 2. In a room in the laboratory.

It is planned to have these specimens tested at 10 intervals over a century. Results of tests up to 5 years are now reported.

*For presentation and discussion at 27th Annual Convention, Milwaukee, Feb. 24-26, 1931.

†Professor of Mechanics, College of Mechanics and Engineering, University of Wisconsin, Madison.

Acknowledgments

The courtesy of the Wisconsin Granite Company, of Redgranite, in providing the crushed granite used in the tests of Series B is gratefully acknowledged.

Assistance in making the specimens of Series A was rendered by E. B. Nelson, '13; E. J. Paulus, '11; A. Ludberg, '11; and C. M. Scudder, '11. Messrs. S. D. Wonders, '13; C. M. Osterheld, '14; F. D. Bickel, '15; O. A. Bailey, '15; M. B. Hunder, '30; and L. M. Basford have assisted in testing and in preparation of data for reports.

The tests of Series B were made by C. A. Wiepking, with the assistance of R. S. Phillips, both at the time instructors in Mechanics, and W. Laflash, laboratory attendant. Mr. Wiepking also prepared many of the data for this report, A. H. Armstrong and M. B. Hunder assisted.

TESTS OF SERIES A

Materials

Cement—Atlas portland cement from Hannibal, Mo., was used in these tests. A sufficient supply for the entire program was mixed and stored in tightly covered milk cans. One 10-gallon can of this cement was set aside and retested from time to time when tests were made on the concrete specimens. Fig. 1 shows the effects of long storage in the tightly covered can on the tensile strength properties of this cement.

Aggregates—Janesville sand containing about 60 per cent quartz and 30 per cent dolomite was used in making the concrete specimens of the earlier tests. It weighed, when measured dry and loose, 109 lbs. per cu. ft. and contained 34.3 per cent voids. Approximately 97 per cent passed a ¼-in. sieve, 62 per cent passed a No. 30, and 3 per cent passed a No. 100 sieve. The specific gravity of the sand was 2.66.

A rather soft magnesian limestone crushed to pass a 1¼-in. sieve with 64 per cent passing a ¾-in., and 5 per cent passing a ¼-in. mesh was obtained from a local quarry and used in these tests. It weighed 87½ lb. per cu. ft. and contained 48 per cent voids. The specific gravity was 2.74.

Making and Testing Specimens

Making Specimens—The volumes of cement and air dry aggregate for each batch of 15 6 x 18-in. concrete cylinders were weighed; water was measured by a calibrated tank. Materials were mixed in a No. 0 Smith mixer ¾ min. dry and 2¼ min. after water was added. In emptying the mixer and in filling the molds care was taken to insure uniform disposition of the mixed concrete. Metal molds were assembled on leveled steel plates and every mold was filled about ⅓ full of concrete from each of the three wheelbarrows used in emptying the mixer. The concrete was puddled with an iron rod to expel air bubbles. After the concrete had partially hardened, tops of cylinders were capped with a thin layer of 1:1½ mortar.

Neat cement and mortar test pieces were made in accordance with the standard methods used in cement testing in 1910.

Curing—Concrete specimens were kept in molds three days, then marked, measured, weighed, and placed in a moist chamber where they were sprinkled twice a day for eleven days. Five specimens from each batch were subjected to each of the following curing conditions:

1. Cylinders were submerged in a 4½ x 4 x 2¾-ft. water tank at a temperature usually between 60 deg. and 70 deg. F. but occasionally dropping to 35 deg. F. for short periods in winter. During the first two months of storage the water in the tank was changed frequently, and for the first four years thereafter it was changed once a month. Subsequently it was changed at irregular intervals but usually three or four times a year.

2. Cylinders were placed with ends on the ground in an uncovered cage having a northeast exposure. The temperature range for the 20-year period was 25 deg. to 101 deg. F., the average was 46 deg. F. The mean humidity for that period was approximately 75 per cent with occasional departures of ± 10 per cent.

The average annual precipitation at Madison is 32 in. (includes snow). The average snowfal is 38 in. It is estimated that the specimens were subjected to 300 to 350 cycles of freezing and thawing during the twenty-year test period.

3. Cylinders were placed with ends in contact with the ground

in a cellar. The estimated range in temperature approximated 35 deg. to 70 deg. F. and the humidity range 50 to 75 per cent.

The neat cement and mortar specimens were stored one day in the moist closet and 13 days in a water bath at room temperature prior to being subjected to the previously mentioned storage conditions. In the cage and in the cellar these specimens rested on shelves.

One week before testing, concrete specimens were brought into the laboratory and were again weighed on the day broken. Neat cement and mortar specimens were tested immediately after removal from the given storage condition. In the early tests during the winter months frozen specimens were thawed before testing.

The schedule was so arranged that only one concrete specimen from a batch and curing condition was tested at a given time. For each age, mix, and curing condition five cylinders and three or four mortar specimens were broken.

Testing—Rough spots on the ends of cylinders and cubes were removed. In the tests made up to the ten year period two thicknesses of blotting paper were used on the top and bottom surfaces of compression specimens. In subsequent tests they were bedded with plaster of Paris. Speed of testing in the first seven years was somewhat less than 0.1 in. per min. Thereafter, the speeds were 0.06 in. per min.

Briquettes were tested in a Riehlé automatic shot briquette tester, but the roller bearings used in the early tests were inferior to those used in 1930.

Results of Tests

Tests on Stored Cement—The data in Fig. 1 and similar data on the compressive strengths of mortars show that portland cement may be stored for a very long time in a tightly closed vessel without suffering any material change in its strength properties. The changes represented by the data probably reflect discrepancies in testing procedure exercised by the different operators more than variability in properties due to age.

Effect of Curing Conditions on Strength of Mortars—The results of the tensile tests of neat cement and 1:3 standard sand mortar

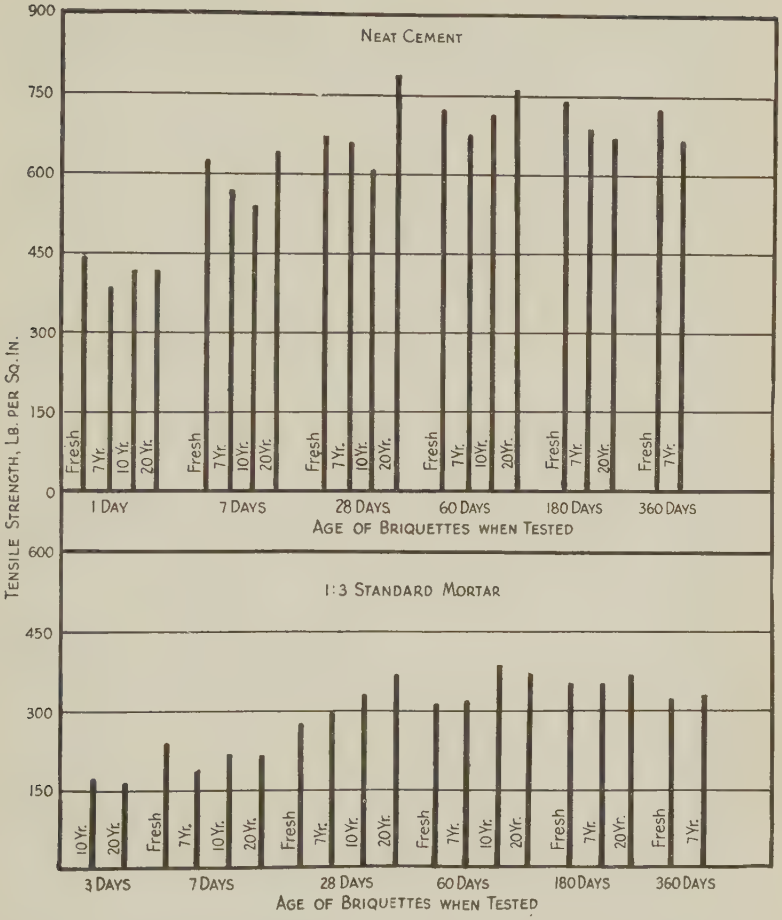

FIG. 1—THE EFFECT OF STORAGE IN A CLOSED MILK CAN ON THE TENSILE STRENGTH OF ATLAS PORTLAND CEMENT

briquets subjected to the different curing conditions are shown in Fig. 2. The neat cement specimens show wide variations in tensile strength under all three curing conditions. Much of this variability was undoubtedly due to surface cracks which were more or less pronounced in many of the neat briquets. The tensile strength of the 1:3 mortar briquets cured in the cage or

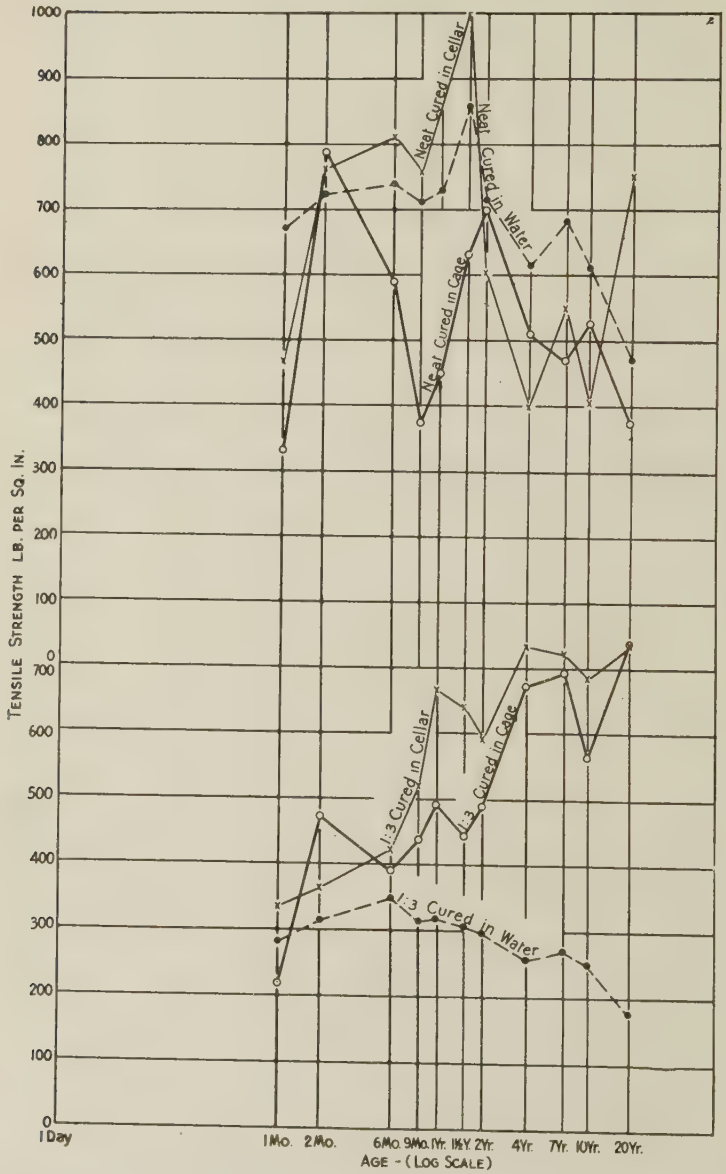

FIG. 2—RELATIONSHIP BETWEEN AGE AND CURING CONDITIONS ON THE TENSILE STRENGTH OF ATLAS CEMENT MORTAR BRIQUETS

in the cellar increased approximately as the logarithm of the age, as Fig. 2 shows, with the cellar-cured specimens showing slightly higher tenacity. On the other hand, the tensile strength of the water-cured 1:3 mortar specimens exhibited a decided retrogression after six months. Chemical analyses of the 1:3 briquettes subjected to the different storage conditions for 20 years showed the following cement contents in terms of the weight of the sand: for the cellar-cured specimens 34 per cent, for the cage-cured specimens 33 per cent, and for the water-cured specimens 31 per cent. From these data it seems likely that leaching out of the cement from the surfaces of the porous water-cured 1:3 briquets was the probable cause of their weakness in the late tests.

Effect of Curing Conditions on Compressive Strength of Concrete—Curves showing the relationship of the compressive strength of the concretes cured in the three ways to the logarithm of the age at test are shown in Fig. 3. Each point represents the average of five tests. It is apparent that the compressive strength of both the 1:2:4 and the 1:3:6 mixes cured out of doors or in the water tank increased approximately as the logarithm of the age. These two storage conditions gave approximately equal strengths. It is of interest to note that the 1:2:4 mixes cured under the more favorable conditions were slightly more than 2½ times as strong at 20 years as at one month, and that the 1:3:6 mixes under similar conditions were over 3½ times as strong. This increased percentage gain should not be interpreted as meaning that the weaker mixtures are gaining on the stronger, for Fig. 3 shows that the general trend of the curves is divergent and that the margin of strength between the rich and lean mixes is widening as the age increases. Both mixes of concrete cured in the cellar exhibited at 20 years about twice the one-month strength.

TESTS OF SERIES B

Materials

Cements—To ascertain the effect of different brands of cement on the age-strength relationships, three 10-bag shipments from each of four brands commonly used in Wisconsin were purchased from different consignments. Each shipment was sampled and tested and also the mixture of the three shipments of each brand. The four mixtures were used in the major tests of Series B. Table

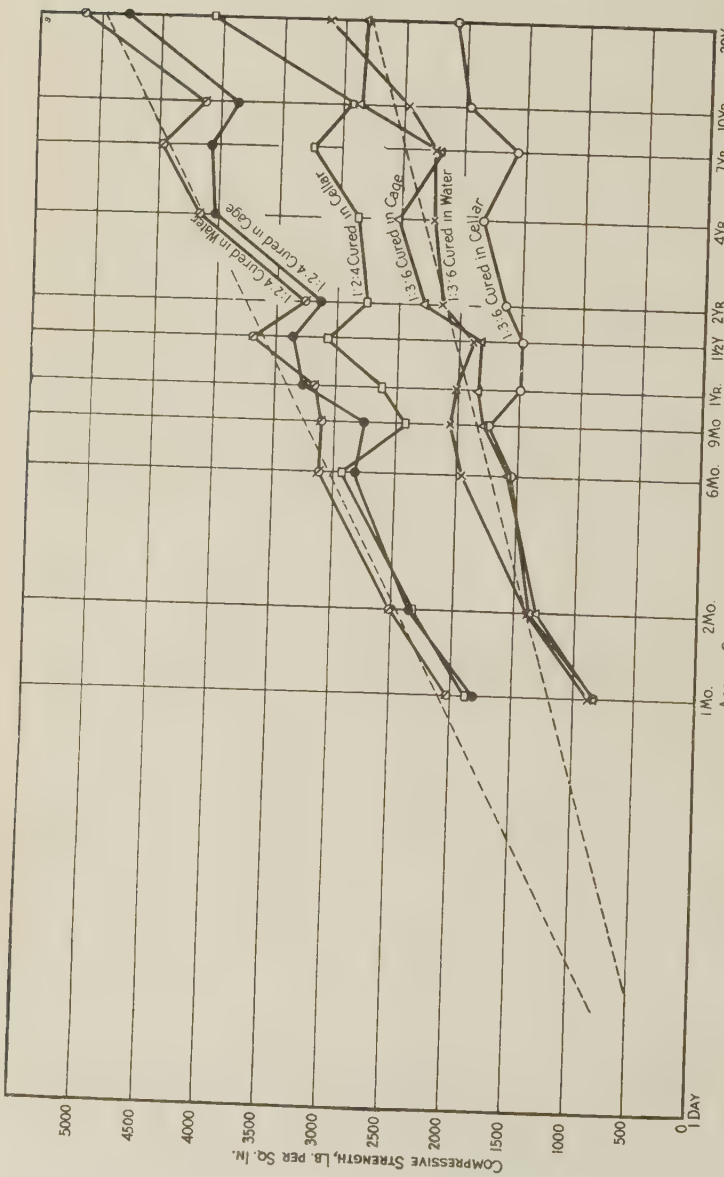

FIG. 3—STRENGTH-AGE CURVES FOR CONCRETE CURED IN VARIOUS MANNERS

1 shows results of standard physical tests on the mixtures representing the four brands. All brands exhibited good strength properties at 3, 7, and 28 days and passed other standard requirements. However, between the 90-day and 5-year periods all brands showed retrogression in both neat cement and mortar strengths. It is of interest to note that brand 3M which exhibited the greatest retrogression in mortar strength was the only brand which had a higher neat strength at five years than at one year.

*Average of tests on individual shipments.

Chemical compositions of these cements are given in Table 2. The calculated constitutions of the cements are given in Table 9.

Autoclave tests were also made on the cements, but the results appear to have little correlation to the data thus far obtained in other tests.

Janesville gravel contained approximately 50 per cent broken fragments, and is composed of approximately ¾ dolomite, 1/5 quartz, the remainder being igneous material.

Janesville sand contained approximately 3/5 quartz, ¼ dolomite, and the remainder was largely igneous material.

Red granite is composed essentially of quartsite and feldspar.

Aggregates—Table 3 shows the physical properties of the aggregates used in tests of Series B. The Janesville sand and gravel are representative of the better types of glacial sand and gravel commonly used in concrete construction in Southern Wisconsin. Lannon dolomite and red granite represent hard and durable crushed rock aggregates of their respective types. The gravel particles were the most nearly equiaxed, the granite particles the least. It will be noted that all the coarse aggregates had approximately the same grading as indicated by the values of the fineness modulus (m).

Making and Testing Specimens

Auxiliary Test Specimens of Mortars—Besides the standard strength tests of cements, additional tensile and compressive tests of mortars made with standard sand and others made with Janesville sand are scheduled as outlined in Table 4.

TABLE 4—SCHEDULE OF MORTAR TESTS OF SERIES B

Brand of Cement	Kind of Sand	Mix by Weight	Curing Condition	Age at Test	Number of Specimens to be Tested

As above	Standard	1:3	In water	As above	3		120	
					Total. .	. . . . .	960	840

The consistencies for these mortar tests were based on Feret's formula,

$$w = \frac{2}{3}\frac{p}{s+1} + k;$$

where w = percentage of water for the given mix, s = number of parts sand to one of cement, by weight, p = percentage of water for standard neat consistency, and k = 6.5 for standard sand and 6.9 for Janesville sand.

Mortar briquets and cylinders were made in groups of six in separate batches. Specimens were numbered and stored so that not more than one specimen of a given batch was tested at an age. Specimens were cured one day in molds, 27 days in water. Those to be stored outdoors were then placed on wood shelves in the same cage used for the storage of specimens of Series A.

Concrete Test Specimens—Cylinders 6 in. in diameter and 12 in. high were made in batches of 20 in accordance with the program in Table 5. The materials were weighed and mixed in the same type of mixer as specimens of Series A. Dry cement and aggregate were mixed for ½ min., then the water was added and mixing was continued for 1½ min. Each batch from the mixer was discharged into wheelbarrows and thence onto a mixing tray where it was turned over to render it homogeneous. The requisite water for the desired consistency was determined by hand-mixing small preliminary batches. The consistency of every batch was checked on a 30-in. flow table using an 8 x 12 x 6-in. frustrum and 15 ½-in. drops in 15 sec. Molds were filled quarter full at a time and each layer was puddled 25 times with a ½-in. rod. A neat cement cap was placed on each cylinder about four hours after molding. After one day in the molds specimens were marked and stored for 27 days in a moist closet. Then they were removed and subjected to the appropriate storage conditions. The outside curing is conducted in the same cage as the specimens of Series A. The inside curing is done in a room where the temperature ranges from 65 to 85 deg. F. and the humidity ranges from 40 to 80 per cent. The schedule is so arranged that not more than two cylinders from a given batch are broken at a given age.

The 4 x 6 x 24-in. contraction prisms were made from certain of the batches used in making cylinders. Brass plugs spaced

TABLE 5—SCHEDULE OF CONCRETE TESTS OF SERIES B

Janesville sand was used in making all specimens.
Specimens for compression, absorption, and freezing tests were 6 x 12-in. cylinders; for contraction tests were 4 x 6 x 24-in. prisms.

20 in. apart were molded in the axis of each 6 in. face. These were provided with holes for strain gage readings. The slabs were subjected to the same curing conditions as the cylinders.

The 6 x 12-in. cylinders for the absorption and freezing tests were selected from those made in different batches. The absorption cylinders were roughened with wire brushes when one day old. For both types of test the cylinders were cured in the moist closet for 27 days.

Methods of Testing

Absorption Tests—After the roughened 6 x 12-in. cylinders for the absorption tests had been stored 27 days in the moist closet they were dried to constant weight at temperatures just above the boiling point of water. They were then immersed in water at room temperature for 48 hr. to determine the percentage of absorption. After an interval of a few days the cylinders were boiled in water for 5 hr. to ascertain how much additional water they would absorb. The percentages of absorption were based on weights.

Method for Freezing and Thawing Tests—The cylinders to be subjected to the freezing and thawing tests, after curing in moist closet for 28 days, were immersed in hot water, at approximately 190 deg. F., for several hours to saturate them. They were cooled in running tap water and then placed in a freezing chamber having an average temperature of 21 deg. F., and kept there until thoroughly frozen. All of these specimens were subjected to twenty such cycles. They were then broken in compression.

Contraction Measurements—Measurements on the lengths of the 4 x 6 x 24-in. contraction prisms were made with a 20-in. Berry strain gage reading to 0.0001 in. Initial readings were taken when the specimens were one day old. They were again read after 27 days in the moist closet while still in the closet and then removed to the assigned storage condition. Measurements of lengths and weights have since been taken at regular intervals, usually at the test periods for the concrete cylinders.

Procedure in Strength Tests—Mortar and concrete specimens stored in the cage have been removed to the laboratory and stored two days prior to testing. Other specimens were carried directly from storage to testing machine. Wherever necessary

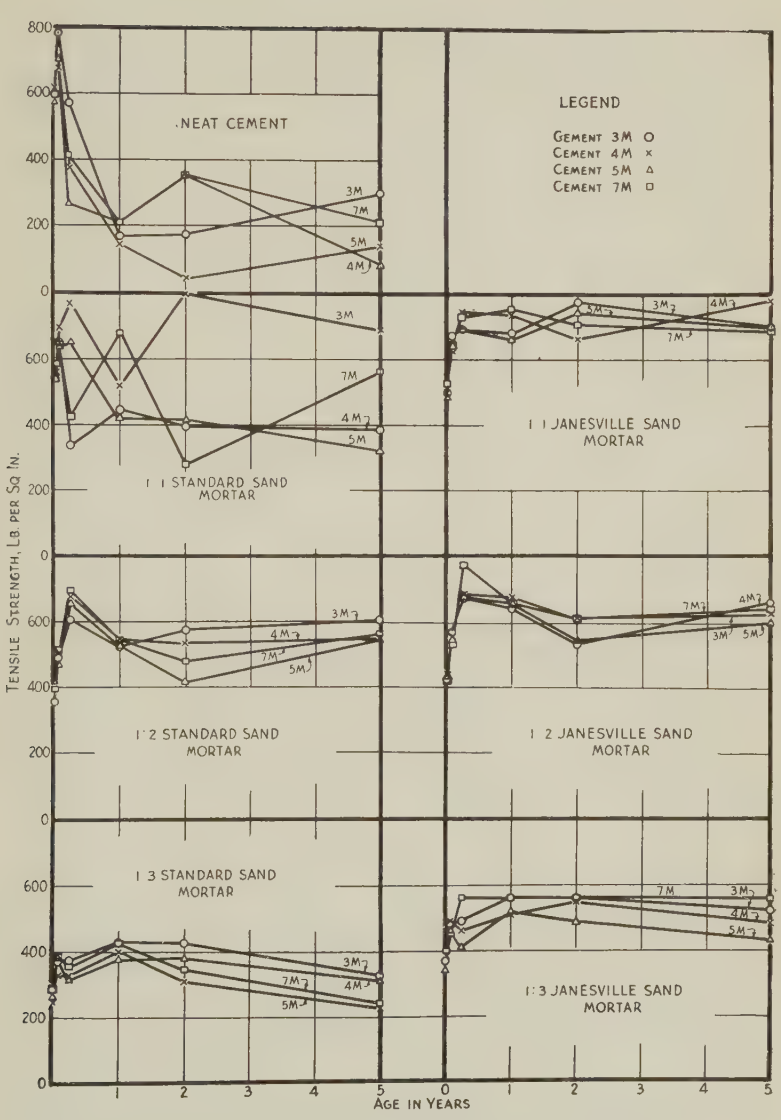

FIG. 4—RESULTS OF TENSION TESTS ON MORTAR AND NEAT CEMENT BRIQUETS CURED OUTSIDE AFTER 28 DAYS

defective caps have been removed from compression cylinders and they have been recapped with plaster of Paris.

The 6 x 12-in. concrete compression cylinders have been broken on a 200,000-lb. 3-screw Riehlé testing machine equipped with a spherical bearing on the movable head. The speed used in applying maximum loads was 0.06 in. per min.

The 2 x 4-in. mortar cylinders have been broken at a speed of 0.03 in. per min. under a small spherical bearing.

Briquettes have been tested in a Riehlé automatic shot briquet tester equipped with standard roller bearings.

RESULTS OF TESTS OF SERIES B

Mortar Strength Tests—Fig. 4 shows the effect of outside curing on the tensile strength of briquets made in 1923. These data show that neat cement briquets and 1:1 standard sand mortar briquets suffered severely from weathering. In some instances briquets of these rich mixes were badly checked and gave little strength. Since these very low values were averaged with the other results, they account for the marked fluctuations in the tensile-strength-age curves. Why the tenacity of the 1:1 mortars of standard sand suffered so markedly in contrast to 1:1 mortars of Janesville sand is not apparent. All 1:3 standard-sand mortars cured outside exhibited a pronounced retrogression in tensile strength after the one-year period. The 1:3 Janesville-sand mortars also showed a slight retrogression after the one-year period. The 1:2 mortars and the 1:1 Janesville-sand mortars showed little change in tensile strength after the one-year period.

The results of the compression tests (not presented herein) on 2 x 4-in. mortar cylinders cured outside show much less variation in compressive strength than in tensile strength. Furthermore, there is no pronounced retrogression in strength with age for any of the mixes. As in the tensile tests, the Janesville sand mortars exhibited compressive strengths superior to those attained by standard sand mortars, especially in the 1:3 mixes.

In the mortar tests the influence of brand on strength was not large. Considering the results of tests with Janesville sand and averaging the data for the 28-day to 5-year periods, brand 7M showed the highest tensile strength and brand 5M the lowest. The difference between the average for the highest brand and the

lowest brand amounted to 4 per cent for the 1:1, 7 per cent for the 1:2, and 15 per cent for the 1:3 mix. In compression brand 4M gave the highest average strength and brand 5M the lowest. The difference between the average for the highest and lowest brands was 9 per cent for the 1:1 mix, 8 per cent for the 1:2 mix, and 6 per cent for the 1:3 mix.

The differences in tensile strengths of the neat cement mixes due to curing conditions was very marked. Neat briquettes stored in water exhibited much higher and more uniform strengths than those stored outside. The discrepancies in the tensile strengths of the 1:3 standard sand mortar briquets due to the two storage conditions was not marked, but the 1:3 cylinders of standard sand cured outside averaged about fifty to seventy-five per cent stronger than companion specimens cured in water at room temperature.

It is believed that the wide discrepancies in the tensile strengths of the specimens cured outside was due to surface checks which seriously diminish tenacity, especially of small specimens, but which affect the compressive strength little.

Physical Properties of Concretes—Data on average cement contents, water-cement ratios, consistencies and densities of the concretes used in these tests are given in Table 6. The water-cement ratios are based on ratio of the volume of free water (absorbed water subtracted) to the volume of cement. Cement contents, specific weights, and densities were determined on concrete after removal from molds.

Results of Absorption Tests—Data on the absorption tests are given in Table 7 and in Fig. 5. The absorptions of the individual cylinders were very uniform in most cases, the average variation from the mean in a group of five was less than 5 per cent and in only one case did it reach 8 per cent. The data in column 7 of Table 7 show the variations of the mean for each brand from the average for the given mix.

The absorption for the 1:2:4 Red granite mix was least, and that mix also had the lowest ratio of absorption after 4-hr. immersion to absorption after boiling. Considering tests with Janesville gravel, the absorption appears to increase as the water-

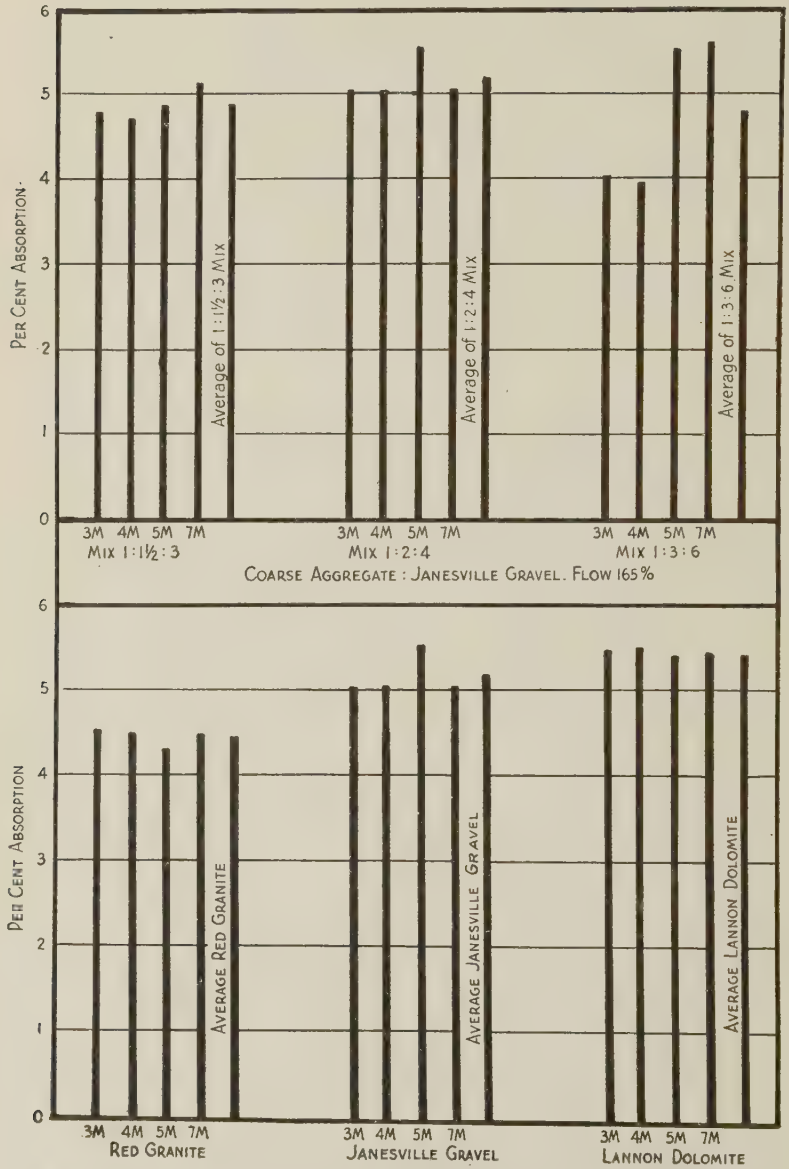

FIG. 5—EFFECT OF MIX AND TYPE OF AGGREGATE ON ABSORPTION OF CONCRETE

TABLE 7—RESULTS OF ABSORPTION TESTS ON CONCRETE

Specimens were stored in moist closet for 27 days, dried to constant weight, then immersed in water for 48 hours. After a few days the cylinders were boiled in water for half a day to show how much more additional water would be absorbed by this treatment.

Each value represents the average of 5 test specimens.

[a]This value represents the average of 4 test specimens.
[b]This value represents the average of 2 test specimens

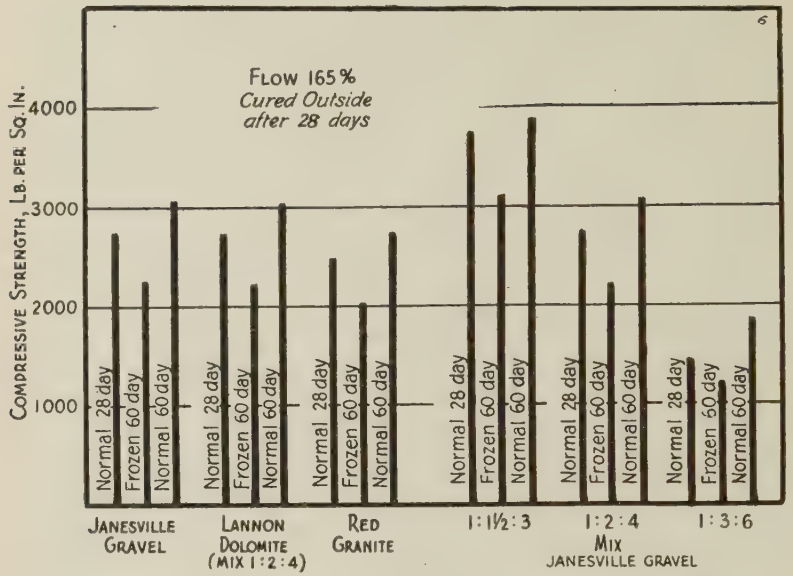

FIG. 6—EFFECT OF AGGREGATES AND PROPORTIONS ON STRENGTH OF CONCRETE SUBJECTED TO FREEZING AND THAWING

cement ratio (w/c) increases. A higher w/c undoubtedly accounts for the absorption of the 1:2:4 Lannon stone mix being greater than the absorption of the 1:2:4 mix of Janesville gravel.

Neglecting values for the 1:3:6 mix, in which the values for brands 3M and 4M appear abnormal, the average absorptions for 25 specimens of a given brand were:

Brand	3M	4M	5M	7M
Average Percentage Absorption	5.15	5.21	5.35	5.17

Hence there appears to be little difference in the absorption of concrete made from these brands of cement.

Results of Freezing and Thawing Tests—The data from the freezing and thawing tests on the concrete cylinders are summarized in Table 8 and Fig. 6. Although the freezing and thawing tests were started when the specimens were 28 days old the

TABLE 8—RESULTS OF FREEZING TESTS

Test specimens were cured normally for 28 days, then subjected to 20 cycles of freezing at a temperature of approximately 21° F. and thawing in water heated at a temperature of approximately 190° F. Temperature reversals extended over a period of one month.

All normal specimens were cured outside after 28 days.

The 60-day normal strength values were interpolated from strength curves plotted against the logarithm of the age.

A/B is the ratio of the percentage absorption at 48 hours to the percentage increase in weight due to boiling 5 hours in water after drying.

Mix	Coarse Aggregate	Cement Brand	W/C Ratio	Flow, Per Cent	Comp. Strength, Lb. per Sq. In.			% Reduction in Str. of Frozen Concrete Based on 60-Day Normal Str.	Ratio, A/B

20 cycles were not completed until the specimens were about 60 days old. Since no tests were made on normal concrete at 60 days, for purposes of comparison the strengths of normal specimens in column 8 of Table 8 were estimated by interpolating between the 28-day strengths and the 90-day strengths. In making this interpolation the strength was assumed to vary with the logarithm of the age.

It will be noted from the data in column 9, Table 8 and Fig. 6 that in every case the concrete which was subjected to freezing and thawing had less strength than the normally-cured concrete 28-days old and considerably less strength than the estimated 60-day strength for normal concrete. Considering all mixes, the concrete which was frozen and thawed had an average strength eighteen per cent less than the normally-cured concrete 28-days old and 26 per cent less than the estimated strength of normally-cured concrete 60-days old.

From the chemical analyses in Table 2 the constitution of each of these cements has been calculated and the percentages of the components are listed in Table 9. In the same table are listed the average absorption data from Table 7, the values of Schurecht's ratio, A/B, from column 10 of Table 8, and the average percentage loss in compressive strength due to freezing. Values for the 1:3:6 mix are excluded in these tabulations. Comparisons show that there was not a great difference in the freezing resistances of the concretes made of these different cements, that made from cement 3M had the lowest absorption, the lowest Schurecht's ratio (A/B), and the lowest loss in strength due to freezing and thawing.

A study of these data indicates that the losses in the freezing and thawing test were greatest for mixes having high water ratios and high absorptions and least for those mixes made with lowest water ratios and having the lowest absorptions. Hence, as Fig. 6 shows, the 1:1½:3 mix of high cement content and low water-cement ratio exhibited the lowest loss, 19 per cent, in freezing and thawing, whereas the lean 1:3:6 mix showed the highest loss, 33 per cent. Making allowances for the discrepancies in the water-cement ratios of the 1:2:4 mixes made with different aggregates, a comparison of the data in Fig. 6 indicates that there

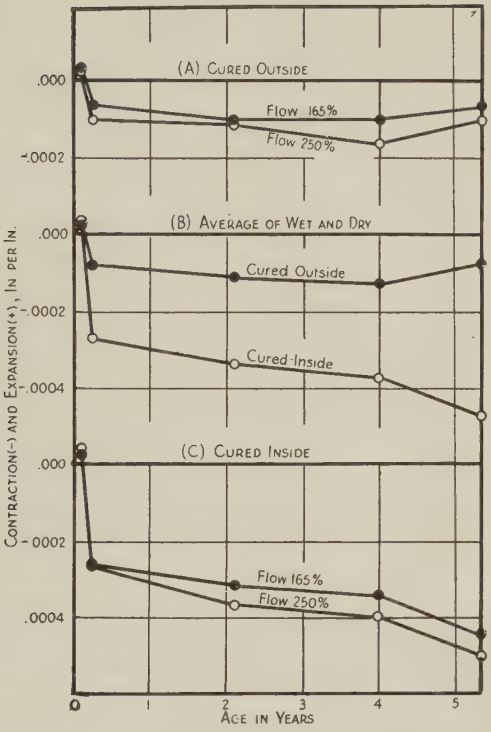

Fig. 7—Expansion and contraction of 1:2:4 concrete of different consistencies made of Janesville gravel

was little difference in resistance to freezing of the concretes made with these aggregates.

Results of Expansion and Contraction Tests—The data on effect of outside curing on the linear contraction of 4 x 6 x 24-in. slabs show that at 1 month the mean linear dimensional change in all cases was a small initial expansion (0.00006 to 0.00008) due to curing in the moist closet, but at subsequent periods the outside curing caused a somewhat greater contraction in nearly all cases. The data indicate that the average contraction on concrete made with cement 3M was the least of the average values for the four cements used in these tests. Data from the concrete cured indoors indicated a similar relationship.

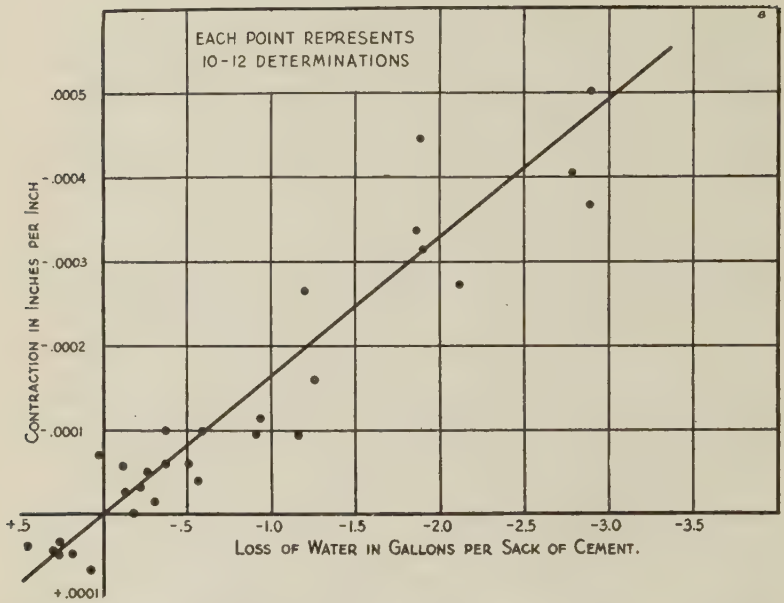

FIG. 8—THE RELATIONSHIP BETWEEN EXPANSION, CONTRACTION, AND LOSS OF WATER IN CURING FOR 1:2:4 CONCRETE

Cement Content of Concrete 5.0 to 5.5 Sacks per cu. yd.

Concrete made of the dolomite showed the most expansion and the least contraction due to outside curing, whereas that made of gravel showed the greatest contraction. In no cases, however, did the average change exceed 0.0001.

The evidence concerning the effect of proportion of cement, is not conclusive, but it indicates that the contraction in curing outside was greatest for the 1:1½:3 mix.

The curves in Fig. 7 (A) and (C) show that the 1:2:4 concrete with a flow of 165 per cent contracted less than the wetter mix with a flow of 250 per cent. Fig. 7 (B) indicates that curing inside caused three to six times as much contraction as the outside curing. At five years contraction of the 1:2:4 concrete due to indoor curing amounted to .04 to .05 per cent.

The most significant relationship obtained in these expansion and contraction tests is that between the percentage of water lost

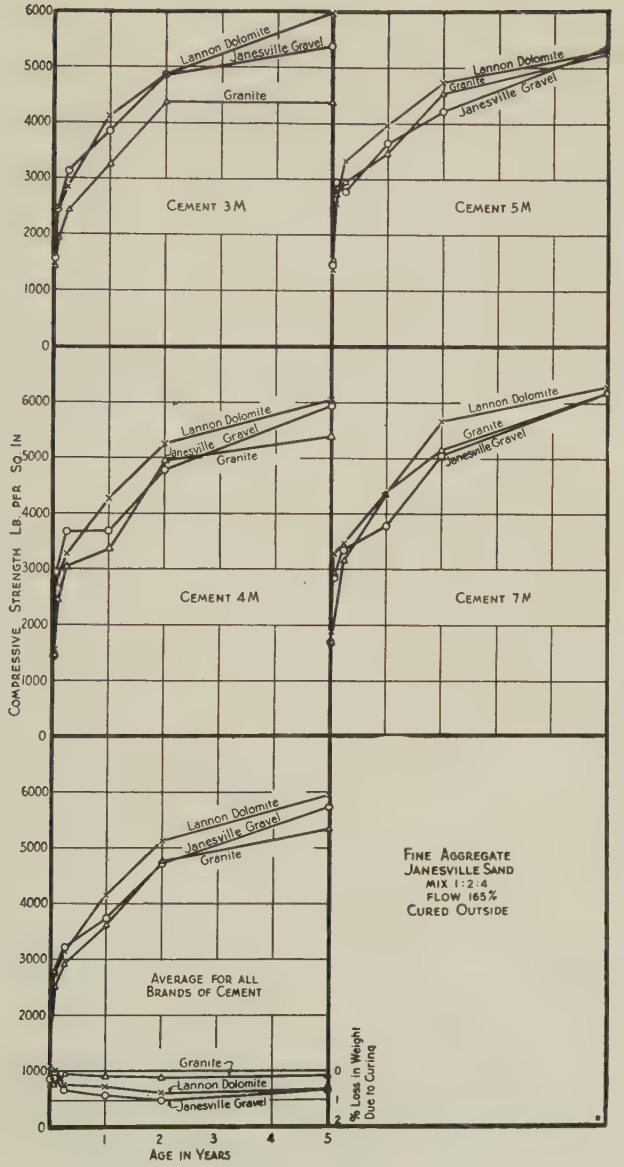

FIG. 9—STRENGTH-AGE RELATIONSHIP FOR CONCRETE MADE OF DIFFERENT BRANDS OF CEMENT AND DIFFERENT AGGREGATES

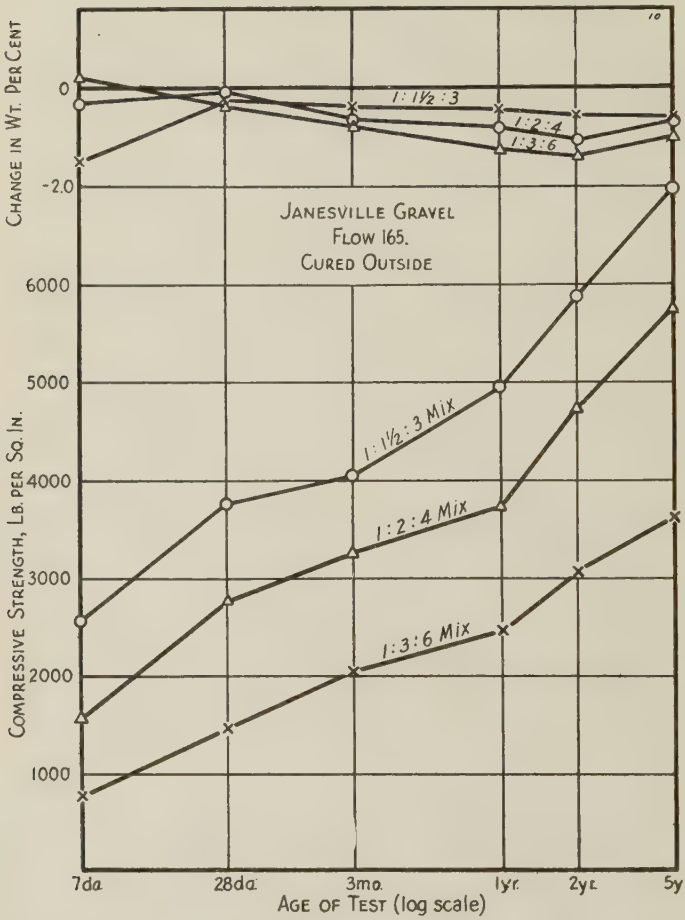

FIG. 10—EFFECT OF MIX ON THE COMPRESSIVE STRENGTH OF CONCRETE AND ON LOSS IN WEIGHT DUE TO CURING

and the change in linear dimension, see Fig. 8. Doubtless most of the discrepancies are due to losses in weight from spalling of the specimens in handling. The line in Fig. 8 checks very closely data obtained at the Portland Cement Association Research Laboratory by M. B. Lagaard.* With this relationship in mind,

*See diagram in Johnson's *Materials of Construction*, 7th Ed., p. 480

one would expect that the contraction would be least for the cement paste exhibiting the lowest absorption. The data herein, though meager, substantiate this view.

Results of Compression Tests of Concrete—The effects of age on the compressive strength of 1:2:4 concrete cured outside are plotted in Fig. 9 to a uniform age scale. The strength-age data for the tests on 1:1½:3, 1:2:4 and 1:3:6 mixes of Janesville sand and gravel are plotted to a logarithmic age scale in Fig. 10. No retrogressions in strength are exhibited in any of these curves, but the retarding influence of seasonal variations in temperature and humidity during the first year are manifested by the corresponding irregularities in the strength-age curves. As in tests of Series A, the data of Fig. 10 show that the strength increased with the logarithm of the age at test.

The curves in Fig. 9 show that the concrete made of Lannon dolomite was slightly stronger than that made of the other aggregates despite the fact that it was mixed with a higher water cement ratio. The concrete from this aggregate also contained a larger proportion of cement than the concrete made with the gravel. The latter fact and the superior bond afforded by the surfaces of the angular dolomite particles undoubtedly account for the superior strength of the dolomite concrete.

The effects of the outside and of the inside curing conditions on the age-strength relationships are shown in Fig. 11. Concrete cured inside exhibited little change in strength after the 3 month tests, and at 5 years had only about 65 per cent of the strength of concrete cured outside.

The data show that 1:2:4 concrete with a flow of 165 percent (w/c = 0.76) had, when cured outside for one year, 35 per cent greater strength than similar concrete with a flow of 250 (w/c = 1.01). At 5 years the mix with 165 per cent flow had 50 per cent greater strength than the wetter mix. Under inside curing the drier mix exhibited from 25 to 35 per cent greater strength than the mix with a flow of 250 per cent.

Since loss in weight during curing is a measure of the desiccating influence of the storage medium on the concrete, it is of interest

TABLE 9—A COMPARISON OF CALCULATED CONSTITUTIONS OF CEMENTS 3M, 4M, 5M, AND 7M WITH RESULTS OF VARIOUS TESTS

Brand of Cement	5M	3M	4M	7M
Per cent $3CaO.SiO_2$	35.1	33.5	21.3	17.6

Gain in neat strength in autoclave, per cent	48	25	24	34
Expansion in autoclave, per cent	.09	.21	.13	.14
Ave. percentage absorption of 1:2:4 concrete	5.35	5.15	5.21	5.17
Ave. Schurecht's ratio	0.88	0.84	0.87	0.87
Ave. loss of crushing strength of concrete due to freezing and thawing, per cent	31	22	24	25
Ave. contraction of 1:2:4 concrete, flow 165 per cent cured outside 4 yr., per cent	0.010	0.0007	0.007	0.008
Ave. contraction of 1:2:4 concrete, flow 165 per cent cured inside 4 yr., per cent	0.036	0.027	0.032	0.040
Ave. crushing strength of 1:2:4 concrete, flow 165 per cent, cured in moist closet 1 mo., lb/in.^{2}	2945	2430	2950	2800
Ave. crushing strength of 1:2:4 concrete, flow 165 per cent, cured outside 5 yr., lb/in.^{2}	5395	5370	5925	6190
Ave. crushing strength of 1:2:4 concrete, flow 250 per cent, cured in moist closet 1 mo., lb/in.^{2}	2125	1445	1780	1790
Ave. crushing strength of 1:2:4 concrete, flow 250 per cent, cured outside 5 yr., lb/in.^{2}	3640	3505	3815	4280

to note the marked discrepancy between the percentage loss in weight of the concrete with flow of 165 cured indoors and the loss in weight of like concrete cured outside. At five years the concrete cured indoors had lost 3 per cent of its weight whereas that cured outside had lost about 0.7 per cent. Losses in weight sustained by the 1:2:4 concrete with a flow of 250 per cent at the

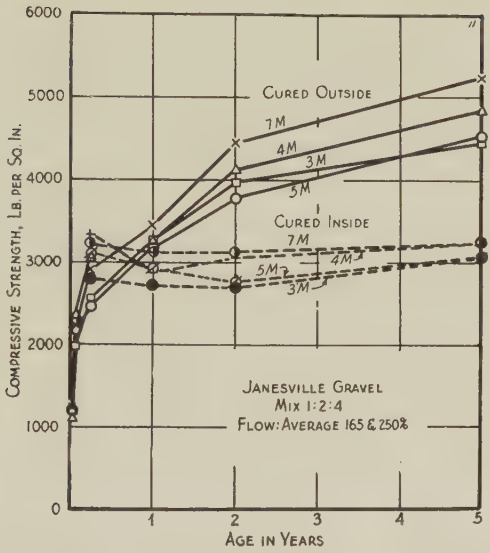

Fig. 11—Effect of curing conditions on strength of 1:2:4 concrete with different cements

same age were 3.6 per cent for the concrete cured inside and 1.1 per cent for that cured outside.

The linear relationship between the compressive strength of concrete of 165 per cent flow and the cement-voids ratio is well shown by the curves of Fig. 12. Each point in the diagram represents five tests.

The relationship of compressive strength of concrete to the water-cement ratio, by volume, is indicated in Fig. 13. Each point on these diagrams represents 20 tests.

Influence of Kind of Cement on Properties—Table 9 shows the amounts of the principal constituents in the different cements used in these tests. The percentage of these constituents were calculated from the chemical analysis by Bogue's method.* In Fig. 14 are shown the compressive strength-age curves for the concretes made of each brand of cement. In constructing these

*Paper No. 21, Portland Cement Association Fellowship at the National Bureau of Standards, Washington, D. C.

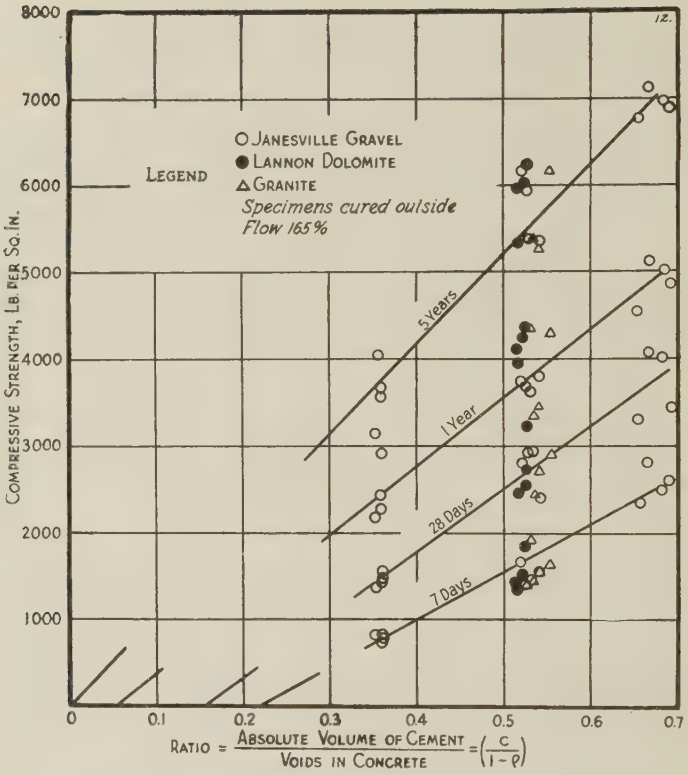

FIG. 12—RELATION BETWEEN THE COMPRESSIVE STRENGTH AND THE RATIO OF THE VOLUME OF CEMENT TO THE VOLUME OF VOIDS IN CONCRETE

curves the strengths of concretes of 165 per cent flow made with the various aggregates and proportions were averaged.

From the data in Table 9 it appears that there were considerable differences in the constitutions of these cements but the discrepancies in the various physical properties are much less. In most cases it will be noted that the cements containing the lower proportions of tri-calcium silicate (3 $CaO.SiO_2$) and the higher proportions of di-calcium silicate (2 $CaO.SiO_2$), brands 7M and 4M, exhibited in these long time tests slightly better strengths

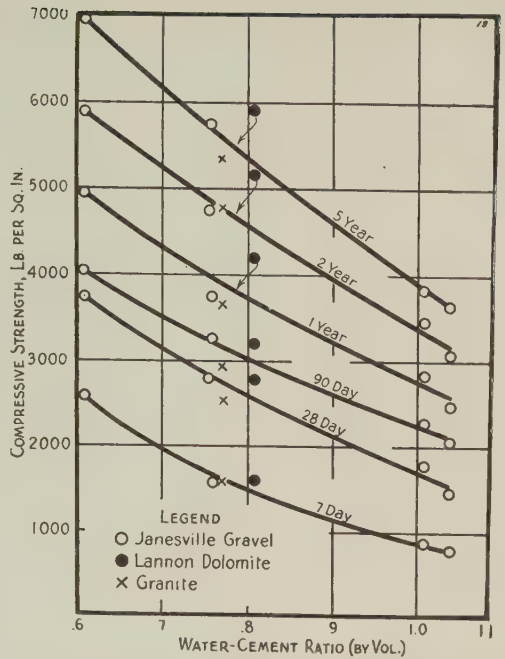

Fig. 13—Strength water-cement ratio relationship for concrete of different ages

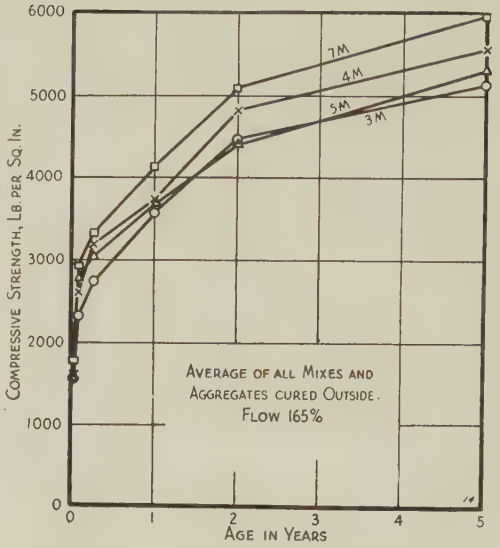

Fig. 14—Effect of brand of cement on the strength-age relationship

than the other two brands 5M and 3M which contained higher percentages of tri-calcium silicate.

As previously mentioned, the absorption and the loss in crushing strength due to freezing were slightly greater for the concrete of cement 5M (which was high in tri-calcium silicate and tri-calcium aluminate) than for the concretes made of other cements. The differences in other physical properties listed in Table 9 do not appear to be significant.

Comparison of Compressive Strengths of Concretes of Series A and B with Present Day Concrete—Table 10 has been inserted to furnish comparisons between the average compressive strengths of concrete of Series A (Fig. 3) and Series B (Fig. 13), cured outside, with similar data from the w/c-curves for the moist-cured concretes of Series 210, Fig. 9, p. 158 of the Report of the Director of Research of the Portland Cement Association (1928). The latter tests were begun in 1926. These data indicate that there was not much difference in strengths of concretes of Series A and B but the more recently made concrete of Series 210 was 30 to 50 per cent stronger than the concrete in the Wisconsin tests.

The calculated constitutions in per cent of the cements used in Series A and in Series 210 were:

Cement Used in Series	3 CaO. SiO_2	2 CaO. SiO_2	3 CaO. Al_2O_3	4 CaO. Al_2O_3 FE_2O_3	$CaSO_4$	MgO
A	28.8	40.2	13.8	8.3	3.6	2.5
210	33.0	39.0	12.0	9.0	3.0	2.4

These data indicate that the constitutions of these two cements were quite similar. However, the cement used in Series 210 had a residue on the 200-mesh sieve of 17.5 per cent and was finer ground than the cement used in Series A or Series B. Apparently the difference in fineness of the cements used was a more potent factor in producing the marked difference between the strengths of the earlier-made and the more-recently-made concretes than the difference in constitution. On the other hand, it does not seem possible that the marked discrepancy in the strengths of

TABLE 10—A COMPARISON OF THE AVERAGE COMPRESSIVE STRENGTHS OF CONCRETE IN THESE LONG TIME TESTS WITH PRESENT DAY CONCRETE

Series of Tests	$\frac{w}{c}$, by Vol.	0.94	0.94	0.94	1.36	1.36	1.36
	Age	28 da.	1 yr.	5 yr.	28 da.	1 yr.	5 yr.
Series A Tests* (1910)		1900	3400	4200	900	1900	2400
Series B Tests (1923)		2000	3000	4300			
Series 210 P. C. A. (1926)		3000	5000		1150	2400	

*In order to make the comparison on a basis of strength of 6 by 12-in. cylinders the values from series A, in which 6 by 18-in. cylinders were used, were increased 5 per cent and recorded in the adjoining columns.

these concretes was entirely due to the difference in fineness of the constituent cements.

CONCLUSIONS

1. Portland cement may be stored in a tight container, such as a milk can, for at least 20 years without suffering material change in its strength properties.

2. Tensile strengths of the 1:3 standard sand mortar briquettes cured in water over a 20-year period exhibited retrogression in strength after six months. In the five-year tests of Series B similar retrogression occurred after the 90-day tests.

3. The tensile strengths of 1:3 standard sand mortars cured outside and of those mortars cured in the cellar over the 20-year period increased approximately as the logarithm of the age, but the tensile strengths of the 1:3 standard sand mortars of the later tests cured outside decreased with age after the one-year period.

4. In the five-year tests, mortars of Janesville sand exhibited less retrogression in the tensile strengths of the 1:3 mixes than the similar standard sand mortars. The 1:1 and 1:2 mortars of Janesville sand showed little change in tenacity after curing outside one year.

5. Neat cement mortars exhibited great variations in tensile strength under the curing conditions imposed in both series of tests.

6. In many instances low tensile strengths were undoubtedly due to the presence of surface checks at the minimum cross-sections of the briquettes. In the water-cured specimens of the 20-year tests, leaching appeared to have weakened the tenacity of the 1:3 standard sand mortars.

7. The compressive strengths of neat cement mortars were much more variable than the compressive strengths of the sand mortars. Part of this variability in the neat cement tests of Series A was undoubtedly due to poor bedments and part was due to checking. The compressive strengths of the sand mortars in both series of tests continued to exhibit upward trends with age after the one-year period.

8. The absorptions of the individual specimens of a given concrete, in tests of Series B, were very uniform. There appeared to be little difference in absorption due to aggregate or brand of cement. Absorption appears to increase with the water-cement ratio.

9. All concretes of Series B exhibited losses in compressive strength due to 20 cycles of the freezing and thawing test. Loss in strength due to this treatment was greatest in the mixes having the high water-cement ratios and high absorptions and least in the rich mixes of low water-cement ratios and low absorptions. The aggregates and brands of cement used exercised little effect on resistance to freezing and thawing.

10. Curing the concrete out of doors caused in most cases small linear contractions which for 1:2:4 mixes were usually less than 0.01 per cent at the time measurements were made. The data indicate that either rich mixes or wet mixes contract more than lean or dry mixes. Specimens cured in the dry air of the laboratory contracted three to six times as much as similar specimens cured out of doors and after five years of indoor curing exhibited contractions of 0.04 to 0.05 per cent. Linear dimensional change appears to be directly proportional to the change in water content of concrete during curing.

11. The compressive strengths of the concretes cured in water or cured outside increased approximately with the logarithm of

the age. In the tests begun in 1910 this relationship has persisted through 20 years. In the tests of Series B it has held for 5 years of outside curing despite the evidence from the freezing and thawing tests. The effects of seasonal variations on the strengths of specimens tested during the first year is reflected in the strength-age curves of Series B.

12. The rate of increase in the strength of concrete with age is affected markedly by the humidity of the surrounding atmosphere. Concretes cured in the dry air of the laboratory for five years exhibited water losses of 3 or more per cent and little change in strength after three months. Concretes cured in the cellar where the humidity was less than outside but greater than in the laboratory exhibited a progressive increase in strength but a slower rate of increase than the concretes cured outside.

13. A comparison of the average compressive strengths of the concretes of a given water-cement ratio made in Series A (1910) and in Series B (1923) with later made concrete, Series 210 (1926), indicates that there was not much difference in the strength-producing properties of the cements used in Series A and in Series B; but the more recent tests demonstrate that the early hardening properties of present-day cements have been considerably increased. It is therefore questionable whether the compressive strength of present-day concrete will increase over a period of twenty years in accordance with the logarithmic relationship which obtained in the tests of Series A.

14. Although there was considerable difference in the calculated constitutions of the cements of Series B, the differences in the compressive strengths of the concretes made of these cements were small. Contrary to expectation, in these tests the concrete made of the cement, which was calculated to contain the highest proportion of tri-calcium silicate, was somewhat more absorptive, exhibited greater loss in crushing strength due to freezing and thawing, and slightly less crushing strength in the outdoor tests than the concretes of other cements containing lesser proportions of tri-calcium silicate.

15. Concrete made of crushed Lannon dolomite, though carrying a higher water-cement ratio, was slightly stronger than

that made of other aggregates. This superiority appears to have been due to surface characteristics.

16. With the consistency constant the data from tests of Series B show that the strength varies linearly with the cement-voids ratio.

17. The data from both series of tests confirm the general relationship between the compressive strength and the water-cement ratio. The tests of Series B indicate that this relationship is influenced to some extent by the character of the aggregate.

Readers are referred to the JOURNAL *for June, 1931, for discussion which may develop. Such discussion should reach the Secretary by May 1, 1931.*

Cinders as Concrete Aggregate

Report of Committee 203

BY EINAR CHRISTENSEN*, AUTHOR-CHAIRMAN

Because Mr. Christensen had intimate touch, as engineer and chemist, with the development of an industry dependent on cinders in the manufacture of cinder concrete masonry units, and had given a decade of study to cinder aggregates, their characteristics, properties and the special characteristics and properties which they give to concrete made from them—studies not confined to one factory or condition or locality but to many —he was asked to prepare, as Author-chairman of Committee 203, a report which should summarize available information on cinders as concrete aggregate. His report written, it was submitted to W. D. M. Allan, R. D. Bradbury, Miles N. Clair, Emil Praeger and M. J. Roach—serving as critic members of the committee. Their responses were not perfunctory; were for the most part, detailed and thorough-going—numerous revisions being suggested particularly by Messrs. Allan and Clair. Mr. Christensen acknowledges their assistance in a general strengthening of the report in its revision for publication. At Mr. Christensen's request, the report was also submitted to George A. Strehan. Mr. Strehan's response, too late for consideration prior to the present publication, takes issue in some details with opinions expressed in the report. It will appear later, together with further data and critical comment by critic members of the committee and others. In the report as published Mr. Christensen has had the last word. It does not completely reflect in every detail the views of all the critic-members of the committee, but in general has their approval as an excellent presentation of the subject assigned.—EDITOR.

*Consulting Engineer, New York City.

INTRODUCTION

A COMMON attitude towards cinder (or sand-cinder) concrete is expressed in the anonymous letter in the *News Letter* pages of this JOURNAL for November, 1929—the attitude, briefly, that here is a material to be viewed with suspicion. Its author appears in accord with a British architect (D. B. Butler, 1909) who wrote:

> Judging from the quality of breeze (here "cinders") which may daily be seen delivered to buildings in course of construction, presumably for incorporation in fireproof floors, etc., many a clerk of works must be imbued with a pleasing and childlike faith in the ability of portland cement to stick together any kind of rubbish.

While in the 20 years between these two opinions millions of tons of cinders have been used in making concrete, the skeptical attitude of the anonymous writer to this JOURNAL is somewhat justified. Few data have been published to throw light on the mystery of cinders and their use in concrete.

Text books and technical publications give very little information. Authors generally copy faithfully what has been written before—not altogether condemning cinder concrete, yet warning against its use.

The belief that cinder (sand-cinder) concrete is "dangerous" is not confined to the Anglo-Saxon world. *Die Tonindustrie Zeitung*, for April 25, 1908, reports that the German Department of Public Works recommends the prohibition of cinders as an aggregate for reinforced concrete. The concluding paragraph of the recommendation states:

> Die Verwendung der Schlacke zur Herstellung von sonstigem Beton, sogenannten Stampfbeton, wird nur da zuzulassen sein, wo die Gefahr, die tragende Eisenteile mit derartigem Beton in Berührung kommen oder Menschen von herabfallendem Putzmörtel getroffen werden können, ausgeschlossen ist.

In other words, cinder concrete must not be used where people may be hurt by the falling concrete. This is a sad specification. "Menschen von herabfallendem Putzmörtel getroffen werden können." It should be very unsafe to live in New York.

As cinder concrete is now being used in the United States and in Canada, in masonry units, equivalent to approximately 500

million brick per year, and sand-cinder concrete in floors and fireproofing of many noteworthy buildings, it is timely to attempt evaluation of the knowledge we have of these materials. It is discomforting that one large city permits what another flatly condemns—and that one engineer places thousands of cubic yards of a material which another believes doomed to failure.

The common attitude towards cinder concrete, particularly sand-cinder concrete made on the job, is not surprising. The contractor is not inspired by the looks of the aggregate, nor by a "1:2:5" specification. He pays less attention to this than to stone concrete; the aggregate is ordered over the telephone and passes directly from the truck to the mixer without much inspection. Twenty thousand cubic yards may be placed in one building in this manner. The result, sometimes good and sometimes bad, is generally not known in advance. Aside from extraneous matter the cinders look rather dirty and unreliable, because cinders are always wet, their color and the true nature of their particles being disguised.

To see what cinders look like, a sample should be dried and split by a standard sieve analysis. It will then be found, generally, that the aggregate contains a range of sizes and consists of particles which have sufficient strength to offer concrete-making possibilities. By the same simple process it is possible to observe the peculiar shape and cellularity of the particles. How many engineers make sieve analyses of cinders? Even while using larger quantities of them in the floors of one building.

Here the cinder unit industry has contributed to our knowledge. Factory-made cinder units could be studied readily with reference to their general characteristics—and that naturally suggested a study of the raw material and the quality factors. In preparing this report, the writer is relying on ten years' experience in the manufacture of cinder concrete building units. In the light of this experience he attempts to interpret the work of other investigators of cinders and the resulting concrete. It is hoped facts will be established tending towards the making of better cinder and sand-cinder concrete, and a better understanding of the material.

The committee has been directed to present in summary a survey of the whole field, from the nature of cinders to the characteristics of the resulting concrete. Within the last few years, certain problems of cinders and cinder concrete have been subjected to careful study; prior to that, the matter has been treated so broadly and repetitiously that a thousand references may well be condensed to ten or less.

While this committee's assignment is in reference to cinder aggregate, the report is concerned chiefly with the type of concrete in which cinders are used as the sole aggregate—the type of cinder concrete at present used most extensively in precast masonry units. This must be clearly understood, inasmuch as the term "cinder concrete" is frequently applied to "sand-cinder concrete" (1:2:5 or so) as used in floor arches and the like. The definitions used in this paper should be carefully noted. When the paper deals with cinder concrete it is mainly because the writer's experience has been with the cinder unit industry where cinders alone are used as aggregate. The cinders, however, are the important and typical constituent of both types of concrete—the nature of this raw material and the character which it gives to the concrete are of primary interest.

DEFINITIONS

The following definitions may not meet the wholehearted approval of all readers, but they will apply throughout this paper.

Cinder Concrete: A concrete made from an aggregate composed of cinders (commonly used in the manufacture of cinder concrete masonry units—the aggregate usually prepared by crushing).

Sand-Cinder Concrete: A concrete made from a mixed aggregate of sand and cinder (commonly used under the name "cinder concrete" in floors, fireproofing and the like—the sand generally considered the fine aggregate; the cinders sometimes screened but rarely crushed).

Cinders: The residue, containing more or less carbonaceous matter, from high temperature combustion of coal or coke— known as "industrial cinders," "boiler cinders" or "steam cinders," to the exclusion of the residue from domestic furnaces. Forced draft is generally applied in the combustion process.

Ashes: The residue, containing more or less carbonaceous matter, which remains after the incomplete combustion of coal, coke, wood, or the like. This is an inclusive term, most frequently applied to the residue from domestic furnaces.

Ash: The inorganic residue which remains after complete combustion of coal, coke, wood or other carbonaceous matter. This may be considered a "laboratory term."

Clinker: That part of the cinders which has been partly or completely fused during the combustion process. The clinker may be dense or more or less cellular.

The present report is primarily concerned with cinder concrete as here defined, and is concerned *only* with cinders as an aggregate. Cinders, as here defined, contain clinker (fused), ash (unfused), and unconsumed carbon (coke or coal). This raw material is obtained from industrial plants, gas works, locomotives, and similar sources. It is not to be confused with the residue from small domestic furnaces, which here comes within the category "ashes," and which is not used in making good concrete.

Confusion arises when the term "ashes" is also applied to the finer (partly unfused) particles of cinders. The physical character of these fines in the residue from high temperature combustion, is different from the soft and dusty ashes of the domestic furnace, and is generally of real value in making concrete. Perhaps some of the skepticism regarding cinder concrete resides in the fact that even learned men associate the material with the unpleasant refuse of their basement fire.

It is of primary importance to the maker of cinder concrete (or of sand-cinder concrete) to know that his raw material is coming from a source where a large amount of coal is burned. This usually entails uniformity of coal and uniformity and efficiency of firing, with the result that the cinders do not vary greatly from day to day. In most places, cinders have ceased to be a waste product; they are now considered a commodity, and a large producer takes care to prevent the use of his cinder pile as a general dump.

No general differentiation is here made between anthracite and bituminous cinders. While they differ in their physical character, they are both suitable for concrete when meeting the requirements here proposed for cinders. The "sulphur controversy" has given rise to the idea that anthracite cinders are superior, and certain specifications exclude bituminous cinders.

Evidence at hand does not justify this attitude. As a matter of fact, the writer prefers a well prepared bituminous cinder because the particles are usually stronger and because the major part of the combustible matter is usually present as coke.

In England, "breeze" and "coke breeze" complicate the terminology. The former is broader in scope than the term "cinders;" the latter applies to the small coke produced by coke ovens and gas works. The term "furnace clinkers" comes rather close to the definition of "cinders" proposed here. In Germany the word "Schlacke" applies to both cinders and blast furnace slag. When designating the former it should be "Kesselschlacke" —in case of the latter "Hochofenschlacke." The writer has encountered several misunderstandings (notably in patent cases) because of erroneous translation of these terms.

CINDERS

The inorganic residue from the combustion of coal is composed largely of silica, alumina, lime and iron, with smaller quantities of magnesium, titanium and alkali compounds. A small amount of sulphur compounds is generally present, mainly in the form of sulphates and sulphides. The combustion process is practically always incomplete, and the residue therefore contains carbon as coal or coke or both.

A complete chemical analysis of cinders is of very little value in judging the concrete-making possibilities of the raw material. The maker of cinder concrete is more interested in the physical character, and this may readily be judged by an experienced observer. An analysis, if at all desired, may be confined to a determination of coal, coke, sulphates, sulphides, and (perhaps) lime.

Cinders from well fired bituminous coal contain their carbon mainly in coke, formed by distillation on the grate, while anthracite cinders may contain considerable unchanged coal. Average percentages are of little interest, but the average combustible content of industrial cinders of the United States may well be close to 30 per cent. The frequently-encountered specification for cinder concrete, that the cinders "must be free from unburned coal," would eliminate most of the raw materials which have come

to the writer's attention. While such a specification is not justified, the carbon content of the cinders deserves, nevertheless, some attention.

Effect on Strength: When a specimen of cinder concrete is broken in compression, it will usually be observed that particles of coal are exposed as such, while particles of coke are fractured. This indicates that the smooth surface of the coal does not adhere to the cement, and that the coke has less strength than other particles of the aggregate. No definite relationship has been established between carbon content and strength—the main reason being that it is difficult, in comparative tests, to control the variable of consistency when varying the amounts of dense coal or porous coke.

Effect on Fire Resistance: It is natural to expect that the presence of coal and coke in cinders will reduce the fire resistance of concrete. Such an effect is, however, surprisingly small. Free combustion cannot take place when a piece of coal or coke is well protected in properly made cinder concrete. The only apparent effect is a distillation of bituminous coal when a certain temperature is reached—but that is a factor of minor importance in view of the high insulating quality of well-made cinder concrete. The effect is different when the concrete is so loosely packed, or the aggregate so void of fines, that fire may gain free access to the interior.

In factory-made cinder concrete units, the effect of carbon content upon fire resistance has been studied in a series of tests. The units were 8 x 8 x 16-in. hollow blocks, 2 cores, about 27 per cent air space, 2-in webs, having a compressive strength at 28 days ranging from an average of 825 lbs. per sq. in. of gross area for one batch to an average of 1156 lbs. for another. In preliminary tests, small panels (32½ in. square) were built of these units. The combustible content of the aggregate consisted, approximately, of ¼ anthracite coal, ¼ bituminous coal, and ½ coke—the extremes being an aggregate with about 20 per cent and another with about 75 per cent combustible content. The latter was prepared from nothing but coal and coke, the percentage being the result of chemical analysis, deducting ash. Considering these two extremes, the two panels had approxi-

mately the same endpoint (250 deg. F. above initial temperature of unexposed face) while the compressive strength after fire test had decreased 31.7 per cent with the lower carbon content, and 55 per cent with the higher carbon content. The panels behaved remarkably well, and even the "pure coal-and-coke block" did not "catch fire." The bituminous coal of this block suffered from distillation, evidenced by gas and smoke. At the same time, this distillation apparently retarded the heat flow through the wall. Later, test was made on a large panel (about 10 ft. x 11 ft.) which was subjected to a load of 80 lbs. per square inch during test. Three types of cinder blocks were included, made as before, and containing three percentages of combustible matter,—20, 35 and 45 (by weight of aggregate) respectively. After three hours fire exposure the endpoint was not reached. Next day the wall was loaded to failure, and failed in the 45 per cent carbon block at approximately triple load, or about 250 lbs. per square inch. On the basis of these data, the Underwriters Laboratories incorporated in their specifications for hollow concrete building units: "When cinders are used the average combustible content of the mixed fine and coarse aggregate shall not exceed 35 per cent by weight of the dried mixed aggregates."

Effect on Permanence: This has been given particular attention in England where instances have been reported of expansional movements of cinder concrete attributable to the presence of certain types of coal in the cinders. The writer has seen very few such instances in the United States, and only in one case (that of a poorly burned bituminous cinder) could it be ascribed to the presence of coal. Bearing in mind the foregoing definition of "cinders," it is believed that the phenomenon is of less interest here than in England where the material is less clearly defined.

The problem has been studied by D. B. Butler[5] and F. M. Lea.[15] The investigation by Lea is the most recent and the most comprehensive; it is part of the interesting work on cinders by the British Department of Scientific and Industrial Research.

According to Lea,[15] coals which are dangerous in concretes are so because of expansional movements which they produce during the setting period and early life of the concrete. The effect depends upon the nature of the coal; the amount present does

not by itself afford a test of the soundness of the material. The amount of moisture or of oxygen taken up by the coal are the characteristics to consider. With increasing rate of absorption the coal becomes dangerous.

Lea develops a test to determine the nature of the coal in cinders in its relation to the permanence of the concrete. It consists in making a 3-in. pat of 1 part binder (equal parts by weight of cement and plaster of paris) and 3 parts of finely ground (No. 76) cinders, gauged with water to a plastic condition. The pat is kept in a moist atmosphere for 3 to 4 hours, thereafter left totally immersed in water, and is examined after one to four days. If fine radial cracks appear, running from edge to center, or if the edges lift, or if the pat becomes loose, the cinders are unsound.

Cinders from high temperature combustion should contain very little coal of this nature, except due to accidents in firing the boiler. Such cinders, when bituminous, should contain the major part of their carbon in the form of coke. Anthracite coal appears to be harmless. Lea states: "If the coal has been treated to a sufficiently high temperature, its dangerous properties will be largely or entirely removed."

Sulphur Compounds

Various sulphur compounds may be present in cinders. In the unburned coal (if any) sulphur may remain as pyrites, marcasite or organic sulphur compounds; in the ash or clinker the sulphur may be present as sulphates or sulphides. Most cinders which have come to the writer's attention over a period of ten years contain less than 1 per cent of sulphur (S) in these compounds. They are present in the coarse as well as in the fine particles of the cinders.

When considering the possible effect of such combinations of sulphur, it should be borne in mind that they are not present in readily reactive form, but usually embedded in the coal or clinker or as an occasional large piece of pyrite. The behavior under such conditions is quite different from that of pure powders, and "laboratory deductions" do not always apply.

Corrosive Effect: It is well established that corrosion has occurred in several instances of reinforcing steel in cinder concrete

or of pipes and the like in cinder fill. Such instances, however, are many times outweighed in number by the performance of sand-cinder concrete or of cinder concrete building units where the behavior towards steel could be observed.

Corrosion of steel in cinder concrete has usually been explained as due to "sulphur," the supposition being that this element (seldom more clearly defined) by oxidation would form sulphuric acid which would then attack the steel. The chemical terms so appealed to many concrete engineers that this corrosion process became an axiom of the art. Instead of "sulphur" the word "acid" is frequently used to indicate that something is bound to happen when cinders are used—not merely corrosion, but staining as well.

It may be well, for a moment, to consider stone concrete. It is not uncommon to find corrosion of steel embedded in this material, but such instances are always explained by the fact that the concrete is poorly made or that the steel is improperly protected—a matter of mixing, making and placing—and no one would consider it necessary to assume chemically active elements in the aggregate. It would appear reasonable that the same explanation is at least to some extent applicable to concretes made with cinders as an aggregate.

Prof. C. L. Norton[1] came very close to this explanation in his well-known investigation of sand-cinder concrete. After pointing out that "sulphur" cannot be the cause in the "presence of the strongly alkaline cement," he concludes:

> There is one cure and one only: *Mix wet and mix well.* With this precaution I would trust cinder concrete quite as quickly as stone concrete in the matter of corrosion.

While Professor Norton absolves the "sulphur" of all blame and reaches the general conclusion that the protection of steel is a matter of the quality of concrete, he does attach some significance to the iron oxide, or rust, which may be found in cinders. He states that "a rust spot on reinforcement was invariably coincident with a void in the concrete or a badly rusted cinder." and concludes that this iron oxide may cause trouble. The explanation seems rather strange. It is far more plausible that the voids (permeability) were the sole cause, as they would allow moisture

to attack the reinforcement as well as the iron present in the cinders. The rust spots would naturally be coincident.

That the protection of steel in cinder concrete is primarily a matter of quality of concrete (mixing and placing) rather than a matter of some constituent of cinders, is supported by the evidence of several observers. Reference is here made to the investigation of sand-cinder concrete reported by Perrine and Strehan,[10] together with the discussion following that paper, notably by A. L. A. Himmelwright. Perrine and Strehan conclude as follows:

> Anthracite cinder concrete (1:2:5), well mixed, cast in a viscous to wet consistency, constantly stirred and mixed during placement, in such a manner as to coat the reinforcement thoroughly with mortar, will not cause the corrosion of embedded steel.

Millions of cubic yards of sand-cinder concrete have been placed in New York city. It is therefore significant when Rudolph P. Miller[7] (former Superintendent of Buildings, New York City) states (1911) that he has yet to hear of the first instance of corrosion of steel in this type of floors. While the cinders of New York are, most commonly, from anthracite coal, they nevertheless contain sulphur compounds to practically the same degree, and of the same nature, as cinders in other parts of the country. If corrosion is a matter of chemically active sulphur compounds, there would presumably be a large number of instances on record in New York. On the other hand, if it is a question of quality of workmanship, it is to be expected that the New York contractors would gain more than usual experience in the making of sand-cinder concrete, with the result that a better grade of concrete would be produced.

Factory-made cinder units represent well made cinder concrete —the cinders being crushed, well mixed with cement and water, and molded under pressure. These units are made throughout the United States and Canada—involving all kinds of cinders, anthracite, bituminous, Pennsylvania, West Virginia, etc., etc. The aggregate is all cinders, with no sand added. Therefore, if the corrosion of steel in cinder concrete were due to chemically active elements of the cinders, it would certainly have occurred somewhere and at some time in case of these cinder units. More so than in case of concrete where part of the aggregate is sand.

The writer has examined a great number of nails which for years had been embedded in this kind of cinder concrete—and also some cinder concrete lintels containing reinforcing rods. In no instance has he found sign of corrosion in the concrete. When a nail is driven into cinder concrete some of the aggregate particles are crushed and the dust is forced into adjoining pores, filling them and giving a firm hold on the nail. Fresh surfaces of cement are laid open, and if moisture gets into the concrete, further hydration takes place, with the result that the wound heals and the nail becomes cemented together with the surroundings.

Based on the above observations it appears unnecessary to assume any chemical reaction of sulphur compounds in order to explain occasional corrosion of steel in cinder concrete. It is possible that sulphates or other soluble salts of the cinders may accelerate rusting if moisture and air get into contact with the steel of the concrete. This is indicated by a recent investigation by F. L. Brady.[16] The method employed by Brady may, however, be subject to some criticism. The aggregates used included "coal clinker," "coke breeze," "furnace ashes" and "clinker from refuse destructor." These were ground to pass No. 20 mesh and made into mortar blocks (1:6). After one week, the mortar blocks were crushed to pass No. 10 mesh, and this dried mixture of aggregate and cement was used to make three series of tests. Steel strips were surrounded by the crushed mortars and various exposure to moisture and humid air were tried. As a basis for comparison of corroding power a comparable mixture was prepared using standard sand as aggregate. These tests showed (practically) an absence of corrosion in case of the sand mortar, and increasing corrosion in case of increasing amounts of sulphur compounds in the other mortars. This indicates that the corrosion process, under the conditions of the test, is accelerated by the soluble salts present as well as by the moisture adsorption, the latter being particularly large in cinder mortars.

In only one test series did Brady embed his steel in "cinder concrete"—and this concrete appears to have been of a somewhat unusual design. It is reported to consist of 1 cement, 2 "clinker," finer than No. 10 mesh, 4 "clinker" coarser than ¼-in. and finer than ¾-in., all parts by weight. It will be noted that inter-

mediate sizes are absent, indicating a rather inferior concrete. Furthermore, the steel was protected by only 1 in. of concrete. Corrosion occurred to varying degrees when the steel was examined after about two months, increasing with increasing content of sulphur compounds.

It should be observed that this effect of sulphur compounds is quite different from the effect commonly ascribed to "sulphur." It is a matter of accelerating the corrosion process when such process is possible because of improper protection of the steel in the cinder concrete (or in cinder fill). It is not a matter of an "acid attack" which would take place regardless of the quality of concrete. Such oxidation of sulphides to sulphuric acid is highly improbable, and even if acid were formed, certainly it would not attack the steel inasmuch as it would be neutralized immediately by the bases present in concrete.

The observations of the performance of reinforced cinder and sand-cinder concrete in the field are not upset by the above quoted laboratory test. The fact remains that millions of cubic yards of such concrete have given excellent protection to the embedded steel. The quality of the concrete (mixing and placing) is the determining factor. If the steel is not protected, corrosion is probably accelerated by the presence of soluble salts. Pipes and the like in cinder fill generally have no protection against air and moisture.

The steel must be protected. In floors, the sand-cinder concrete must have a waterproof top covering. The concrete should be well agitated and mixed while placing, and it is well to coat the steel with cement mortar. In masonry walls, cinder concrete building units must be protected against water forced in from the outside and the usual care must be taken in construction details at spandrel beams and the like where, otherwise, leakage may occur.

Expansional Effect: Dr. H. Nitzsche[13] has investigated the effect of sulphates in cinders on the permanence of cinder concrete. His work is concerned with the possible reaction between these sulphates and the lime of the cement. The reaction, if any, results in a volume change. Nitzche used a cinder containing "insoluble" $CaSo_4$ and soluble $MgSo_4$, K_2So_4 and Na_2SO_4. Start-

ing with a raw material rather high in these sulphates (containing .93 per cent "insoluble" and .81 per cent soluble) he reduced the percentages by repeated washing or increased them by adding the salts in powder form. The significance of tests involving the latter may be questioned, inasmuch as sulphates are not present in cinders in such readily reactive form. With an aggregate finer than ¼ in., and with 66.7 per cent retained on No. 16 mesh, he produced small Bauschinger prisms of 1 cement: 2 sand: 7 cinders. These prisms were measured for volume change under water, in air, as well as in sealed glass containers where the original moisture was maintained. On the basis of this investigation, Nitzsche reached the conclusion that for permanent concrete, the cinders must contain not more than 1.0 per cent $CaSO_4$ and 0.2 per cent soluble sulphates. He found the volume change to be considerably less when blast furnace cement (Hochofenzement) was used instead of portland cement.

Lea also investigates[15] the expansion of cinder concrete which may be ascribed to the sulphates. He goes further than Nitzsche in that he produces higher sulphate contents by fusing or sintering the admixed sulphates with the cinders. In this form, the effect of the sulphates is far less marked than as fine powders. Lea concludes that the limits proposed by Nitzsche are unnecessarily severe. He says of soluble sulphates (page 65) that "it is concluded that the average content of alkali, and magnesium, sulphates present in breezes and clinkers is small and may be neglected as of little importance." Of the effect of calcium sulphate he states (page 66) that "on the basis of these results it can be concluded that a limit of 0.4 per cent sulphate as sulphur trioxide (= 1.00 per cent SO_3 = 1.70 per cent $CaSo_4$) can be safely tolerated, and that in many cases much higher percentages are unlikely to cause trouble."

The ash and clinker may contain a small amount of sulphide and the unconsumed coal may contain Pyrite (FeS_2). The latter, however, decomposes at a temperature below 1290 deg. F., which is below the temperature of the furnaces considered here; it can therefore only be present due to accident in firing and the like. Lea produced oxidation and/or hydrolysis of calcium sulphide in cinder concrete when the sulphide had been added as

a fine powder—and he suggests a limit, in this case, of 0.4 per cent sulphide sulphur. However, when the sulphide was fused with a clinker it was found to be efficiently protected against hydrolysis by high pressure steam and apparently also protected against air oxidation. No effect was found with ferrous sulphide. Lee proposes a limit for "all sulphur other than sulphate sulphur" of .75 per cent S.

While the writer has observed occasional expansional movements of cinder concrete during its early life, he has never been able to identify definitely the cause of the phenomenon. The most common cause appears to be that of slow hydration of free lime (discussed later). Having no contradictory evidence on record, it is well to accept the limits proposed by Lea. Cinders, as previously defined will nearly always come well within these limits.

Lime

Small lumps of free lime may occur occasionally in cinders. Usually the lime is fused with the silica and alumina of the ash to form totally inert compounds. Small lumps of free lime may remain, partly hydrated or otherwise combined on the outside so that the result is a nucelus of CaO surrounded by a rather dense shell of hydroxide, carbonate, silicate or the like. Moisture may eventually penetrate this shell and hydrate the CaO. In a cinder concrete, the result is like that of "lime spots" in clay brick. The phenomenon is known as "popping." It is not a frequent occurrence and is evidently confined to certain types of coal. In cinder unit plants using steam curing, hydration lime spots will generally take place during the steaming process.

Contaminations

According to the definition, we are considering as a raw material only those cinders, which are the residue from high temperature combustion of coal and coke. If wood ash, pulp or the like are burned with the coal or coke on the grate, the cinders are contaminated. In selecting cinders for concrete, it is necessary to know something about how they are made. The specification should be written accordingly.

Cinders may be contaminated after they leave the boiler. Fortunately, most large producers of cinders have realized their

commercial value and the cinder pile is no longer considered a general dump. It is essential for the maker of cinder concrete to be sure that the cinder deposit is kept clean. The writer knows of a few scattered instances of caustic soda, molasses, and the like, being dumped with the cinders. These contaminations were readily discovered because the concrete would not harden. Particular attention is required where cinders are obtained from chemical plants.

Stray iron may be considered a contamination. It may occur as scalings from the fire place, as nails, bolts, grate bars, etc. In cinder unit plants this iron may be removed, with a fair degree of efficiency, by a magnetic separator. It does no general harm except when it gets into the equipment.

General Physical Character

The structural strength of the particles of cinders depends upon the nature of the coal and the temperature of burning. The clinker is the strongest part; it is formed by fusion of the ash constituents of the coal when subjected to the high temperature of the furnace. The fusing point of coal ash increases with the amount of alumina and the sum total of silica and alumina, and decreases with the sum total of iron oxide, lime and magnesia. A fusible ash will produce a dark clinker containing a relatively small amount of friable or fine material. A less fusible ash may yield laminated or honeycombed material which possesses less structural strength.

Because of the high fusibility temperature of anthracite, cinders from this coal do not contain clinker as thoroughly fused as cinders from bituminous coal similarly burned. The clinkers from anthracite are structurally weaker. The permissible maximum size of anthracite cinder aggregate is therefore usually less than for the average bituminous cinder.

Anthracite cinders usually contain more coal than bituminous cinders. While this coal is less objectionable than bituminous coal in concrete (it is chemically more stable and physically stronger) it nevertheless does not improve the concrete because of its smooth surfaces. As far as its effect upon the cellular structure of the concrete is concerned, the density of this anthracite coal is offset by the relatively high porosity of the clinker.

On the other hand, in bituminous cinders the carbon (present mainly as coke) increases the cellularity while the clinkers are relatively dense.

The weight depends upon the nature of the cinders (coke, clinker, etc.) and the grading from coarse to fine. Averages are of little interest. In one series of tests, a typical Eastern anthracite cinder (crushed to maximum ¾-in., F. M. 4.1) weighed 55 lbs. damp loose and 61 lbs. dry rodded per cu. ft. In another series, a bituminous railroad cinder weighed 53 lbs. damp loose and 60 lbs. per cu. ft. dry rodded. In a third series, a bituminous cinder from an electric power plant (crushed to maximum ¾-in., F. M. 4.5) weighed 64 lbs. damp loose and 71 lbs. per cu. ft. dry rodded. This cinder had about 20 per cent combustible content. With 60 per cent coke(weighing 42 lbs. damp loose) the cinder weighed 54 lbs. per cu. ft. dry rodded, showing the effect of the coke. With cinders from one source, the weight has been found to be of some value as a check on the uniformity of the product.

A SPECIFICATION FOR CINDERS

In proposing this specification for cinders, the writer has in mind both the raw material used in sand-cinder concrete (usually without crushing or other preparation) and that used in the manufacture of cinder building units (where it is further prepared by crushing, etc.) or in other types of cinder concrete.

Cinders, when used for concrete, shall be the product of high temperature combustion of coal and/or coke—known as "Industrial Cinders," "Boiler Cinders," or "Steam Cinders," to the exclusion of the residue from domestic furnaces. The cinders shall be well burned, free from foreign matter, and so graded from coarse to fine as to produce a cinder concrete (or sand-cinder concrete) meeting the strength requirement of the building code. The cinders shall contain not more than 35 per cent of combustible content by weight, nor more than 0.45 per cent sulphur (*S*) as sulphide, nor more than 1.00 per cent sulphur trioxide (SO_3) as sulphate.

The experience of the writer has shown that if the cinders meet the first part of the specification, they will also meet the requirements for unconsumed carbon (here adopted from the specifications of the Underwriters' Laboratories) and those for sulphur compounds (here adopted from the recommendations of Lea). It would then appear unnecessary to impose these further

tests on the producer. Accurate sampling of cinders for chemical analysis is extremely difficult—it is more conducive to the making of good concrete to expend time and effort in obtaining cinders from a reliable source, free from contaminations.

As fas as a general specification is concerned, a strength requirement is usually sufficient to govern the quality of cinder concrete, provided the raw material is "cinders" as here defined. It is not necessary to go into details of the physical makeup of the aggregate, or the design of mix, if the strength is produced. The specification as to maximum size naturally depends upon the purpose for which the concrete is used and should not be included in a general specification. The peculiar characteristics of cinder concrete, which depend upon its cellular structure, cannot be anticipated in a general specification for the raw material; they are developed to a varying degree dependent upon the admixture of other aggregate (sand) and the methods of making the concrete.

The writer knows of few suitable specifications developed by other investigators. Selecting a text book at random, the following specification is found:

> The standard specification for cinders states that they shall be of hard, clean, vitreous clinkers, free from sulphides, unburned coal, or ashes.

No such cinders are ever found. The author of this specification might as well have said: "Cinders are never to be used." The fact remains that cinders have been used with excellent results, although violating this and other specifications. The writer is of the opinion that a specification governing this or other materials, should be liberal enough to be practical. Otherwise it is not enforced.

JUDGING CINDERS FOR CONCRETE

Notwithstanding all exactness of the science of concrete making, judgment is still an important factor. When using cinders as an aggregate, it is well to be able to judge the quality of the raw material without having to resort to elaborate physical and chemical tests.

The manufacturer of cinder concrete building units usually contracts for his cinders, getting them from the same source

over a long period of time. He is more assured of uniformity than the user of an occasional few thousand yards of cinders for sand-cinder concrete in floors or fireproofing. The latter has to depend, largely, upon a cinder broker, and fluctuations in the cinder market make it difficult sometimes to be very exacting in the demands. The contractor may have to "take what he can get;" then the matter passes beyond the realm of exactness into the land of chance which cannot possibly be charted here. It is appreciated that sand-cinder concrete has occupied a peculiar position because of this element of uncertainty. No one would accept sand and gravel from "any pit," and if there is no choice among cinders, the writer is the first to advocate the use of something else.

It is certainly not good engineering practice to specify an aggregate by name only and then accept anything which may be pressed within the category. The foregoing specification is not as indefinite as that; the aggregate may, perhaps, not be judged to its second decimal—nevertheless it is fairly well defined.

An idea of the quality of a cinder may be based upon the following knowledge and observation:

1. Ascertain whether the producer has a steady and large output of cinders —employing forced draft or other means of efficient combustion. Much knowledge may be gained from the daily records of the producer, frequently furnishing chemical analysis.

2. Examine the pile of cinders to see if it contains any rubbish. If so, the pile may have been used as a general dump, and the cinders are not reliable.

3. From cinders from a chemical plant, obtain an average sample of about 1 cu. ft. Divide this by quartering, and boil a fraction with distilled water. Test the water extract with litmus paper. The paper should turn slightly blue. If it turns strongly blue—or red—the cinders should be analyzed to determine the cause.

4. Obtain an average sample as above. This sampling is done by taking shovel-fulls from edges, middle and top of pile. Mix well, quarter, re-quarter, and examine as follows:

4a. Dump these cinders in a bucket of water. The fine ash and the lighter coke will float on the surface, and the amount and the nature of these may be judged. A fair amount of each is desirable—the coke contributing to lightness and cellularity, the ash forming mortar with the cement.

4b. Drain the water from the bucket and compare the appearance of the washed cinders with that of the unwashed. The washing makes it possible to

determine with a fair degree of accuracy the relative amounts of coke, coal, fines, porous, flaky, or fully vitrified clinker. The grading may be observed.

4c. The structural soundness may be judged by breaking down the larger particles.

5. Determine the weight per cubic foot, damp loose, drained of free water. It should be not less than 35 lbs., preferably about 45 lbs. Pass it over a screen with ¼-in. mesh thoroughly shaking the screen. The amount retained on the screen should be at least 50 per cent by weight.

These suggestions may appear very crude to the engineer who is accustomed to deal with other aggregates where (theoretically at least) far more exact rules may be laid down. Surely, it is a far cry from judging cinders in a bucket full of water to obtaining a stone aggregate with a fully defined pedigree. Nevertheless, the use of the bucket has been very useful in revealing much regarding the nature of the cinders at hand. It is a matter of experience.

TESTING CINDERS FOR CONCRETE

In the foregoing the writer has suggested a shortcut for judging the quality of cinders for concrete. When it is a matter of examining the raw material for a cinder unit plant (which may well use 25,000 yds. or more per year), or for a large job of cinder or sand-cinder concrete (which may well require that amount in the floors alone), a definite effort should be made to obtain the cinders from one reliable source. They should then be subjected to more exhaustive tests.

If possible, cinders should be obtained from the source in question over a period of at least one week before signing contract. Daily test specimens should then be prepared in accordance with standard practice so that the uniformity and the quality of the resulting concrete may be determined. A week's average from a reliable source may well be taken as representative of the output.

It should not be necessary to emphasize that a trial run is of little value unless all factors are observed. The grading of the aggregate must be checked, the water content of the cinders must be known (it varies and is frequently very large), the amount of added mixing water must be determined, the method of mixing and making must be uniform. This is obvious for stone concrete; for some reason the rules are not always observed with cinder concrete.

The cinders should be submitted to a recognized laboratory for the following tests:

1. Determination of total combustible content. Nature of coal to be reported. Information may be gained from producer's records.

2. Examination of coal in accordance with method proposed by Lea and previously described. This test may be made upon the cinders or upon the coal picked by hand; the latter method will naturally emphasize results. The test is not necessary with anthracite.

3. Determination of total as well as water-soluble sulphates, quantitatively and qualitatively. Determination of sulphides.

4. Examination for impurities, visual as well as in water extract. Reaction of water extract to be reported.

5. Standard sieve analysis on representative samples to determine daily averages.

The results of this examination may then be judged in the light of previous discussion.

MAKING CINDER CONCRETE BUILDING UNITS

This chapter is concerned with concrete made with an aggregate of cinders only. It is primarily concerned with making this concrete in masonry units—at present the most important field for "self-contained" cinder aggregate.

The cinder concrete here considered is manufactured on pressure or tamping machines. It is of such consistency that the freshly molded unit retains its shape when carried from the machine, resting on a "pallet." The problem is therefore quite different from that of poured concrete, to be discussed later. The relatively dry consistency of machine-made cinder concrete units is made necessary by the manufacturing method. A type of concrete has been evolved which is not to be considered merely a compromise, but as having distinct advantages, among others a most interesting surface texture.

The standard unit is the 8 x 8 x 16-in. hollow block, containing two or three vertical cores, or from 30 to 40 per cent hollow space. This is the usual test specimen referred to. Most specifications require this unit to have a compressive strength, at 28 days, of 700 lbs. per sq. in. of gross area. It is well to bear this in mind when reading the following pages.

Before considering the various factors involved in making cinder concrete building units, we shall state the problem which

the industry is trying to solve. It is, briefly: To produce at the lowest possible cost a cinder concrete which combines cellular structure with the necessary structural strength. Strength, then, is not the sole criterion for quality—the cellular structure should be developed to the fullest possible degree.

Full understanding of the value of cinder concrete is not attained without realizing the peculiar character of the aggregate —its porosity. This porosity, and the corresponding limited strength, places certain limitations upon the use of the resulting concrete; but these limitations do not make the concrete inferior except when it is considered beyond its proper field of application. Within the field it has its distinct advantages.

While strength is not the sole criterion for quality, the required strength for the particular purpose must, of course, be met. As above stated, 700 lbs. per sq. in. is the usual requirement for hollow, load-bearing units. The manufacturer is primarily interested in obtaining this strength, and obtaining it economically. His first concern in his design of mix and in his method of making is that of obtaining the greatest possible yield per sack of cement for the strength necessary. Strength can be measured very simply—the other qualities residing in the cellular structure usually become secondary, but they should never be lost from sight.

Cinder Aggregate

The permissible maximum size is limited by the type of unit to be manufactured from the aggregate. The particles must be sufficiently strong to withstand the pressure or tamping—otherwise they are broken in the mold box of the machine, thereby creating new surfaces not coated with cement mortar. Generally speaking, the particle size should not exceed one-quarter to one-third the smallest dimension of the unit.

The cellular structure of cinder concrete is dependent upon the cells (sealed) and the pores (open) of the cinder aggregate. Of these, the sealed cells are particularly desirable, while the open, inter-connecting pores should be reduced to minimum size. The strength is dependent upon the strength of the particles and their bond. To get strength and proper porosity of the concrete,

grading of the aggregate is necessary. The unevenly shaped particles of the cinders contain numerous contact surfaces—these must be covered with mortar composed of cement and finer particles, and must be in contact. It is not desired, however, to fill the pores of the individual particles. Mortar lodged in these pores does not perform its function—on the contrary, it reduces cellularity.

The voids of a typical cinder aggregate, as used by the makers of masonry units, appear to approximate 55 per cent of the total volume of the loosely packed aggregate, when measured by the water displacement method. These "voids" represent not only the pores or pockets of the particles, but also open space between the particles. In making cinder concrete, such open space should be filled as completely as possible by cement mortar, to eliminate large channels through the mass. The pores or pockets of the particles are, to a large extent, filled with water which prevents mortar from getting in (unless the mixing process is *too* thorough). As far as the sealed and inaccessible cells are concerned, Nitzsche[11] found them to represent from 8 to 16 per cent of the total volume. These cells may be determined from the specific gravity of the finely ground material. A cinder aggregate should be graded from coarse to fine so the cement paste becomes most efficient. We are concerned with contact surfaces of rather irregularly shaped particles, and the problem is certainly less elementary than with stone concrete. The method of solving it is, of necessity, empirical.

The writer has conducted a large number of tests involving anthracite cinders; 8 x 8 x 16-in blocks, two-core, 30 per cent air space, 1 to 7 mix, were manufactured on a power press. All variables were controlled to give best results. The water content was varied according to porosity of aggregate, but was close to 10 gal. per sack of cement. For these particular conditions, a maximum strength cement ratio was obtained at a fineness modulus of 4.00 to 4.50 (¾-in.-0). Other tests by manufacturers of cinder units have generally supported this, but conditions vary and it is difficult to evolve universal rules. More recent tests, using a highly clinkered bituminous cinder, point towards a lower fineness modulus and a lower maximum size, but the data are not conclusive. The common maximum size of the

cinder unit industry is probably less than ¾-in. A large variety of units are made with thin webs which necessitate smaller maximum particles.

Nitzsche conducted similar experiments, but does not report his grading in great detail. He prepared prisms which he tested for transverse strength. The results are quoted as follows:

Aggregate No.	A	B	C
Sizes, by volume:			
.47″—28″ (12 mm—7 mm)	1 part	1.00 part	1.00 part
.28″—16″ (7 mm—4 mm)	1.25 part	2.00 part	1.00 part
.16″—08″ (4 mm—2 mm)	.18 part	.50 part	.50 part
.08″—00″ (2 mm—0 mm)	.33 part	.25 part	2.00 part
Weight per cu. ft.	60.6	56.8	68.8 lbs.
1:4.5 cinder concrete			
Weight per cu. ft.	85.0	75.0	81.8 lbs.
Porosity by absorp. test	28.5%	27.2%	31.0%
Transverse strength lbs. per sq. in.	2440	1720	1400
1:7.0 cinder concrete			
Weight per cu. ft.	78.1	70.0	74.9 lbs.
Porosity by absorp. test	32.6%	32.2%	30.7%
Transverse strength lbs. per sq. in.	1460	940	1170

Aggregate *A* is the best graded of the three and produces the strongest concrete. *B* contains too much material in the range from about ¼-in to 3/16-in. Its showing is particularly bad with the leaner mix (1:7) where the lack of fines becomes more pronounced in its effect. *C* contains too much fine material. In lean mixes these fines are of increasing importance. Note that this aggregate is rather heavy; evidently the weight is not a safe indicator of proper grading.

If a general rule were to be given for the grading of cinder aggregate to produce masonry units of strength 700 lbs. per sq. in. for maximum yield per sack of cement, a fineness modulus of 4.0 to 4.5 (¾-in.-0) might be suggested. It is important, however, to remember that so many other variables enter the manufacture, that it becomes necessary for the maker of cinder units to run his own tests to obtain data applying to his conditions. The variables not only involve those of the raw material, but also the machine used and general method of making and curing.

Experience shows that the run of the grate of cinders from one reliable source, crushed by a uniform method to produce the desirable maximum size, is generally surprisingly uniform in its grading. If this were not the case, it would be impossible for cinder unit plants to produce a uniform product. Separation of cinders into definite sizes, by screening, is very difficult because of the nature of this damp, sticky material. From a practical point of view, (not losing sight of cost), it is perhaps better to endeavor to keep the cinders together, i. e., to prevent segregation. This segregation is a real difficulty in many plants, and it is readily multiplied when screening is used. The manufacturer, then, relies on a uniform and reliable source of supply

Scientific grading by separation and recombination is desirable and deserves considerable attention. The above grading is proposed, mainly, as guidance in empirical selection of the raw material. Considerable control may be obtained by proper operation of the crusher.

Much has been said of the effect of the fine particles of cinders. The writer refers to his definition of cinders to exclude household ashes. Cinders from high temperature combustion do not contain any appreciable amount of fine, fluffy ash—they contain some of fine gritty material. These fines are rarely present in any undesirable excess—they are needed to make the otherwise harsh mix workable. A typical cinder aggregate usually contains less than 10 per cent finer than No. 100 mesh.

The average manufacturer of cinder units unfortunately does not perform a large number of sieve analyses. Realizing that the raw material, as run of the grate, usually contains the full range of particles, the writer has proposed as a simple rule that the aggregate should "split" 50-50 or 40-60 on ¼-in. sieve. In other words, the manufacturer should endeavor to obtain such division through selection of supply and operation of crusher. It is admitted that freak aggregates can be produced without violating this rule of division on ¼-in.—but the writer has rarely encountered them except in patent litigation.

Mixing Water

When considering the amount of mixing water to be used in making cinder concrete building units, it must be borne in mind

(1) that we are here dealing with a highly absorptive aggregate and (2) that this concrete mixture cannot be considered as being truly plastic.

A large amount of water is usually present in the cinders when they arrive at the plant, or in the aggregate when it reaches the mixer. The manufacturer describes his aggregate as "dry," "wet" or "damp", but few realize how much moisture is actually contained. Part of the water which may be absorbed by a cinder aggregate is readily drained off—but a considerable amount remains even after prolonged drainage. The following data may be of interest:

A bituminous cinder aggregate was obtained from a plant in which the cinders were washed before crushing; they were therefore very wet in the storage bin. The fineness modulus was 3.85.

	Moisture	Weight Per Cu. Ft. Loose	Rodded
	%	Lbs.	Lbs.
Aggregate as received	38.7	57.0	62.6
Dry cinders in wet aggregate		41.1	45.2
Dried aggregate	0.0	54.0	61.7
Same soaked 15 min. and then drained of free water	31.4	57.2	64.0
Dry cinders in this aggregate		43.5	48.7
Same drained 18 hours	9.2	47.7	56.2
Dry cinders in this aggregate		43.6	51.4
The cinders were then inundated:			
Dry cinders per cu. ft. of inundated aggregate		50.0	
Water per cu. ft. of inundated aggregate		33.5	

The cinders of the above test were drained by being placed in a canvas bag. After 18 hours they still contained 9.2 per cent of water. The aggregate, when taken from the storage bin, contained close to 16 lbs. of water per cu. ft. Used in a 1:7 mix, this would mean more than 13 gallons per sack of cement. In this particular plant, where the cinders were washed, no water was added in the mixer when the aggregate under consideration was used.

From the above data it is possible to determine the bulking of the cinder aggregate, loose:

54 lbs. dry cinder aggregate (F. M. 3.85) ..... 1.00 cu. ft.
54 lbs. dry plus 9.2% water ..... 1.24 cu. ft.
54 lbs. dry plus 31.4% water ..... 1.24 cu. ft.
54 lbs. dry plus 38.7% water ..... 1.31 cu. ft.
54 lbs. dry plus 67.0% water (inundated) ..... 1.08 cu. ft.

It is apparent that considerable bulking takes place. For the percentages recorded, this bulking is approximately constant within the limits of moisture usually found in cinders. When inundated, the aggregate did not return to the volume of the dry aggregate, presumably because of the presence of particles of low specific gravity. A "pushing apart" may take place.

The data emphasize the necessity of using care in applying results obtained with dry cinders in the laboratory to wet cinders on the job.

While the above data were obtained from a plant using washed cinders, the writer has found the moisture content, in cinder unit plants using cinders as they come from the source, to range from 10 to 25 per cent, ignoring extremes. The percentages quoted here are based on dry weight.

It is evident from all figures that a large part of the total mixing water, with this aggregate, is present in the cinders and that this must be taken into account. The writer is aware of many experiments in which only the water added in the mixer was measured. Inasmuch as the mixing water is an important factor, here as in other concretes, such experiments cannot be accepted.

The amount of mixing water to be used to obtain maximum strength-cement ratio, depends upon the nature of the aggregate. The following series involves 8 x 8 x 16-in. hollow blocks made on a tamping machine. The carbon content of the cinders was varied—starting with a well clinkered bituminous cinder and adding carbon in the form of ¼ anthracite, ¼ bituminous coal, and ½ coke. It was difficult under these conditions to judge the consistency of the mix, but it is believed that "best results" were obtained in each case.

Mix 1:7 Dry Rodded. Coal and Coke in Cinders—Mixed as Above Stated	U. S. Gallons Water/Sack of Cement	U. S. Gallons Water/Cu. Ft. of Aggregate
20%	13.0	1.85
35%	11.9	1.70
50%	10.8	1.55
75%	10.2	1.45
100% (aggregate consisting of coal and coke only)	9.1	1.31
Mix 1:9 dry rodded. 20% carbon in cinders	16.7	1.85

The addition of dense coal reduces the amount of mixing water to be used. The density of the coal here more than offsets the effect of the porous coke.

The amount of mixing water to be used in making cinder concrete building units must be determined in every instance under the conditions prevailing in a plant. For example, a test run in an Eastern plant, using anthracite cinders (F. M. 4.0) in making 8 x 8 x 16-in. hollow blocks (30 per cent air space) on a power press, gave the following results for a 1:7 mix:

Mixing Water	Compressive Strength 28 Days
7.8 gallons per sack of cement	624 lbs. per sq. in.
9.6 gallons per sack of cement	741 lbs. per sq. in.
10.5 gallons per sack of cement	835 lbs. per sq. in.

A later test run at this plant, using a somethat coarser aggregate (F. M. 4.5) brought best results when using 12 gal. of water per sack cement—additional water giving slump of the block and decrease in strength.

It may be of interest to consider another test run involving two types of mixes. Anthracite cinders of fineness modulus 4.0 were used throughout, same cement, 7 min. mixing time, same type of 8 x 8 x 16-in. hollow block (30 per cent air space), same method of curing. Three different types of block machines were used, but in each instance the one variable of water content was controlled with a fair degree of accuracy to produce maximum strength for the machine in question.

1. Power press:
   1: 7 mix: 10.4 gal. water per sack of cement.
   1:10 mix: 15.9 gal. water per sack of cement.
2. Heavy tamping machine:
   1: 7 mix: 11.8 gal. water per sack of cement.
   1:10 mix: 15.5 gal. water per sack of cement.
3. Light tamping machine:
   1: 7 mix: 11.0 gal. water per sack of cement.
   1:10 mix: 14.3 gal. water per sack of cement.

If a general rule were to be deduced from these tests on anthracite cinder aggregate of fineness modulus 4.0, it would be that a 1:7 mix requires about 10 to 12 gal. of water per sack of cement, and that a 1:10 mix requires about 15 to 16 gal. In the last

mentioned series we may figure the amount of water used per cubic foot of aggregate, loosely packed:

1. 1: 7 mix: 1.49 gal. per cu. ft. of aggregate.
   1:10 mix: 1.59 gal. per cu. ft. of aggregate.
2. 1: 7 mix: 1.71 gal. per cu. ft. of aggregate.
   1:10 mix: 1.55 gal. per cu. ft. of aggregate.
3. 1: 7 mix: 1.57 gal. per cu. ft. of aggregate.
   1:10 mix: 1.43 gal. per cu. ft. of aggregate.

Average: 1.56 gal. per cu. ft. of aggregate.

In the above described test on bituminous cinders of varying carbon content, it was found that the mixing water for the aggregate containing 20 per cent carbon (mainly coke) was the same in 1:7 and 1:10 mixes, viz., 1.85 gal. per cu. ft.

As previously pointed out, one-half or more of the total mixing water is generally present in the cinders as received from the original source. It is believed that it is desirable to have at least part of the water present in the aggregate when the cement is introduced—otherwise part of the binder may be lodged in the open pores of the particles.

In cinder unit plants, the amount of water to be added in the mixer is mainly a matter of judgment. Drainage of the aggregate in the storage bin causes considerable variation; a mix is used which cannot be judged by slump; it is thus for the mixer man to know. Frequent test runs are important. It is well to employ an automatic measuring tank for the water, even if it has to be adjusted several times a day; it does reduce a variable in the manufacture.

Method of Mixing

The paddle mixer with open stationary drum is the type most commonly used in cinder unit plants. The lightness of the aggregate and the harshness of the mixture favor this type of equipment.

Tests have shown that the length of mixing time has a marked influence upon the quality of cinder concrete. This is readily understood when considering the nature of the aggregate. The shape of the particles is such that the surface area is very large. The cement paste (mortar) must be distributed throughout. It is probable that the shape of the particles (and perhaps their lightness) also require thorough mixing in order to obtain the

desired distribution of all sizes throughout. Tests indicate that too prolonged mixing may lead past the desired maximum—probably because cement is forced into pores where it does not serve as binder.

The majority of tests on record indicate that an increase in strength of cinder concrete continues up to a mixing time of seven minutes. The following test is selected at random:

Aggregate: Anthracite cinders, fineness modulus 3.82.
Total mixing water: 86 lbs. per sack cement.
Proportions: 1 to 7 damp loose.
9 cu. ft. paddle mixer, speed of shaft, 20 R. P. M.
8 x 8 x 16-in. blocks, 30 per cent air space, made on power press and stored in air for 28 days to 1 year.
Mixing time: 2 minutes.
28 day strength: 676 lbs. per sq. in.
1 year strength: 838 lbs. per sq. in.
Mixing time: 7 minutes.
28 day strength: 835 lbs. per sq. in.
1 year strength: 950 lbs. per sq. in.

The speed of the mixer blades is naturally of importance. It usually varies from 18 to 25 R. P. M. in cinder unit plants. The writer has conducted tests with mixer speeds up to 48 R. P. M., but the results at this high speed were erratic due to difficulty in charging and discharging the mix as well as in keeping the materials in the mixer. For the type of mixer commonly used in these plants, a speed of 25 R. P. M. appears most satisfactory. This applies to several makes of mixers, apparently of about the same efficiency in mixing.

Method of Molding

It is not within the scope of this paper to discuss the large number of machines on the market. The dominating type in the cinder unit field today is the so-called "stripper" which ejects the unit either upward or downward after tamping or pressing in the mold box.

Naturally, the strength of the cinder concrete increases with increased packing, provided the particles of aggregate are of sufficient strength to avoid crushing in the mold box. The method of feeding is important. Generally, the unit (usually 8 in. high) is weaker in its lower part ("the pallet side") because of the

bridging effect of the rather harsh cinders. This is particularly true of units with narrow webs. Best results are obtained, apparently, when machines strip the unit downward, as this permits the web to be wider towards the bottom, reducing the bridging effect. Feeding the material in layers also helps (see report of Committee P-1 in the A. C. I. Proceedings 1928).

Method of Curing and Aging

The hydration of cement in cinder concrete proceeds as in other concretes. It is of importance here to consider the amount of water present in the freshly made concrete.

Because of the porosity of the cinder aggregate, a large water reserve is available for hydration of the cement, and because of the nature of the concrete, the water is slow in reaching the surface where it evaporates. We have previously quoted instances of machine-made units containing more than 10 gal. of water per sack of cement with a 1:7 mix and more than 15 gal. in case of a 1:10 mix.

This water reserve simplifies the curing method. The "green" units may well be stored at a temperature of 70 to 80 deg F. without danger of too rapid drying. As a matter of fact, it becomes a problem to get rid of the water if the units are to be ready for safe use at 28 days. The significance of "dry" units becomes apparent when considering the problem of volume changes.

In one series of tests, the writer found 8 x 8 x 16-in. cinder units to contain more than 2 lbs. of water per unit after 28 days storage in the laboratory. The drying is more rapid when the units are properly stored in the yard. It is of the greatest importance to have the yard covered with a shed in order to prevent wetting from rains. The general problem of piling, etc. is now being studied. Of course, too rapid drying is possible, due to exposure to sun or to certain atmospheric conditions. But this is a rare occurrence.

Manufacturing Methods Generally

While the mechanical operations of mixing, molding, curing and storing the cinder unit, closely resemble those of a typical concrete block plant, the manufacturer of cinder units is, in addition, confronted with the problem of turning raw cinders into

a suitable aggregate. We shall briefly consider this part of the manufacture.

A plant producing one million 8 x 8 x 16-in. hollow units will consume approximately 20,000 cu. yds. of raw cinders, depending upon the nature of the material. Inasmuch as the manufacture of the units is rarely synchronized with the supply of raw material (usually contracted for), it is necessary to provide reserve storage and facilities for handling. Ground storage and exposure to weather offer the advantage of getting the cinders washed by rain (weather permitting) more thoroughly than is possible by any mechanical washer. The content of soluble sulphates is reduced. Of course, drainage must be provided and the cinders must be drawn from the top of the pile; otherwise the aggregate may suffer from a concentration of soluble salts. While a clamshell bucket is very satisfactory for handling the cinders from the pile to the aggregate plant, it is generally too expensive to operate except in large plants; it requires a licensed operator. Drag line buckets have been used successfully, the main difficulty here being the wear on the cables sliding through the abrasive cinders. A system of portable belt conveyors is used in many plants. Others use a tractor with a scraper attachment.

The effort in cinder unit plants is to consume the cinders as soon as they arrive. They are usually delivered in gondola cars holding 40 to 80 cubic yards. In designing conveyors for cinders, raw or crushed, it must be borne in mind that the material is highly abrasive. Elevators should be slow moving of the continuous bucket type and the feeding so arranged that spilling is avoided as far as possible and that facilities are present for easy cleaning of the boot. Belt conveyors should be wide and well troughed and provided with skirt boards to prevent spilling.

The crushing method depends upon the nature of the cinders. Usually a primary crusher is employed for reduction to 1½ to 2 in., while a secondary crusher completes the reduction to the required aggregate size, say ¾ in. Jaw crushers and hammer mills are most frequently used as primary crushers. The former type serves well when there is not too much fine material present to cause clogging. When the latter type is used, the hammers should move at much less speed than for limestone. The grate

bars should be spaced about two inches. To attempt the complete reduction of raw cinders in a hammer mill (requiring high speed and close spacing) does not appear economical. Roll crushers are used for secondary reduction. A common type consists of two pairs of rolls, each of 16 in. diameter. If but one set of rolls is used, larger diameter is required to get the necessary nip. Of course, rolls may also be used in primary reduction if the rolls are properly spaced. The usual care must be used in obtaining the proper spring adjustment; perhaps this is particularly important here because of the difference in hardness of the particles of cinders. It is necessary to have the feed evenly distributed over the full width of the rolls—otherwise the wear becomes excessive in spots. Sometimes cinders are obtained of maximum size less than 2 in.; the reduction may then be obtained in one step, using a roll crusher.

The crusher units should always be operated in circuit with a screen. The crushers cannot be relied upon to control the maximum size of the aggregate, and the output should therefore be screened so that any oversize may be returned. It is not good practice to pass anything through a crusher that does not need crushing; the cinders should therefore first be screened. The two screening operations may be combined, at least in a medium size plant, by first elevating all cinders to a screen on top of the aggregate bin, letting the aggregate pass through and returning the oversize to the crusher, thereafter joining the raw cinders on their way to the screen. This type of closed circuit is most desirable; it saves the crushers, prevents undersirable breaking down of particles not in need of reduction, and insures against over-size getting into the storage bin. Of course, the layout of equipment of this type depends upon the nature of the raw material and the capacity of the plant.

Screening of cinders is, at the best, an incomplete operation. Cinders are always wet when they arrive at the plant, and fine particles adhere to the surface of, or are occluded in, the pores of coarser particles, and cannot be removed except after drying. The dampness of the cinders and the irregular shape of the particles cause blinding of even the best screen. It is not necessary, however, to obtain complete separation when the

object is merely to save the crusher from unnecessary work or to prevent too coarse particles from getting into the aggregate bin.

Revolving screens are very unsatisfactory for cinders. The screening efficiency is notoriously low, and blinding quickly takes place when damp cinders are introduced. Fast vibrating screens, mechanically or electrically agitated, produce the best results. The type of screen cloth to be used depends upon the nature of the raw material. Each case deserves expert attention.

One of the significant problems of a cinder unit plant is the prevention of segregation of the raw cinders and the cinder aggregate. This segregation is particularly pronounced when the aggregate is fed into a large bin from a bucket elevator. The thin stream discharged by the elevator segregates readily when striking the cone of aggregate built up in the bin. In several plants this is successfully overcome by having the elevator discharge into a dumping box of capacity ½ to 1 cu. yd. When the box is full, it dumps its entire contents into the bin, thereby avoiding the slow building up of the cone. It is further desirable to have the storage bins of small diameter (8 ft. or so), with steeply inclined bottom (about 45 degrees) leading to a central discharge opening. It is well to endeavor to keep the storage bin full.

Cinders, consisting of rough particles, light and damp, do not flow readily, and all chutes should be designed with a slope of at least 50 degrees. Otherwise segregation occurs.

MAKING SAND-CINDER CONCRETE

The writer has done little work with sand-cinder concrete, and must therefore rely, to a great extent, upon published data. Unfortunately, such data are incomplete. All that is generally reported are the arbitrary proportions and the compressive strength—with no information regarding the properties of the raw material, sand and cinders, or the design of mix (grading and water content), or the method of making. To know that a "1:2:5 sand-cinder concrete" developed a compressive strength of 800 lbs. per sq. in. is of no help to the maker of such material unless he knows more about its history. The wide variation in compressive strength reported certainly suggests the need of more data.

We are here concerned only with sand-cinder concrete as it is poured on the job, usually for floors and fireproofing. The problem is different from that of cinder concrete building units, where the concrete is machine made under pressure. Under such conditions, the harshness of the cinder concrete does not make it impossible to obtain uniformity. On the other hand, if the concrete is placed by hand, around reinforcing, it must flow more readily, and this is helped by the introduction of sand.

The main reason for the use of cinders in this type of concrete is the lightness of the aggregate. The main reason for the addition of sand is to produce workability. Strength and density are not the only criteria for quality in the field where sand-cinder concrete properly belongs. A certain strength is necessary, and sand is a helpful agent because conditions on the job cannot be controlled to the same extent as conditions in a plant. A certain density is necessary, but it is unfortunate that many investigators of sand-cinder concrete place density as a chief aim.

Cinder concrete may serve the purpose of sand-cinder concrete if the aggregate can be well enough controlled on the job and if the necessary care and effort are used in placing. The writer is familiar with several jobs of reinforced concrete (roofs, floors, beams) where a straight cinder aggregate was used—and large quantities of reinforced cinder concrete lintels are being produced by cinder unit plants, using consistencies ranging from "dry" to "wet."

The difficulty of rigid control of the cinders on the job suggests the use of sand as part aggregate. With a weight of 100-120 lbs. per cu. ft. (85-90 lbs. for cinder concrete) the sand-cinder concrete is still considerably lighter than stone concrete.

Of course, in addition to its lightness, sand-cinder concrete has other advantages inherent in the cellular cinders. These will be considered later.

Sand-Cinder Aggregate

The mixture of dense and cellular aggregates naturally possesses characteristics intermediate between the two extremes. What has been said about cinder aggregate will to some extent apply here.

Nitzsche[11] reports the following, in which he uses the cinder mixtures previously described under cinder aggregate, substituting for ¼ of the cinders, sand graded from about ¼ in. down.

Cinder *A:*

Sizes, by volume:

.47—.28 in. (12—7mm)	1 part	
.28—.16 in. (7—4mm)	1.25 part	
.16—.08 in. (4—2mm)	.18 part	
.08—.00 in. (2—0mm)	.33 part	
1 cement:4.5 cinders:	85.0 lbs. per cu. ft.	
	28.5 per cent pores (by absorption test)	
	2440 lbs. per sq. in., transverse strength.	
1 cement:3.4 cinders:		
:1.1 sand	95.5 lbs. per cu. ft.	
	26.3 per cent pores	
	2140 lbs. per sq. in., transverse strength.	
1 cement:7.0 cinders:	78.1 lbs. per cu. ft.	
	32.6 per cent pores	
	1460 lbs. per sq. in., transverse strength.	
1 cement:5.3 cinders:		
:1.7 sand	88.1 lbs. per cu. ft.	
	28.7 per cent pores	
	1310 lbs. per sq. in., transverse strength.	

The cinder aggregate appears to be well graded. Substituting sand for ¼ of these cinders does not improve this concrete; the weight increases (the sand being heavier)—the porosity decreases (the sand being denser)—but the compressive strength falls off. The reduction in transverse strength is more noticeable in the richer mix.

Cinder *B:*

Sizes, by volume:

.47—.28 in. (12—7mm)	1.00 part	
.28—.16 in. (7—4mm)	2.00 part	
.16—.08 in. (4—2mm)	.50 part	
.08—.00 in. (2—0mm)	.25 part	
1 cement:4.5 cinders:	75.0 lbs. per cu. ft.	
	27.2 per cent porosity (by absorption test)	
	1720 lbs. per sq. in., transverse strength.	
1 cement:3.4 cinders		
:1.1 sand	96.2 lbs. per cu. ft.	
	24.4 per cent porosity	
	2820 lbs. per sq. in., transverse strength.	

1 cement:7.0 cinders: 70.0 lbs. per cu. ft.
32.2 per cent porosity
940 lbs. per sq. in., transverse strength.

1 cement:5.3 cinders
:1.7 sand: 87.5 lbs. per cu. ft.
26.1 per cent porosity
1770 lbs. per sq. in., transverse strength.

This cinder aggregate is not well graded; it lacks finer particles. The addition of sand is therefore beneficial, and the strength increases notably in the leaner mix.

Cinder *C:*

Sizes, by volume:

.47—.28 in. (12—7mm) 1.00 part
.28—.16 in. (7—4mm) 1.00 part
.16—.08 in. (4—2mm) .50 part
.08—.00 in. (2—0mm) 2.00 part

1 cement:4.5 cinders: 81.8 lbs. per cu. ft.
31.0 per cent porosity
1400 lbs. per sq. in., transverse strength.

1 cement:3.4 cinders:
:1.1 sand: 91.2 lbs. per cu. ft.
27.3 per cent porosity
1600 lbs. per sq. in., transverse strength.

1 cement:7.0 cinders: 74.9 lbs. per cu. ft.
30.7 per cent porosity
1170 lbs. per sq. in., transverse strength.

1 cement:5.3 cinders:
:1.7 sand: 86.2 lbs. per cu. ft.
27.8 per cent porosity
1205 lbs. per sq. in., transverse strength.

This cinder aggregate contains too many fines. Substituting sand for ¼ of the aggregate (mostly fine) does not alter the strength much—it reduces the porosity and increases the weight.

It is apparent that in these tests the introduction of sand does not necessarily improve the strength of the concrete. Much may be accomplished with cinders alone, if the aggregate is well designed.

In their comprehensive paper on reinforced sand-cinder concrete, Perrine and Strehan[10] present some information regarding the aggregate used in tests. Cinders, and 8 x 16-in. cylinders of sand cinder concrete, were obtained from jobs in New York City.

The cinders (anthracite) were described as follows:

A: Cinders from apartment house zone (1914).
B: Cinders from zone between apartment house section and downtown.
C: Cinders from downtown section.
D: Cinders from Columbia University power plant.

The sand was the typical bank material obtained from the north shore of Long Island.

The grading of the cinders and sand was as follows:

	Percentage of Cinders Coarser than Sieve No.			
Sieve No.	A	B	C	D
1¼ in.	2.2	5.6	1.9	0.0
1 in.	2.8		3.7	5.7
¾ in.	6.6	19.7	11.7	9.7
½ in.	14.1	42.7	35.5	19.5
¼ in.	36.6	75.7	74.6	26.1
10	61.2	88.3	88.9	84.9
16				90.5
30	75.6	90.7	97.0	94.9
50	78.4	93.8	98.7	96.6
100	86.3	96.4	99.5	97.7
Estimated F. M. standard scale	4.29	6.02	6.00	5.14
F. M. of sand (approximate)	2.37	2.72	2.64	2.66

Combining cinders and sand for a 1:2:5 mix should produce the following fineness moduli of the combined aggregates:

	Fineness Modulus		
	Sand	Cinders	2:5 Mixture
A	2.37	4.29	3.75
B	2.72	6.02	5.08
C	2.64	6.00	5.04
D	2.66	5.14	4.43

In making (on the job) concrete specimens (8 x 16-in. cylinders) from these aggregates, the mixer used and the brand of cement were not the same, nor is there any record of the amount of mixing water. The results are not entirely comparable—yet it may be of some interest.

	A	B	C	D
F. M. of cinders	4.29	6.02	6.00	5.14
F. M. of 2:5 sand-cinders	3.75	5.08	5.04	4.43
1:2:5 sand-cinder concrete:				
Weight per cu. ft.	107	107	109	113 lbs.
Compressive strength lbs. per sq. in.:				
One month	407	818	980	787
Six months	933	1744	1478	
One Year	913	1465	1475	

Cinders *B* and *C* are particularly coarse, with about 75 per cent retained on ¼ in. The addition of sand should materially improve such aggregates. Cinder *A* contains a large percentage of fine material; it would have been interesting to know what kind of cinder concrete it would have produced; mixed with sand it did not make a very good concrete. Cinder *D* is rich in medium sizes (¼ in. to No. 10), and the addition of sand does not bring it quite on par with *B* and *C*

If it were possible to draw a definite conclusion from these tests (if other variables were really controlled), it would favor a fineness modulus of the combined aggregates of about 4.5 to 5.0. Taken together with the previous test by Nitzsche, it again appears that blindly adding sand to cinders does not necessarily mean good or better concrete.

The lack of fines in the above cinders, as compared to the aggregate discussed under cinder concrete building units, is partly to be explained by the fact that these cinders were not crushed (beyond a breaking of large lumps with shovels), and partly to be explained by the usual wetness of New York cinders which may lead to actual washing away of fines during transport. It is also probable that the samples of aggregate were not taken with a view towards eliminating segregation.

Perrine and Strehan report tests on *D* with the cinders finer than ¼ in. "screened out." These tests show that the screening resulted in a decrease in strength of 1:2:4, 1:2:5 and 1:2:6 sand-cinder concrete as compared to same with the cinders unscreened. It is not stated, however, whether the screening was done while the cinders were wet, nor how efficient it was. Knowing the difficulty of screening cinders, it is impossible for the writer to draw any conclusions without knowing more how the screening was performed.

Richard L. Humphrey,[3] and Humphrey and Losse,[4] made tests on sand-cinder concrete beams at St. Louis in which considerable care was used in making the concrete. A product of excellent quality and remarkable uniformity was obtained, and the data are illuminating.

In the first series of tests, cinders were obtained from a power house of the United Railway Co. of St. Louis; this was presumably

a bituminous cinder. Weight, 47.0 lbs. per cu. ft. The sieve analysis was as follows, maximum size 1¼ in.:

Retained on	¾ in.	½ in.	¼ in.	No. 10	No. 20	No. 30	No. 50	No. 100
Percentage	18.6	39.7	63.1	78.9	86.3	89.5	93.5	95.8

Fineness Modulus of cinders: 5.65. Fineness Modulus of Meramac River sand: 2.42.

The mixtures were proportioned by weight to obtain a 1:2:4 mix of dry loose aggregate. Due to an error in determining the moisture content of the cinders (it proved to be 23 per cent), the actual mixes turned out to be close to 1:2:5. A 1 cu. yd. mixer was used, and the materials were mixed 2 minutes dry and 3 minutes wet. Three consistencies were used, described as "Wet," "Medium" and "Damp." In each the total water was measured and expressed (including moisture in aggregate) in percentage of weight of dry mixed materials. Cement was here assumed to weigh 100 lbs. per cu. ft. In each case a number of 8 x 16-in. cylinders were prepared, the following data having reference to these cylinders:

Proportions By Volume	Proportions By Weight	Water % of Dry	Weight of Concrete at 13 Weeks	28 Days Strength Lbs. Per Sq. In.
"Wet Consistency"				
1:2:5.06	1:2.02:2.38	21.6		1,243
same	same	21.8	116.5 lbs.	1,000
same	same	21.6		1,000
			Average:	1,081
"Medium Consistency"				
1:2:5.06	1:2.02:2.38	19.4		1,114
1:2.06:5.40	1:2.07:2.54	20.4	115.6 lbs.	1,250
same	same	20.4		1,240
			Average:	1,201
"Damp consistency"				
1:2:5.19	1:2.01:2.44	19.0		1,055
same	same	same	112.5 lbs.	1,210
same	same	same		1,090
			Average:	1,118

The average compressive strength of these cylinders at 6 months may be reported as follows:

	Weight Per Cu. Ft.	Compressive Strength Lbs. Per Sq. In.
Wet consistency	113.9 lbs.	2,021
Medium consistency	114.3 lbs.	2,203
Damp consistency	113.7 lbs.	1,945

In the second series of tests, cinders were obtained from the same source. With a maximum size of 1¼ in., the grading was:

Retained on	¾ in.	½ in.	¼ in.	No. 10	No. 20	No. 30	No. 50	No. 100
Percentage	6.8	22.9	78.4	85.8	90.9	92.9	95.1	96.8

Fineness modulus: 5.69.

In this series of tests, sand-cinder concrete was prepared in the same manner as before, but the mixes were actually designed to be 1:2:4 by volume. This corresponded to about 1:2:2 by weight, the dry sand weighing about 100 lbs. and the dry cinders 50 lbs. per cu. ft. The total mixing water averaged 19 per cent of the dry materials for "medium consistency." Cylinders (8 x 16 in.) were prepared as before, and averaged as follows:

	Weight Per Cu. Ft.		Compressive Strength Lbs. Per Sq. In.
28 days	118.4 lbs.	High 1964 Low 1499	
		Average	1,647
13 weeks	119.4 lbs.		2,217
6 months	119.5 lbs.		2,525
1 year	119.7 lbs.		2,761

When observing the sand-cinder aggregate used in these tests it is interesting to find, first, how closely alike the cinders of the two series are. They were from one source, evidently producing a good grade of cinders. The fineness moduli are almost the same. Characteristic for both is a lack of fine material. Combining sand and cinders in the two general proportions produces the following:

	Fineness Modulus		
	Sand	Cinders	Mixture
1:2:5	2.42	5.65	4.72
1:2:4	2.42	5.69	4.60

The sand-cinder concrete of these tests was apparently of good quality. The strength for the 1:2:5 mixture is above those re-

ported by Perrine and Strehan, as representing "job made" New York concrete. It is unfortunately impossible to judge whether the sand cinder proportion was the most desirable for maximum strength/cement ratio, and it is also impossible to judge the density and other characteristics of the concrete. The many test specimens (representing the large number of reinforced beams prepared) show a most remarkable uniformity of strength. It is evidently quite possible to produce a uniform sand-cinder concrete if care is used in proportioning and if the cinders are from a reliable source. Other features of these tests will be considered later.

Some information regarding the effect of sand upon sand-cinder mixtures may be gained from tests made by C. M. Spofford and H. W. Hayward, as reported by Taylor and Thompson, "Concrete, Plain and Reinforced," 1916 edition, p. 328. We shall here omit the reference to the appearance of the cinders and the nature of the coal.

1:2:5 Sand-Cinder Concrete. 8 x 8 x 16-in. Prisms

% of Cinders Passing				Weight in Lbs. Per	28 Days Strength Lbs. Per
1 in.	¾ in.	½ in.	¼ in.	Cu. Ft.	Sq. In.
100	96	84	71	89	400
100	93	78	65	95	492
100	93	76	60	91	645
100	89	63	43	97	812
100	81	70	50	104	828
100	84	57	36	101	868
100	80	49	33	109	883
100	66	53	26	113	1088
100	83	47	26	111	1246
½-in. stone and coarse sand				145	1620

Different cinders were used in making these specimens and it is not known to what extent that affected the results. Nevertheless, it appears evident that there is a very definite relation between the grading and the strength, the latter increasing as the cinder-fines decrease from 71 to 26 per cent passing ¼ in. (the material through ½ in. decreasing in parallel manner from 84 to 71 per cent). It would be interesting to know how some of these mixtures would have behaved if no sand had been added. To add $^2/_5$

sand (by volume) to a cinder already having 71 per cent finer than ¼ in. will, of course, produce an altogether too fine aggregate.

Sand-cinder aggregate may be designed to produce definite results. It may not be possible to obtain the same degree of accuracy as with more expensive and better controlled aggregates, but an attempt should be well worth while.

Mixing and Placing

The purpose for which the sand-cinder concrete here considered is used, makes it necessary to obtain a mixture of greater plasticity than is required in cinder unit plants. It must be possible to work it around the wire mesh and rods of the floor slab, and distribute it well in the forms around the steel. On the other hand, it must not be so wet that the heavy sand and the light cinders segregate. There are few data available as to the effect of mixing water, mixing time or mixing methods on such concrete.

Perrine and Strehan state (page 580):

Cinder concrete should be mechanically mixed, for not less than 2 min., not leaner than 1:2:5, giving a minimum compressive strength, with standard cylinders at 28 days, of 800 lbs. per sq. in., and be in a wet to viscous consistency when cast.

Describing the making of floor slabs in the Columbia University laboratory, they state (page 550):

The process of mixing occupied about 2 min. per batch. The concrete was taken to the forms in wheel barrows, and when deposited was of a wet, viscous consistency. It was stirred and pushed into the spaces between the wires or rods with narrow pieces of scantling, the material being too wet to permit tamping, as the term is generally understood. An excellent, dense homogeneous concrete was thus obtained.

Note: A ¼-cu. yd. Blystone mixer was used.

As previously mentioned, Humphrey and Losse actually report the amount of mixing water used. Accepting the statement that "the water is figured in percentage of total weight of dry materials" to mean that the percentages are based on the weight of cement plus aggregates, the amount of water may be readily figured. Humphrey describes what is meant by "wet," "medium" and "damp" consistency, but it is not clear whether his descrip-

tion applies equally well to granite, gravel, limestone and sand-cinder concrete of his investigation.

It is apparent, immediately, that there is not much difference between the amounts of water used in producing the three consistencies. Apparently, the sand-cinder concrete mixture is just as sensitive to a pound of water at the point of proper consistency as other concrete mixtures. This is in accordance with the writer's observations of wet (almost plastic) mixtures of cinder concrete.

In the first series (1908) the mixing water (including absorbed moisture in the aggregates) is reported to be (in U. S. gal.).

1:2:5.06 sand-cinder concrete
"Wet" consistency:
14.1 gal. per sack cement.
1:2:5.06 sand-cinder concrete
"Medium" consistency:
12.6 gal. per sack cement.
1:2.06:5.40 sand-cinder concrete
"Medium" consistency:
13.7 gal. per sack cement.
1:2:5.19 sand cinders concrete
"Damp" consistency:
12.4 gal. per sack cement.

In the second (1911) series, the mixing water was about:
1:2:4 sand-cinder concrete:
11.4 gal. per sack cement

On the average, the amount of water for the 1:2:5 mix is about the same as the water used in a 1:7 cinder concrete mix as used in the manufacture of cinder concrete building units. The sand-cinder concrete, with the dense sand as part of the aggregate, has, of course, a consistency quite different from that obtained with straight cinder aggregate.

In the tests by Humphrey and Losse it is apparent that, for the particular cinder used, the amount of mixing water (including the large amount of moisture in the aggregates) should be about 13 to 14 gallons per sack of cement for a 1:2:5 mix, and about 11 to 12 gallons per sack of cement for a 1:2:4 mix. The mixing time used here (5 minutes total) should be sufficient.

Most authors agree that the sand-cinder concrete mixture must be wet. It can unquestionably be too wet. The test by

Humphrey indicates that (see above). The temptation of adding altogether too much water to stone concrete is well known—the same temptation is present here, perhaps to a greater extent. The cinders make the mixture harsh, yet the mixture can be properly placed without approaching the "liquid" form. The writer has observed that for reinforced cinder concrete, with no sand, carefully placed in cinder unit plants where the workmen knew a bit about the material they were handling, the sand-cinder concrete can be made so wet that it flows without any effort on part of the workman, but there is then great danger of segregation of the two aggregates, sand and cinders, because of the different specific gravities.

Stone concrete is gradually getting on a basis of rational design. The writer can see no reason why sand-cinder concrete should not follow. To specify arbitrarily a mixture of 1:2:5 just because one of the aggregates is not known to the second decimal is rather absurd. The engineer should know a little about his aggregate beyond the fact that it is "cinders," and he should run regular trial batches to determine just what he can accomplish with the material at hand.

On the Making of Sand-Cinder Concrete Generally

It is more difficult here to watch the cinders than in a cinder unit plant which usually contracts for a year-round supply. The storing of cinders on the job is usually limited to small quantities; generally the material is conveyed directly from the truck. The problem, however, is the same as in the cinder unit plant, viz., to prevent segregation.

The difficulty (if not impossibility) of crushing and screening on the job makes it necessary to obtain a cinder that does not contain much in excess of 1 in., or which is readily broken by shovel or in the mixer. The anthracite cinder of New York is of this type, as indicated by tests quoted.

Most of the data here quoted deal with 1:2:5 sand-cinder concrete, the apparently typical New York mixture. While it cannot be judged without knowing the nature and grading of the cinders to which the sand is added, it must be considered as being, generally, too lean. Attention should be directed to richer

mixtures, and to the proper gradation of the combined aggregates. A too harsh sand-cinder concrete leads to the use of too much water to get it to flow into place—with the result that the cement paste is diluted and segregation is likely to occur. The deficiencies of 1:2:5 mixtures should not be considered a reflection upon better designed mixtures of sand-cinder concrete.

The writer is convinced that there should be a considerable market for a prepared cinder, crushed and graded to meet definite requirements. This is probably the only way in which rationally designed cinder or sand-cinder concrete mixtures may be obtained. The chief obstacle is perhaps the fact that the contractor, faced with a "1:2:5" specification does not care what the "5" represents. Until this is remedied, sand-cinder concrete will not emerge from its present twilight zone.

Note on Job-Made Cinder Concrete

The foregoing pages may give the impression that job-made concrete (structural concrete), utilizing cinder aggregate, must of necessity contain sand. The writer has discussed sand-cinder concrete for this purpose, mainly because this type of concrete has been so generally used. He has pointed out, however, that the admixture of sand does not always improve the quality of the concrete—it all depends upon the nature (the design) of the cinder aggregate.

Since this report was first written, the writer has become familiar with some of the data obtained by the Thompson & Lichtner Co., Boston, in their work on structural, straight-cinder concrete. While these data (furnished by Miles N. Clair) are not incorporated in the present paper, it is hoped that they will be available in discussion of this report.

Cinder concrete mixtures of well defined slump were here produced. Small difference was found in the workability of cinders and other aggregates if they were all of the same grading. This applies particularly to mixtures 1:2:4 or richer. The data suggest as the most desirable a straight line grading on the semi-log plot with an allowable percentage of fines somewhat greater than is usual for sand. Ten per cent are permitted finer than No. 100 mesh. For usual maximum size (¾ in.) about 50 per cent should be retained on No. 4 mesh.

CHARACTERISTICS OF CINDER AND SAND-CINDER CONCRETE

In the preceding discussion of cinders it has been pointed out that the physical character of this aggregate is quite different from that of such aggregates as sand or stone, and that the resulting concrete should not be measured by the usual standards of strength and density. The field in which cinder, or sand-cinder concrete is used should be distinguished from the general field of stone concrete. The cinders should not be considered a substitute material—they produce a concrete possessing some highly desirable characteristics. These characteristics will briefly be reviewed here in the general discussion of the material.

Strength

First, concerning cinder concrete.

The effect of raw material and method of making upon the resulting concrete have already been discussed. The compressive strength will, of course, always depend upon the size and shape of test specimen, moisture content, etc. Hollow cinder concrete building units are usually made for a compressive strength of not less than 700 lbs. per sq. in. of gross area at 28 days. Because of many variables in the present day manufacture, it is necessary to aim at about 900 lbs. in order to be well above the minimum.

The compressive strength decreases with increasing moisture content. One series of tests on 8 x 8 x 16-in. hollow block of average compressive strength 827 lbs. per sq. in. showed a decrease in strength of 12 per cent after 48 hours immersion in water (tested wet). Another series of tests on brick of average compressive strength 4920 lbs. per sq. in. (tested flatwise) showed a decrease of 36.7 per cent after 48 hours immersion. The brick were denser than the block—evidently the effect of the water is more pronounced with lesser porosity.

Accepting cinders as an inert aggregate, it is natural to expect an increase in strength with age. Such increase is evidenced by many tests. When subjected to freezing and thawing treatments (described later), cinder concrete generally shows an increase in strength after completion of the test, obviously due to increased hydration of the cement during the submersion period.

There are few tests on record to show the strength of walls constructed of cinder concrete masonry units. They indicate a high wall efficiency (54.7 to 75.8 per cent), which is to be expected when considering the surface texture of machine-made cinder concrete. These same tests (on hollow cinder block piers, 54 in. high by 24 in. wide by 8 in. deep, laid in 1:3 cement mortar) showed a modulus of elasticity of the pier of 698,000 lbs. per sq. in. based on the intensity of stress on the gross cross section, and 1,035,000 lbs. per sq. in. based on the net section of 130 sq. in.

The transverse strength of cinder concrete building units is of interest chiefly in brick shapes, the larger unit rarely being exposed to tensile stresses in the wall. The transverse strength of cinder concrete brick increases with the compressive strength as indicated by the following representative tests: Cinder brick—standard size.

Compressive Strength	Modulus of Rupture
1221 lbs. per sq. in.	379 lbs. per sq. in.
1890 lbs. per sq. in.	496 lbs. per sq. in.
3035 lbs. per sq. in.	581 lbs. per sq. in.
4920 lbs. per sq. in.	765 lbs. per sq. in.

Second, concerning sand-cinder concrete.

It is not within the scope of this report to consider the design and behavior of reinforced sand-cinder concrete. The reader is referred to the papers by Humphrey, Guy B. Waite and Perrine and Strehan.

As to the concrete itself, Perrine and Strehan observe that:

> The crushing strength of standard (8 x 16″) cylinders of good cinder concrete (sand-cinder) as used in New York is between 800 and 1,000 lbs. per sq. in. at 28 days.
>
> The modulus of elasticity, E, under working loads, determined from standard cylinders, is about 1,200,000 lbs. per sq. in. for average concrete at 28 days.

As previously pointed out, Humphrey produced a considerably better sand-cinder concrete in his tests than the New York job concrete cited above. His 1:2:5 concrete ranged well above 1,000 lbs. at 28 days (8 x 16-in. cylinders), and his 1:2:4 concrete averaged 1647 lbs. at 28 days and reached an average of 2761 lbs. at 1 year. In the latter series of tests he produced 1:2:4 sand-gravel concrete of 3175 lbs. per sq. in., 1:2:4 sand-limestone con-

crete of 2492 lbs. per sq. in., and 1:2:4 sand-granite concrete of 3054 lbs. per sq. in.,at 28 days.

Humphrey and Losse report the initial modulus of elasticity (second series) to be:

1:2:4 sand-cinder concrete: 21 8 x 16-in. cylinders: 28 days:

High:	2,320,000 lbs. per sq. in.
Low:	1,180,000 lbs. per sq. In.
Average:	1,610,000 lbs. per sq. in.

For the 1:2:5 mixture, medium consistency, he reports the following initial modulus of elasticity:

At 28 days	Average: 1,352,000 lbs. per sq. in.
At 6 months	Average: 1,618,000 lbs. per sq. in.

Weight

The weight of cinder and sand-cinder concrete depends on the nature of the aggregate, design of mix, method of making, moisture content of the concrete.

A recent survey of the cinder concrete building units made by 28 plants gave the following results, 3 units from each plant being tested:

Weight of dry cinder concrete per cu. ft.

High value:	98 lbs.
Low value:	74 lbs.
Average:	87 lbs.

In one plant, the cinder concrete was found to weigh 106 lbs. per cu. ft., but this was due to an exceptional cinder, very high in iron. The above variation is wide—but these plants use widely different methods of making, in addition to representing cinders from all over the United States.

Perrine and Strehan report weights per cu. ft. of 1:2:5 sand-cinder concrete (using New York anthracite) ranging from 107 to 115 lbs. Humphrey reports his 1:2:5 sand-cinder concrete (using, presumably, a bituminous cinder) to weigh from about 112 lbs. to about 117 lbs. per cu. ft., while the average for his 1:2:4 sand-cinder concrete is 118.4 lbs.

Absorption and Allied Phenomena

It is still common belief that the old fashioned absorption test, in which the water absorption is determined by submerging the

specimen in water for a certain length of time, and is calculated in percentage of the dry weight, is indicative of such qualities as resistance to moisture penetration, frost action, etc. It would appear obvious, however, that this absorption test is of value only when it is representative of the actual conditions to which the material in question may be exposed. It may be of value with materials to be used under water—but its value is not clear for materials used in ordinary wall construction.

In the present paper, cinder concrete is considered as an intentionally porous concrete—in other words, a concrete utilizing a cellular aggregate in order to obtain certain characteristics—and not a concrete merely using cinders because they are cheap or because they are light. The value of the usual absorption test is questioned in a field where this porous concrete has proven its place. Cinder concrete does not belong where great density is needed. This may appear obvious, although it is not yet generally realized.

The immersion test gives no information regarding the behavior of cinder concrete in the wall of a building. Capillary attraction is the force which usually moves moisture through a wall, but that force is not measured by the standard test. Frost action depends upon the distribution of moisture throughout the wall, and upon the nature and distribution of the pores of the material, and perhaps upon other factors, but the immersion test gives no information about these matters.

It may be mentioned in passing that it is still quite common to specify an absorption limit for any kind of concrete in percentage of dry weight. How meaningless this is when including lightweight concrete is obvious. Assuming the limit to be 10 per cent by weight, 1 cu. ft. of stone concrete (140 lbs.) is permitted to absorb 14-lbs. of water, while 1-cu. ft. of cinder concrete (85 lbs.) must not absorb more than 8½ lbs. This has been remedied in most modern building codes; if a limit is considered necessary, it should probably be stated in lbs. of water absorbed per cu. ft. of concrete.

Frost action is usually determined in the laboratory by saturation of the material in question followed by alternated freezings and thawings. Such a test on cinder concrete building units is

reported and discussed in detail in the 1928 *Proceedings* of the American Concrete Institute. The freezing test specimens were soaked in water, then placed in the freezing chamber until frozen solid. After freezing for a period of 5 hours or more, during which time the temperature in the freezer was reduced to an average low value of 21 deg. F., the blocks were moved to a tank and thawed in water at 140 deg. F. for one hour. The blocks were cooled in water and put back into the freezer in the saturated condition, and the freezing and thawing was continued in like manner until 100 reversals had been made. The results are summarized as follows:

8 x 8 x 16-in. hollow cinder block.
Average compressive strength at 28 days (3 units): 1030 lbs. per sq. in.
Average dry weight at 28 days (3 units): 32.08 lbs.
Average absorption, percentage by weight at 28 days (3 units) 20.35 per cent.
Blocks normally cured, tested at 109 days:
Average compressive strength (3 units): 1042 lbs. per sq. in.
Average weight (3 units): 31.80 lbs.
Average absorption, percentage by weight (3 units) 20.12 per cent.
Blocks submitted to 100 freezing reversals, tested at 109 days:
Average compressive strength (6 units): 1123 lbs. per sq. in.
Average dry weight before freezing (6 units): 32.18 lbs.
Average dry weight after freezing (6 units): 31.75 lbs.
Average absorption, before freezing (6 units): 19.83 per cent.
Average absorption, after freezing (6 units): 23.12 per cent.

It will be seen that the blocks subjected to 100 freezing reversals showed an average compressive strength which was 7.8 per cent greater than the strength of the blocks normally cured. The absorption increased 16.6 per cent of the value before the freezing reversals, and the weight decreased 1.34 per cent. The increase in strength may be considered due to the warm water thawing treatment; the increase in absorption must be due to the opening, by the force of the freezing water, of cells which were previously inaccessible to water, as well as to other changes in pore structure. The significant facts are that the loss in weight was only 1.34 per cent and that the blocks showed no visible sign of cracking or spalling. No difference could be noted between the fractures from the compressive strength test of the frozen blocks and the blocks not frozen.

The writer has supervised several freezing and thawing tests in the last ten years. Qualitatively, the results were usually the same. An exception, however, is of interest. It involved cinder brick, and may be compared with another cinder brick made by the same plant, but from a different mix. The tests were carried out at Rochester, and at New York respectively. The results are summarized as follows:

	"Rochester" Brick	"New York" Brick
Freezing reversals	42	20
Compressive strength of brick not frozen	3290 lbs. per sq. in.	4920 lbs. per sq. in.
Absorption, by weight	15.8%	6.34%
Absorption corrected for weight according to A. C. I.	11.5%	4.65%
Change in strength due to freezing reversals	2.2% increase	24.1% decrease

Based on the recognized tests for strength and density, the "New York" brick is far superior to the "Rochester" brick, but the recognized freezing and thawing test showed the Rochester brick to be far superior. This may be compared to another test, made in 1922. The writer prepared cinder brick (using the same machine as above) from cinders crushed and screened to pass ⅛-in. mesh. At 28 days the brick tested 3,035 lbs. per sq. in. average, and had an absorption of 10 per cent—thus passing most quality requirements. When subjected to freezing and thawing test, however, they completely disintegrated within 20 reversals.

It would appear from this that with cinder concrete the absorption test does not give any information regarding the resistance to frost action, unless, perhaps, a minimum requirement should be considered. 15-20 per cent absorption by weight appears to be desirable. The action in freezing tests may be explained in two ways. It may be assumed that a highly cellular cinder concrete cannot be completely saturated with water, but that imprisoned air in the open pores (or the closed cells when forced open) permits expansion of freezing water without danger of fracture or disintegration. It may also be assumed that porous cinder concrete, in a standard freezing test, permits the water to drain off so rapidly that the concrete is far from being saturated when placed in the freezing tank. This may be taken to imply

that the standard test should be changed to insure complete saturation at all times—but would that be more truly representative of actual conditions? A material that drains rapidly in the wall, should also be permitted to drain rapidly in a test designed to determine its "wall behavior."

We shall next consider moisture movement through the wall. The usual absorption test is supposed to tell whether or not a material will produce a dry wall. Surely, that supposition is not justified unless we know something about the manner in which moisture travels through the wall. It is safe to assume that 100 per cent density will keep moisture out and that 100 per cent porosity will let moisture pass, but the fixing of a limit between these two extremes is not a matter of round-table discussion.

Suction is an important factor. A driving rainstorm does not ordinarily penetrate an 8-in. wall by its own force; the water is usually drawn by capillary force. It has been claimed for cinder concrete that this capillary force is very low because of the widening out of open channels into air pockets created by the porous cinder aggregate. The dependancy upon the porosity of the cinder concrete has not yet been proven, although most cinder concrete building units appear to have a rather low capillary attraction for water. Tests on cinder concrete and sand-cinder concrete indicate that the shape and distribution of the pores are the important factors, and that these cannot be judged by simple tests for porosity or absorption.

The moisture movement in a wall also involves the rate of drying. It is important that the wall should dry readily after getting wet, otherwise a magazine of water may be built up in the wall, leading to saturation. Of course, the drainage in a porous material helps in removing the water. There is apparently no definite connection between the rate of suction and the rate of drying; the distribution of the fine pores may be of chief importance. The usual absorption test gives no guidance.

The absorption test, or a simple determination of porosity, apparently gives no information regarding the true significance of the cellular structure of cinder concrete. We have previously shown (when discussing cinder aggregate) that there is no relation between porosity (determined by water absorption) and com-

pressive strength. This is also apparent from a number of tests conducted by the writer. The cellular structure, however, is a most important feature of cinder concrete—its chief characteristic—and should be first on the research program of the industry.

The introduction of a denser aggregate in sand-cinder concrete naturally affects the cellular structure. Writers on the subject have frequently indicated that it may be destroyed completely, and have placed the density of stone concrete as the goal for sand-cinder concrete. It is this, more than anything else, which has given cinders the appearance of being a substitute aggregate striving for something it cannot reach. A realization of the true nature of cinders should bring about an understanding of just what this aggregate will accomplish. As previously pointed out, the chief reason for the introduction of sand with cinders in the making of poured concrete is that of workability under prevailing conditions; it is not that of imitating stone concrete in other respects.

Volume Changes

The writer has previously mentioned the expansional movements which may be caused by certain types of coal or by sulphur compounds present in the cinders. It was pointed out that this phenomenon is rarely observed when the cinders come within the definition and specification of this paper.

Any concrete, however, is subject to shrinkage movements due to the hydration of the cement and to drying. Changes in moisture content cause changes in volume. Reference is here made to the paper by W. D. M. Allan, in this Journal (April 1930, Proceedings, Vol. 26, p. 699). It reports on sand concrete as well as cinder concrete. Sand-cinder concrete is perhaps intermediate in its behavior.

Part of the conclusions are quoted:

The use of units which are only partially dry, containing 2 to 5 per cent of moisture by weight, will result in the major amount of shrinkage which will occur in a concrete masonry wall.

For the conditions of air curing used in these studies, 26 days of air curing was generally sufficient to obtain blocks that would result in the minimum amount of shrinkage when laid in the wall.

In his foregoing discussion of manufacture of cinder units, the writer pointed out that the units must be piled in such a manner

that drying is facilitated, and that they must be protected against the weather.

These precautions do not apply to sand-cinder concrete, poured in situ. When properly reinforced it is unquestionably less subject to volume changes, or the evidence of such change does not become apparent. The design of the mixture is presumably of particular importance, but the data on hand do not justify any conclusions.

Fire Resistance

There is considerable evidence, and a great deal of opinion, available regarding the fire resistance of cinder and sand-cinder concrete. The majority seems to favor the material as being quite remarkable in this respect. A dissenting opinion, however, was voiced by the A. C. I. Committee E-4, in the 1929 Proceedings of the Institute (Vol. 25, p. 812). In summarizing its report, the committee concludes with the statement:

> Cinder concrete at high temperature transmits heat rapidly and loses strength.*

This may be compared with some statements of other experienced observers. For example, Prof. Ira H. Woolson (elsewhere quoted by Committee E-4) said at the building code hearing in New York City, June 1909:

> The best fire-resisting material used in construction today is cinder concrete without any qualification.

The divergency of opinion is naturally explained by the fact that the material is not clearly defined. We speak of the fire resistance of concrete—yet no two concretes behave alike. Cinders as an aggregate are less clearly defined than others—it is natural that the resulting concrete will not be uniform to the second decimal.

When cinders are improperly used (poorly graded aggregate, careless mixing and making) the resulting concrete may be so open-textured that it permits free passage of air. The heat transfer through such concrete is naturally rapid, and it is quite possible that exposed carbon particles in the interior may burn.

As an example of such poor cinder concrete may perhaps be cited the three specimens of Technologic Paper No. 130 of the

*It is unfortunate that some qualification and elucidation of this statement by Committee E-4, did not have equal prominence with the original report. It is in statements by N. D. Mitchell, A. C. I. *News Letter*, Nov. 1929, p. 11.—Editor

Bureau of Standards (referred to by Committee E-4). The cinder concretes (sand-cinder) of that paper are described as follows:

Cinder concretes Nos. 1291 and 1292 were extremely weak and friable. The appearance of the concrete indicated too great a proportion of fine material.

Cinder concrete No. 1291a was an extremely rough specimen because of a deficiency of fine material.

Such mixtures are not typical of the cinder and sand-cinder concrete of today and were evidently prepared by someone who was not familiar with designs involving this type of aggregate.

In well designed cinder concretes the fire resistance has been quite remarkable. Tests have been made at the Underwriters' Laboratories by the cinder unit industry and have shown a resistance to fire and water, and a retardance of heat transfer greater than in similar sand concrete units. As previously mentioned, the presence of coal and coke does not materially lower the fire-resistance, within limits. It lowers the strength of the concrete after fire exposure, but even a unit of pure coal and coke aggregate was not destroyed in a test reaching its temperature endpoint (8-in. hollow wall) in 3 hours and 49½ minutes.

In sand-cinder concrete, the evidence of the test house of Columbia University is of particular interest. The permanent walls of this house are built of 1:2:5 sand-cinder concrete. Professor Woolson cited this house at the 1909 hearing on the New York building code:

For these test buildings we have tried brick many times. Brick lined with cinder concrete 3 or 4 inches thick and cinder concrete buildings we have also tried, and as a result of having built several of these buildings I have arrived at the conclusion that the only and best material to use for a building of that character is the cinder concrete.

Before the convention of the National Association of Cement Users, 1911 (Vol. 11), Professor Woolson stated of this test structure, which had then been subjected, in the aggregate, to 24 hours of firing at an average temperature of 1700 degrees, with water applied at the end of tests:

Today (Dec. 13, 1910) the building is standing in as perfect condition as it was the day it was built, having some few temperature cracks which, of course, are due to that very excessively severe treatment.

Concerning this building, Rudolph P. Miller stated in 1925 (in report to Crozier-Straub, Inc.):

Since that statement was made the same structure has passed through over forty hours of such severe treatment in good condition, without the need of repairs.

Perrine and Strehan open the discussion of fire resistance of sand-cinder concrete by saying:

To any one at all familiar with the effect on cinder concrete of flames at high temperature followed by the application of cold water at high pressure, little other evidence is necessary to prove its efficiency under this treatment.

Inasmuch as Committee E-4 is chiefly concerned with the heat transfer through the material, it may be well to point to the tests by Humphrey, as reported in Bulletin 370 of the U. S. Geological Survey. If the writer reads the graphs correctly, 8-in. solid concrete blocks in similar fire tests showed about the following:

	Unexposed Face of Wall	
	Initial Temperature	After 2 Hours
8-in. granite concrete	18 deg. C.	58 deg. C.
8-in. gravel concrete	23 deg. C.	56 deg. C.
8-in. sand cinder concrete. 1:2:4, with 24.5 per cent unconsumed carbon	28 deg. C.	43 deg. C.

Weighing all the evidence at hand, both cinder and sand-cinder concrete appear to possess a remarkable degree of fire-resistance—provided they are well made. 8-in. hollow cinder blocks, 1¾-in. web, not more than 35 per cent combustible, 1 cement to 7 dry rodded cinders, are given a 3-hour rating by the Underwriters' Laboratories, and are certified as such. Cinder concrete building units in fire tests, and in actual fire exposures, have shown a remarkable absence of cracking and spalling, both when exposed to fire and to water. The status of sand-cinder concrete is not as clearly defined—but the fire record of this material has been truly remarkable.

Heat Transmission

The 1930 Guide of the American Society of Heating and Ventilating Engineers lists the following heat transmission coefficients for "cinder concrete" (without specifying the composition of the material):

Solid cinder concrete. Conductivity "k" (per 1 in. thickness) 3.33

12-in. hollow cinder block, four cores, three longitudinal webs. Conductance "C" (face to face) 0.28

8-in. hollow cinder block, two cores. Conductance "C" (face to face) ... 0.45

These values check well with those obtained in laboratory tests witnessed by the writer. The tests are summarized as follows:

At the University of Toronto, Prof. R. W. Angus[17a] conducted tests for Canadian Cincrete, Ltd. The cinder units were built into a wall, 7 blocks high and 3 blocks wide, having a total area of 20.31 sq. ft. The wall was set up in a large box in such a manner as to divide the box into two compartments. One of these compartments communicated directly with the cold room of a refrigerating machine, while the other compartment was heated electrically. Fans distributed the air over the surface of the wall.

The air on the warm side was maintained at approximately 70 deg. F. while the air on the cold side was maintained at about 20 deg. F. When the temperatures on each side remained constant, all the heat put into the warm compartment was transferred through the wall. From this the conductance and transmittance may be calculated, when knowing the temperatures of the air and the surfaces of the wall.

The units under test were 8 x 8 x 16-in. hollow cinder block, having three oval cores and approximately 40 per cent air space. The design of mix is not definitely known, but the units were made from railroad cinders and designed to meet the code requirement of 1,000 lbs. per sq. in. This should represent a relatively dense cinder concrete.

8-in. hollow cinder block wall exposed

Conductance "C" (surface to surface)	0.423
	0.415
Transmittance "U" (air to air)	0.340
	0.335

At Penn State College, Prof. F. G. Hechler[17a] conducted tests for National Building Units Corp. Two identical walls were built of the cinder units under test, each 7 units high and 3 units wide. A hot plate was fitted tightly between the two walls which were clamped together. The hot plate was surrounded by a guard ring which was maintained independently at the same temperature as the plate, so that all heat flowing from the plate passed through the two walls. The hot plate was electrically heated and the heat input as well as the temperature was known. Knowing the temperature of the outside surfaces of the walls, the conductance "C" may be computed.

8 x 8 x 16-in. hollow cinder units were tested. The units were made from railroad cinders, mixed 1:7, to pass a strength requirement of 700 lbs. per sq. in. They had two cores, or about 33 per cent air space.

8-in. hollow cinder block wall exposed

Conductance "C" (surface to surface)	0.457

This value was determined at a mean temperature of 62.7 deg. F. As the temperature was increased, the conductance increased. At 79.8 deg. F. it became .489. This must be caused by increased radiation and convection through the hollow space.

It was also found that the conductance was less when the flue formed by the air space of the hollow units was sealed at the top than when it remained open. The convection of the hollow space evidently increased when the flue acted as a chimney.

4 x 8 x 16-in. solid cinder units, representing the same type of cinder concrete, were also tested, laid in walls of the same size.

4-in. solid cinder concrete exposed
Conductance "C" (surface to surface)
Mean temperature 56.3 deg. F.....1.005
Mean temperature 68.8 deg. F.....1.04
Mean temperature 85.3 deg. F.....1.06

The Conductivity "k" per 1 in. thickness of this solid wall may be figured as 4 x 1.00 = 4.00 (4.25 for the highest temperature). This value is higher than that of 3.33 used in A. S. H. V. E. Guide—but it must be remembered that the 4-in. wall contained mortar joints, comprising probably 10 to 15 per cent of the wall area. If we accept the value of 8.3 (generally used) for the conductivity of this mortar, the value of 3.33 for the conductivity of the cinder concrete checks well with the test.

It may not be amiss to point out that considerable confusion prevails in many discussions of heat transmission data. The nomenclature is not uniform, and it is not always made clear to what conditions the coefficients reported belong. It is quite common, for example, to apply data obtained on one small unit to larger wall assemblies of that unit, or to compute the coefficient for a hollow wall on the basis of data for the solid material without taking into account the air space. In the present paper, the writer is adopting the nomenclature of the A. S. H. V. E.

As far as sand-cinder concrete is concerned, Prof. C. L. Norton reports on a 1:2:4 mixture, tested by the hotplate method. Without giving details regarding the make-up of the concrete, Norton states the conductivity as follows:

1:2:4 sand cinder concrete
Conductivity "k" (per 1 in. thickness)
Mean temperature 122 Deg. F.....2.35

On the other hand, the Guide of the A. S. H. V. E. quotes Peebles as follows:

(Sand-) cinder concrete (110 lbs. per cu. ft.).
Conductivity "k" (per 1 in. thickness)
Mean temperature 75 deg. F.....5.20

These two values are far apart. Aside from probable differences in method (the one used by Peebles is not stated), it is possible that the concretes may have been quite different in their make-up. Norton reports the conductivity for 1:2:5 stone concrete to be 6.27, while Peebles reports the value for stone concrete weighing 145 lbs. per cu. ft. as 6.30. Willard, Lichty and Harding report the value for 1:2:4 stone concrete as 8.30 (140 lbs. per cu. ft., mean temperature 110 deg. F.), and this is the value used in the calculations of the A. S. H. V. E. Guide. It would appear that the value reported by Norton is too low for the average product—perhaps the value reported by Peebles is too high. The method employed and the nature of the material must be known in detail if one is to judge the significance of heat transmission coefficients.

The heat flow through a wall depends to a great extent upon the pore structure of the wall material. If the pores are large and open, free passage of air may occur, and the heat transfer is considerable. The writer knows of cinder concrete, molded on a primitive hand press, which was so porous that a 30-mile wind could be felt through an 8-in. wall of the material. This, however, is not the type of concrete here considered. Following the recommendations for grading, mixing and making, here proposed, the resulting concrete will have the porous, cellular particles of cinders embedded in a relatively dense matrix; the cells will contain "dead air," and contribute to the insulative quality of the material.

The addition of sand will affect the pore structure. There are no data available to show to what extent. Such data can only be produced by carefully designing the concrete mixtures and keeping all variables of test under control.

The pore structure of the concrete is of particular importance when fire retardance is concerned. An open-textured cinder concrete will not only permit a rapid transfer of heat, but may also permit the fire to affect the interior of the concrete. When discussing fire resistance, it was pointed out that such a concrete might well justify the opinion which certain authors hold concerning cinder concrete, but such concrete is not common.

Sound Absorption

The problem of reducing sound reverberation in large rooms, and sound transmission through partition walls is involved. Some experimental data are available regarding cinder concrete building units, but these data will not be reviewed here. Reference is made to manufacturer's publication.

The writer has observed, on numerous occasions, the marked sound absorption of cinder concrete, either exposed or painted. In one building particularly where some of the cinder unit walls were painted while others were plastered, the difference in sound reverberation between rooms of different wall finishes was immediately noticeable. The texture of the cinder concrete—open, when compared to that of ordinary plaster—should be of value in improving the acoustics of the room.

The transfer of sound through a material is naturally considerable when the pore structure is such as to permit free passage of air. Plastered partitions of cinder concrete appear to have given a high degree of satisfaction in many jobs like hotels, hospitals or apartment buildings where sound insulation is an important matter. The writer bases this statement on personal observations, rather than on quantitative tests.

There are apparently no data available regarding the behavior of sand-cinder concrete in this respect.

The Material Generally

Cinder concrete, properly made, will receive and hold nails to an extent depending upon the nature of the cinders, the design of mix, the method of making and the age of the concrete. The advantage of nailable concrete is particularly obvious in walls where the direct fastening of furring strips, plastering grounds, and the like, results in marked economies of construction.

Nailability depends upon the nature of the aggregate, cellular anthracite cinders here being preferable to denser, well clinkered bituminous cinders. Such other factors as cement/aggregate proportion, amount of mixing water, degree of compacting of concrete, naturally affect nailability as they affect the pore structure of the material. The fact remains, however, that cinder concrete building units as usually manufactured (proportions 1:7 to 1:10) to meet a 700 lbs. requirement, are readily nailable

at the time when they are usually placed in the wall. Numerous tests have been made on the holding power of such nails, but the tests have not been devised to show the relation of nailability to the other characteristics of cinder concrete. Addition of sand to the aggregate naturally reduces nailability; quantitative data are not available.

Machine-made cinder concrete building units, made from a relatively dry, non-plastic mix, have an interesting surface texture, caused by the roughness of the particles of aggregate and developed through the method of moulding. Unusual architectural effects have been obtained by painting this surface without destroying the texture. The adhesion of plaster, forced into the crevices of the surface, appears to be considerable; demonstrations of the strength of mortar bond have been made, but no accurate test data are available. The surface texture of wet cast, denser sand-cinder concrete is less interesting.

History and Bibliography

It is not within the scope of this paper to deal with the history of the use of cinders in concrete, beyond the incidental mention of certain facts already considered. It is only just, however, to point out two developments which have greatly influenced the status of the material in the United States.

First, as to sand-cinder concrete. The recognition given to this material in the City of New York, through the work of Ira H. Woolson, Rudolph P. Miller, A. L. A. Himmelwright, Harold Perrine and George E. Strehan, is an important factor in its development, often in the face of the strongest opposition. Fifteen years ago, sand-cinder concrete was a very live subject of discussions—for some unknown reason it lost its actuality.

Second, as to cinder concrete building units. The work of F. J. Straub in putting his "cinder block patent" into practical use is to a great extent responsible for the development of a cinder unit industry. It has been the subject of much litigation—and the writer has been careful to avoid, in this report, all controversial issues. These are reserved for other forums than that of the A. C. I. But the writer wishes to acknowledge his debt to F. J. Straub, and his associates in the present industry, who had the vision and the common sense necessary to overcome a multitude of prejudices.

In the following bibliography, the writer has listed only the papers which he considers to be of primarly interest to the student of the subject. So much of the published data are merely repetitions, and a complete bibliography, including every publication in which cinders are mentioned, would fill many pages and would be of little value.

1. Charles L. Norton—*Engineering News*, October 1902; *Engineering News*, January 1904. Tests to determine the corrosion of steel in concrete.

2. R. T. Surtees—"A few tests and experiments with reinforced concrete." *Engineering Record*, December 14, 1907. Tests to determine the corrosion of steel.

3. Richard L. Humphrey—"The strength of reinforced concrete beams." U. S. Geological Survey, Bulletin 344, 1908.

4. R. L. Humphrey and L. H. Losse—"The strength of reinforced concrete beams." U. S. Bureau of Standards, Technologic paper No. 2, 1912. Two papers reporting interesting data on the design of sand-cinder concrete mixtures.

5. D. B. Butler—"The dangers of breeze concrete." The Journal of the Society of Architects, April 22, 1909. Expansional movement.

6. Ira H. Woolson. *Cement Age*, October 1909. Testimony before the New York Building Code Commission, summarizing experience with sand-cinder concrete in fire tests. Numerous reports by Woolson on fire tests involving sand-cinder concrete will be found in various technical journals, but are not listed here.

7. Charles L. Norton—"Some thermal properties of Concrete." Proceedings, National Association of Cement Users, 1911, p. 78. Heat transmission of sand-cinder concrete. Fire resistance discussed.

8. Ira H. Woolson and Rudolph P. Miller—"Fire tests of floors in the United States." Proceedings, International Association for Testing Materials, Paper XXVII, 2nd. section, 1912. Report on a large number of fire tests involving sand-cinder concrete floors of different designs.

9. Guy B. Waite—"Cinder Concrete Floors." Transactions, American Society of Civil Engineers, Vol. LXXVII, p. 1773, 1914. Tests on reinforced sand-cinder concrete floors.

Admixtures And Workability of Concrete

BY G. M. WILLIAMS*

*Two critics who considered this paper on behalf of the Publications committee recommended that to increase its practical value the author should designate the admixtures by name, rather than disguise them with numbers. Professor Williams has graciously responded with the names and they appear in a footnote on the page with Table 1, in which the admixtures are first listed by number. In justice to the author and to producers of admixtures here given the lower ratings, the author's viewpoint, with respect to his contribution, requires emphasis. Professor Williams' brief paper is to be read as a suggestion for a different approach to the study of admixtures and not for the limited data it presents on the relative merits of the admixtures he used in his studies of a method of test. The author writes: "My purpose was to outline a method of test for the rating of admixtures rather than to discuss the merits or demerits of any particular one or group * * * A satisfactory test should be established first * * * Had I intended to compare the admixtures in this manner I would have included several others which have been used commercially, one of them approaching fairly near to No. 6 in efficiency * * * I included a minimum of test data in tabular form to make comparisons easier * * * Strength, porosity and permeability must be taken into account in any final rating of an admixture, but I felt that to discuss these factors at length would only divert attention from the test methods proposed, toward the admixtures themselves. The statement that admixtures tested 'do not appreciably affect strength or permeability when used in the amount or proportions specified by the manufacturer' briefly sums up any discussion which I might make in connection with these factors." Thus while we*

*Professor of Civil Engineering, University of Saskatchewan.

may look forward to further data on admixtures from Professor Williams, his present contribution is aimed at the method of studying their values and not at the relative values obtained from such study.—EDITOR

IN RECENT YEARS the use of admixtures in concrete has greatly increased due to advantages which their use has demonstrated under certain conditions of concrete practice. The advantages advanced for admixtures, by the manufacturers, vary, but in general, improvement in strength, water-tightness and workability is claimed. The effect of admixtures on the first two qualities can be measured by testing procedure already standardized or developed but their effect on workability is not so easily measured owing to different views as to what is meant by workability as well as absence of well established test to measure this property.

By workability, the writer means the ability of a mixture to remain homogeneous and free from segregation during the process of transportation and placement. Workability is a relative condition. A concrete might have satisfactory workability under certain conditions but be unworkable or segregate badly under others. While this definition may not agree with various laboratory definitions of the term workability, it is believed that the statement defines workability from the view point of the practical concrete maker. In practice a segregating or poor working mixture may result, after transportation difficulties have been overcome, in stone pockets, laitance, porosity, excessive permeability and low compressive strength as well as increase the cost of handling and placing if properly attempted. A homogeneous, workable mix will after placement be free from the foregoing visible and hidden defects. The practical worker will refer to such a mix as "workable."

Non-workability or segregation may be due to low mortar content, an excessively wet or soupy mortar, an excess of coarse aggregate or to a combination of these characteristics. Low mortar content may be due to low cement content (lean mix) with an aggregate which may be well balanced with respect to relative quantities of fine and coarse aggregate. The use of

additional mixing water to obtain flowability as well as workability results, in turn, in an excessively wet segregating mortar which flows away from the coarse aggregate or which permits the coarse aggregate to settle out towards the bottom of the container. Fairly rich mixtures of low sand-gravel ratio may also lack a sufficient volume of mortar to carry the volume of coarse aggregate, and the attempt to attain sufficient flowability to give easy placement results in segregation. The flowability of a mass of concrete is due entirely to the mortar content and when this is insufficient in quantity or too wet to adhere properly to the coarse aggregate particles, segregation will result.

A non-segregating homogeneous mix must have a sufficient volume of mortar to float and hold in suspension the coarser aggregate particles. This implies not only a relatively large mortar volume but a sticky plastic mortar which will adhere to and carry along the aggregate particles without segregation when the mass is set in motion.

For concrete made with given materials workability may be improved by increasing the volume of mortar which in turn will permit the use of a less fluid, more adhesive mortar without reducing the flowability of the whole. The addition of any material to the mix which will increase the relative volume of the mortar will therefore improve workability and that material which for a given weight will produce the greatest mortar volume will probably be most efficient providing the other properties of strength and watertightness are not injured.

The writer has tested a number of admixtures, including portland cement itself as an admixture, and believes that the following conclusions with respect to their effect on workability are justified.

1. All admixtures tested, including portland cement as an admixture, increased relative mortar volume, tended to reduce segregation, and showed merit as a means of increasing workability although not to the same degree.

2. The relative efficiency of admixtures in increasing workability (reducing or preventing segregation) is measured by the relative volumes of paste produced when equal weights to admixtures are made into pastes of approximately the same flowabilities.

Six admixtures of Canadian and American manufacture, in-

cluding portland cement were tested. They were all of the practically insoluble, finely divided powder form, and ranged in composition from silica and lime to clay in the form of bentonite. When prepared in neat paste form with water they varied considerably in adhesiveness or stickiness, especially with low water contents, but much of the stickiness was lost when sufficient water was added to bring them to the approximate consistency which they would have as a part of the mortar volume of a workable concrete mixture.

The following results will indicate the test methods employed to furnish the conclusions outlined above.

TABLE 1—RELATIVE VOLUMES OF PASTES OF SAME FLOWABILITY PRODUCED WITH EQUAL WEIGHT OF ADMIXTURES

Admixture*	Relative Amount of Mixing Water Required	Relative Volume of Paste Per 100 Grams of Admixture
1 (cement)	1.0	1.00
2	3.2	1.95
3	3.3	1.95
4	2.4	1.62
5	3.4	2.00
6	13.0	5.70

In Table 1 it is seen that all admixtures were more efficient than cement as measured by volume of paste produced. Four of the admixtures are grouped fairly closely while No. 6 falls in a third group.

Equal weight of admixtures were then added to identical cement-sand mortars and the volume increase due to the presence of the admixture was determined as listed in Table 2.

TABLE 2—RELATIVE VOLUME INCREASE PRODUCED IN IDENTICAL CEMENT-SAND MORTARS TO WHICH EQUAL WEIGHTS OF ADMIXTURES WERE ADDED. ALL MORTARS WERE OF SAME FLOWABILITY AFTER ADMIXTURES WERE ADDED

Admixture*	Relative Volume of Mortar	Relative Increase in Mortar Volume Per 100 Grams Admixture
None (Plain Mortar)	1.000	——
1 (Cement)	1.040	1.0
2	1.045	1.1
3	1.045	1.1
4	1.052	1.3
5	1.060	1.5
6	1.165	4.7

*No. 1 = Canada Portland Cement; No. 2 = Vankelad A; No. 3 = Vankelad B; No. 4 = Barnsdall Admixture; No. 5 = Hydrated Lime; No. 6 = Celite. See Editor's note at beginning of this paper.—EDITOR

Comparing the results in the right hand column of Table 2 with the same column of Table 1 it is apparent that the relative volume increases in these particular mortars were not of the same magnitude as were those found for the relative volumes of neat pastes but the values are somewhat proportional. Apparently some of the paste has gone to fill void space and the rest swells the volume of the mortar.

Tests were then made to measure the actual segregation which occurred in identical concrete mixtures to which were added equal weights of the different admixtures. Flowability, as measured by spread of mortar on the flow table was made constant by the addition of sufficient water in each case. The mortar content of the batch was not excessively wet, but rather sticky and plastic, and segregation was obtained by the use of an excess of ¾ in. to ⅜ in. aggregate. Amount of segregation was measured by weighing the coarse aggregate particles which rolled from the mass beyond the mortar line on the flow table. It was difficult to obtain concordant results in repeated tests of any one batch or in tests of successive batches since it was difficult to select and properly place a fair sample of the batch in the flow table mold, all of the batches segregating to varying degrees. The results shown in Table 3 do indicate much and varying segregation, but do not permit of rating the admixtures, which in the other tests are shown to be of somewhat equal merit.

TABLE 3—PERCENTAGE OF COARSE AGGREGATE SEGREGATED FROM CONCRETE MASS AND PERCENTAGE OF MORTAR IN CONCRETE

Admixture*	Ratio Volume Mortar to Volume of Concrete	Percentage (by weight) of Coarse Aggregate Segregated from Mass
None (Plain Concrete)	.472	13.13
1 (Cement)	.479	11.30
2	.482	9.91
3	.482	10.57
4	.482	9.90
5	.487	9.92
6	.514	4.95

Since it is difficult to handle and sub-divide a segregating concrete the values above in Table 3 should be considered only approximate, but they indicate greatest segregation for the plain concrete, slightly less for cement as an admixture, still less of the group of four admixtures and least for admixture No. 6.

To determine definitely whether or not the value of an admixture in promoting workability is proportional to its relative paste volume concretes similar to those included in Table 3 were prepared, but instead of using equal weights of admixtures the amounts were increased so as to make the paste volumes of admixtures equal. From the results of Table 1 the relative weights of admixtures required were found to be as follows:

Admixture*	Relative Weights of Admixtures to Furnish Equal Volumes of Admixture Paste
1 (Cement)	5.7
2	3.0
3	3.0
4	3 5
5	2.8
6	1.0

TABLE 4—PERCENTAGE OF COARSE AGGREGATE SEGREGATED FROM CONCRETE MASS AND PERCENTAGE OF MORTAR IN CONCRETES

Admixtures Added to Furnish Equal Volumes of Admixture Paste

Admixture*	Relative Weight of Admixture Used	Ratio Volume Mortar to Volume of Concrete	Percentage by Weight of Coarse Aggregate Segregating from Concrete
1 (Cement)	5.7	.517	4.20
2	3.0	.510	4.85
3	3.0	.514	4.95
4	3.5	.514	4.73
5	2.8	.518	5.00
6	1.0	.517	3.98

Results of tests in Table 4 indicate that the additions of admixtures in quantities to produce equal volumes of admixture pastes do furnish concretes of practically equal mortar contents and equal workability as measured by segregation of coarse aggregate.

From the foregoing test results it would appear that the mortar content of a batch, for these particular aggregates, should be well in excess of 50 per cent to insure workability, and for concretes which may be subjected to considerable jarring and shaking during transportation not only a relatively large volume of mortar but in addition a mortar of comparatively low flowability would be required.

While admixtures are relatively more efficient than cement in obtaining a concrete of workability suited to any given condition

of transportation and placement the writer does not suggest that their use is always necessary or advisable. For concrete of any required cement content first attention should be directed to the most desirable sand-gravel ratio. Relative increase in sand content increases mortar volume which in turn permits the use of a less fluid mortar, thereby increasing workability and postponing likelihood of segregation. After adjusting the sand-gravel ratio and finding segregation under the conditions of use, or that the mix is near the segregation limit the use of an admixture will be advantageous. In work where a surface as true as the face of the mold is desired or in any case where the available fine aggregate is coarse and harsh, lacking in fine particles, the use of an admixture may be of value in obtaining satisfactory results.

The factors of strength and watertightness should not be forgotten. Generally these properties cannot be sacrificed to obtain workability. Tests which the writer has made quite definitely indicate that admixtures do not appreciably affect strength or permeability when used in the amounts or proportions specified by the manufacturer. In cases where excess quantities of an admixture are needed to produce satisfactory workability the possibility of reduction in strength and watertightness must receive consideration. On the basis of workability alone, the data in Table 1 would indicate the use of an admixture to be dependent mainly upon the relative cost of cements and admixtures. The use of admixtures 2 to 5 would not be economical unless their cost were less than twice, and No. 6 less than five or six times, the cost of portland cement. Consideration should also be given to the fact that cement not only increases workability as an admixture but at the same time it definitely increases strength and impermeability.

Readers are referred to the JOURNAL *for May 1931, for discussion which may develop. Such discussion should reach the Secretary by April 1, 1931. (Normally the discussion of a paper in the February* JOURNAL *would appear in June but is in this instance scheduled for May to combine it with discussions of "Slump Tests and Flow-Table Determinations"—two papers appearing in the January* JOURNAL, *involving in part a different approach to the same fundamental problem.)*

A Comparison of Continuous With Batch Mixers In Plant Operation*

BY BENJAMIN WILK†

INTRODUCTION

The advantages of a batch mixer as against a continuous mixer have been the subject of considerable discussion among concrete products manufacturers for many years. The batch mixer has generally been favored because of its longer mixing time and the simplicity with which aggregates can be proportioned into the mixer. The continuous mixer has had its advocates because of the greater amount of concrete that could be mixed per day per dollar of investment.

Until recent years continuous mixers were built generally with short mixing troughs, many of them not over three feet long and with uncertain feeding devices. Mixing time was therefore very short, frequently less than one-half minute. This type of continuous mixer has not been very widely used. Improvements in design, however, during recent years. have developed continuous mixers with more accurate feeding devices and longer mixing troughs.

To determine the comparative value of the improved continuous mixers as against batch mixers a series of tests was made in the plant of the Standard Building Products Co., Detroit, Mich., in 1929 and 1930. Batch mixers had been used in this plant for several years, but a machine requiring a continuous, large supply of concrete was being installed and the question arose whether to use a continuous mixer of a moderate size, or a very large batch mixer. To obtain a practical comparison a continuous mixer was installed. Tests were carried on under the

*For presentation and discussion at the 27th Annual Convention.

†General Manager, Standard Building Products Co., Detroit.

supervision of the writer, assisted by J. Paul Wilson, engineer of the Concrete Products Association of Detroit.

TEST PROCEDURE

Comparative tests were made over a period of six months at intervals of approximately 30 days commencing in November, 1929, and ending in May, 1930. Each test consisted of two successive batches made in the batch mixer followed by an equivalent amount in the continuous mixer. Control was obtained by measuring aggregates in a one cubic foot box for the batch mixer and by determining the proper setting of feeding devices on the continuous mixer based on the yield in terms of block per sack of cement for the previous day's run.

Each batch consisted of three wheelbarrows of aggregate and one sack of cement. Each wheelbarrow contained exactly three cubic feet of aggregate. Batches were mixed three minutes dry and three minutes wet. This mixing procedure was used for the batch mixer because it was found to have given practically the best results in a series of tests made by the Committee on Plant Operation of the American Concrete Institute, reported in the 1929 Proceedings. The amount of water was just enough to give a water-web mark on the finished product. The mixed concrete dropped directly into a hopper feeding the block machine. The yield from these two batches was 39 block, or an average of 19½-eight in. block per sack of cement.

Aggregate and cement were fed simultaneously through the continuous mixer. Two sacks of cement were put into the cement hopper and a measured flow of aggregate started into the aggregate hopper. The mixer was allowed to run until all of the cement from the two sacks ran out. The aggregate and cement was mixed dry in the mixing trough for a distance of approximately thirty-two inches, or one-third the length of the trough. At this point water was added in just sufficient quantity to give a water-web mark on the finished product. Mixing time in the continuous mixer was determined by dropping color in with the cement and also by small colored pieces of wood. Mixing time was slightly less than one minute. As the mixed concrete dropped off the end of the trough it was shoveled into wheelbarrows and immediately moved to the hopper above the block machine. The

yield from the continuous mixer varied from 38 to 43 eight in. block per two sacks of cement, or an average of 20¼ block per sack. The machine in which the block were made was directly below the batch mixer. The block from both mixers were made by an experienced operator in the usual plant practice. They were placed on two racks set in the curing room, one behind the other, so that all the block had the same curing conditions.

AGGREGATE

The aggregate used was washed sand and pebbles so combined as to produce a fineness modulus of 3.4. Sieve analyses of the combined aggregate made at intervals, checked very closely with the calculated finess modulus.

DESCRIPTION OF MIXERS

The continuous mixer was an Eberling driven by a 5 h. p. motor. The cement hopper had a capacity of slightly more than two sacks of cement, and the divided hopper for the aggregate held slightly more than four cubic feet. A chute ran directly from an overhead bin to the aggregate hopper, so that there was a continuous flow of aggregate into the hopper. The feeding belts under the hoppers were 18 in. wide. The roller under the cement hopper was shaped as an octagon. This caused a slight movement of the belt as it passed under the cement hopper and thereby eliminated any arching that might have developed. The mixing trough was semi-circular with a diameter of 20 in. and an overall length including dry and wet mixing of 9 ft. There were 34 double blades, each one approximately 17 in. long, revolving at a speed of 35 r. p. m., mounted on a 3-in. shaft. Theoretically each particle of concrete was pushed ahead and therefore mixed 68 times in traveling through the mixing trough. The volume of concrete mixed per minute was approximately 4 cu. ft.

The batch mixer was a standard oversize 9 cu. ft. Blystone side dumping mixer equipped with six blades. A 15-gal. water tank directly above the mixer was used to control the amount of water added per batch.

CURING AND TESTING OF BLOCK

The block were cured for twenty-four hours in steam at a temperature of approximately 90 deg., and then cured in air

until 72 hours before time of testing. They were then delivered to the laboratory of the Concrete Products Association of Detroit, and stored inside at room temperature for the remaining 72 hours before they were broken. Test results are shown in the following table. "C" results are from the continuous mixer, "B" results from the batch mixer.

SEVEN DAY TESTS

Series No.	C-1	B-1	C-2	B-2	C-3	B-3	C-4	B-4	C-5	B-5
Yield Per 2 Sacks	38	40	42	39	40	39	43	39	41	39
	770	690	680	740	560	580	740	820	560	660
	830	730	640	770	530	580	710	790	610	640
	820	710	610	700	550	600	690	790	630	580
	807	710	643	736	547	587	713	800	600	627

FOURTEEN DAY TESTS

Series No.	C-1	B-1	C-2	B-2	C-3	B-3	C-4	B-4	C-5	B-5
Yield Per 2 Sacks	38	40	42	39	40	39	43	39	41	39
	980	1060	840	1010	780	750	510	910	750	600
	1060	770	840	1000	810	790	530	930	630	620
	1020	915	840	1005	795	770	520	920	690	610

The following table shows comparisons after results were computed on the basis of 39 block per two sacks.

SEVEN DAY TESTS			FOURTEEN DAY TESTS		
Series No.	Yield 2 Sacks	Av. of 3 Block	Series No.	Yield 2 Sacks	Av. of 2 Block
C-1	39	780	C-1	39	990
B-1	39	740	B-1	39	940
C-2	39	690	C-2	39	910
B-2	39	740	B-2	39	1000
C-3	39	560	C-3	39	810
B-3	39	590	B-3	39	770
C-4	39	790	C-4	39	570
B-4	39	800	B-4	39	920
C-5	39	630	C-5	39	730
B-5	39	630	B-5	39	610

The grand average for the seven day block from the continuous mixer is 690 lb., from the batch mixer 700 lbs. The grand average for the fourteen day block from the continuous mixer (including

the unusually low figure of 574 lb. in Series 4) is 802 lbs., and from the batch mixer 848 lbs.

The final testing was at fourteen days because in the Detroit market it is desirable to be able to deliver block on the job at the end of fourteen days which have a strength above the 700 lbs. requirement.

CONCLUSION

The test results indicate that the variation between the strength of the block made from the continuous mixer of the long trough type and the usual batch mixer is very small, although the time of mixing in the continuous mixer is approximately one minute as against six minutes mixing in the batch mixer. Evidently the concrete in this type of continuous mixer is given a thorough mixing by the large number of paddles and the large number of revolutions per minute.

Readers are referred to the JOURNAL *for June 1931 for discussion which may develop. Such discnssion should reach the Secretary by May 1, 1931.*

Discussion of Report of Committee 201

"Blast Furnace Slag as Concrete Aggregate"*

BY L. W. WALTER†

The completeness of this report, dealing as it does with the processing of slag, its physical and chemical properties and with the properties of slag concrete, entitles it to a rating as probably the best single contribution to concrete literature ever presented on this subject.

This may well be true, as the time was opportune, and the National Slag Association had made available to interested committees engaged in formulating specifications for concrete and concrete aggregates a vast amount of information covering test data and service history of slag and slag concrete. This information, furnished through symposiums issued at regular intervals over the last two years, covers more than 500 pages and represents, as far as I can recall, the most comprehensive collection of data on any single concrete aggregate.

This brings to my mind the very meager published information obtainable on slag and slag concrete when, early in 1914, I attempted a collection of available data preliminary to a survey of concrete structures in which slag had been used as a coarse aggregate. At that time, if you wanted real information about slag and needed it, you had to go into the field and get it. I had previously known of its use by iron and steel companies to the exclusion of other aggregates. I had interviewed their engineers, had observed their methods, and examined the materials used. These included natural, puzzolan, and portland cements, granulated slag as a substitute for sand, and the use of coarse aggregate ranging from bank-run of air-cooled slag to pancake slag.

*Journal A. C. I., October, 1930; *Proceedings*, Vol. 27, p. 183.
†Inspecting Engineer, Erie Railroad Co., Jersey City, N. J.

The pancake slag was sufficiently cooled with a water spray to produce brittleness which would encourage its breaking up when dropped into steel gondola cars. The cars, after loading, were shifted to the concrete mixer and the slag used in cold weather before the initial heat had passed off—in some cases from the blast furnace into the concrete on the same working day.

My survey in 1914 of slag concrete structures was largely but not entirely confined to structures at iron and steel plants in the Cleveland, Youngstown, Pittsburg, Johnstown and Birmingham districts. Several Erie railroad structures in which slag had been used as coarse aggregate were carefully inspected, and conclusions then and since have been of a nature favorable to the continued use of slag. As an indication of my viewpoint after this survey, I quote from my discussion of a paper on "Blast Furnace Slag as an Aggregate in Concrete," presented by W. A. Aiken at the A. S. T. M. convention in June, 1914 (A. S. T. M. Proceed., Vol. XIV):

> I desire, therefore, to present for your consideration two reasons why the use of slag as a material in concrete has been so limited, and endeavor thereby to encourage discussion of a subject which must be dealt with in the concrete industry of the future.
>
> 1. Among these reasons must be recognized a lack of confidence in slag as a concrete aggregate, due rather to a limited individual experience with its use and to a very limited publication of data by those who have used it, than to specific objection to it based on personal experience with it, or on a knowledge of its behavior where used by others.
>
> 2. There exists a quite prevalent idea that slag contains elements which may act detrimentally when in combination with cement.
>
> Let us see to what extent these are factors. They are certainly not factors as affecting construction and maintenance of masonry at the large iron and steel plants, where slag has for several years been used to the exclusion of other coarse aggregate in concrete. Here the use of slag was first limited to structures, failure in which would not be vital to the operation of the plants, but confidence once established seems to have begat confidence, and as a result there may be seen at most steel plants, slag concrete in all classes of masonry, including foundations subjected to the pounding of heavy machinery, the stoppage of which, but for an hour, might entail a loss compared with which the first cost of the foundation would be insignificant. I know of no higher compliment that can be paid to slag as a concrete aggregate than its continued use in mill construction by those who have used it most, and who are in position to know it best. This, however, should not be accepted as an argument in favor of its use in concrete for all purposes other than mill construction.

Let us make inquiry as to what is known of slag as a concrete aggregate by those who have not been associated with iron and steel mill construction. Ask of the average man interested in the concrete industry, "What do you know of slag as an aggregate in concrete?" "Have you ever used it?" "What do you think of it?" Then figure on a percentage basis and you will likely conclude that the limited use of slag in concrete for general purposes is due in part to a lack of knowledge as to its behavior where used, and to a suspicion rather than to a knowledge on the part of some that slag as an aggregate will encourage disintegration in concrete.

Each has its bearing on past usage of slag. Each, therefore, will have its influence on future usage until there is sufficient data available to enlighten those interested as to what has been done. In order to allay all fears, these data must be of such a nature as will justify confidence based on both test results and a knowledge of the behavior of slag concrete in service for several years in the various kinds of structures and classes of work.

The revenue to be had from the utilization of slag as a waste by-product, and the desire for a material of economic advantage should stimulate the publication of reliable data concerning the use of slag in concrete, but the commercial feature must not be the predominating factor, as slag must stand on its merits. Its adaptability for use in concrete road construction, in typical highway and railroad structures, and for general building purposes, must be judged from experience with its use, separately in the different classes of work.

* * *

The sum total of all comparative test results which I have been able to collect indicates that concrete in which slag was used compares favorably in strength with that in which either limestone, trap rock, or gravel was used as a coarse aggregate. Based on a careful examination of concrete in actual structure service, I am inclined to the opinion that the failures or partial failures in slag concrete have not been proportionally greater than in concrete in which other materials of accepted good quality have been used.

I have, accordingly, been looking forward with expectancy for a period of fifteen (15) years to the ultimate publication of a report such as the Committee has presented in fulfillment of the need then expressed. In the meantime, I have taken more than a casual interest in current publications of information on slag, and have followed closely the activities in the field of specification development.

The publicity which has been given since 1914 to the use of slag has brought to light many other slag concrete structures in existence at that time. When the Ulmer Building, a reinforced concrete structure in Cleveland, was torn down in 1921 after standing fifteen (15) years, I was privileged along with several other men now members of the Institute to inspect this building

during its demolition. This one instance offered particularly convincing evidence that slag concrete will protect steel against corrosion when the covering is sufficient and the concrete is carefully placed. The inspection of this building is only one of the many observations made which, collectively, afford a background of information that justifies added confidence in the suitability of slag as a concrete aggregate.

Since 1914 my close association with concrete construction on the Erie Railroad and with technical committees has afforded an opportunity to observe the durability of new and old structures of slag concrete in a climatic zone not favorable to exposed concrete structures. I have observed nothing which indicates that any mistake was made in the use of slag.

Although there are no standard tests for durability of concrete aggregates, the sodium sulphate test and the freezing and thawing test are more generally used than any others, and seemingly give promise of ultimate standardization. As brought out on page 194-5, these tests suggest a relatively high degree of durability in slag aggregate, and this is borne out by observation of its behavior in railroad ballast, macadam roads and in sewage disposal beds. These observations, in addition to those made of its behavior in concrete, lend added confidence in its durability.

Information on methods adopted for better quality control in the processing of slag has from time to time been furnished by representatives of the producing interests who have been assigned to memberships on various committees, and slag is now commercially available which is well-graded, free from foreign materials, and handled in the loading by methods calculated to minimize segregation.

In recent years, the trend in concrete practice has been toward higher sanded mixes than were common under the old-time arbitrary proportions. More consideration has been given to the bulking of moist sand, and compensation has been made for it in measuring the sand in volumetric field mixes. The adoption of the water-cement ratio principle and the broader experience with the design of concrete mixes have led to the use of higher sanded mixtures in the interest of better workability, and these have been justified by test results. The subject matter on pages 214-

15, calculated to justify the use of higher sanded mixes, is in my opinion sound. This trend has been decidedly favorable to the extended use of slag aggregate, since it overcomes in a large measure the former objections to the harshness of slag concrete in undersanded mixes. Examination of structures exposed over a long period in freezing climates indicates that outstanding examples of excellent performance are associated generally with highly sanded mixtures.

In conclusion, the fact that the technical committees of practically all the national organizations interested in construction materials have approved slag as a concrete aggregate in their specifications and reports is the one best assurance to the engineering profession that slag is a suitable coarse aggregate for use in concrete and reinforced concrete.

BY P. J. FREEMAN.*

This report should receive more than the casual approval of the American Concrete Institute for the manner in which the Committee has handled its work, the completeness of the review and the method of clearing its findings to all other committees in this and similar organizations.

Blast furnace slag as a commercial commodity has been considered one of the newer ingredients in mass concrete and reinforced concrete construction in perhaps the larger portion of the United States. Its "newness" after one investigates briefly is not that at all. There are examples of concrete construction almost as old as the art of concrete making itself in which blast furnace slag was the large aggregate. The material is handicapped only by being produced and used in a relatively restricted territory and by not being advertised on a comprehensive national scale.

It is the newcomer in slag territory that is confused. To him it is a new material and something to be approached with caution and surrounded by many specification limitations and in general closely watched.

Some fifteen years ago my attention was focused on slag as an aggregate in concrete when I assumed charge of a test program

*Chief Engineer, Bureau of Tests and Specifications, Allagheny Co., Pittsburgh, Pa.

that extended over ten years. In that interval, and during the last few years, I have become well acquainted with the material. My familiarity with slag, inaugurated in the testing laboratory, has been enhanced by first hand contact with it in the field as a material which we are using in important concrete and reinforced concrete construction and also by close observation of such concrete on many inspection trips taken for various committees in this organization and other technical societies.

In the published presentation of the work of Committee 201 there has been drawn a brief but comprehensive picture of the processing, testing and uses of slag and one which has not been equalled for the more commonly used aggregates for concrete. It is particularly pleasing to note that there is so little of personal belief and opinion expressed in the report. Supporting data sustaining a comprehensive story of the subject assigned to this Committee makes the report a most valuable contribution to the technical literature of concrete construction.

A particular hobby of mine for many years has been to investigate the durability of concrete in every type of structure and in all classes of construction. In this effort to learn as much as possible about conditions affecting the durability of concrete I have seen innumerable structures in which slag was used as the coarse aggregate—probably several hundreds of them in all. Among these have been bridges, factories, warehouses, highways and possibly every example of concrete one can conceive of.

Although I have found slag structures that were not in strictly first class condition—some few of them pretty bad in fact —there has never been brought to my attention an example of troubled concrete that could be attributed directly to failure or disintegration of the slag as an aggregate. Such examples may exist, and if so, I would appreciate having them called to my attention in order that studies may be made in connection with the work of Committee 801, on Durability of Concrete.

Tests conducted under my supervision have shown that specimens of reinforcing steel embedded in samples of slag concrete for five years showed no indication of corrosion, except slight rust spots where air-pockets had formed next to the steel. This condition was common to all aggregates, gravel, traprock, granite, limestone and dolomite.

For many years I have claimed that durability should be the predominating factor in concrete construction and that the selection of both fine and coarse aggregates should be based on their ability to resist the forces tending to break down or disrupt the mass.

There has been brought to my attention a digest of something over four hundred specifications covering the uses of slag. Painstaking effort has been put forth to assemble in tabular form all of the words used in these requirements. In reading these data I was greatly interested to note that of all the words used the one which occurred most frequently was "durable." A total of 267 engineers, or groups of engineers, had imposed this requirement in their specifications.

I have seen a lot of rather severe limitations originally imposed on the material dissipated in the face of developed facts and data supported by service history until now the tendency is towards a specification in name only.

It is not my thought to give blanket approval to this material by name alone. However, when slag is adequately prepared, correctly processed, kept uncontaminated and suitably sized, it makes an excellent aggregate. If any criticism is to be made of the report of Committee 201 it is that the members who presented it did not make definite recommendations for specifications. Perhaps there were restrictions imposed on them and they might have exceeded the authority vested in the Committee, and I feel that the members should be congratulated on the scope and comprehensiveness of their work.

Discussion of Paper by Arthur Ruettgers and A. A. Whitmore

"Construction of Main Canal Lining on Kittitas Division, Yakima Reclamation Project, Washington"*

BY S. TREVOR DIBBLE†

Although situated in New Zealand at a remote distance from the main activities of the A. C. I. it is with very keen interest that descriptions of your large undertakings are followed by members here.

As that interest grows and such an excellent medium for the exchange of views is afforded by the Journal of the Institute, every member who contributes a paper for discussion by the Institute earns the thanks and gratitude of a large circle of readers who remain inarticulate through diffidence to enter the discussion for the purpose of obtaining information and replies to questions which may not be of general importance.

I wish, then, to risk that reproach and congratulate the authors, Messrs. Arthur Ruettgers and A. A. Whitmore on behalf of the members of this outpost of the Institute, for an excellent description of the efforts and methods to control the construction of this work under discussion, and also for the splendidly selected photographs which illustrate and amplify the article so well.

The authors referred to considerable transverse cracking of the lining, and found that that increased in the sections which were coated with bitumen as a curing method. May I ask whether the large amount of steel in so thin a lining, combined with the richness of the mix, would contribute largely to that defect?

*A. C. I. Journal, October. 1930, *Proceedings*, Vol. 27, p. 117.
†Registered Surveyor, Karori, Wellington, New Zealand.

It seems to me, notwithstanding that several panels collapsed through hydrostatic pressure from the back, that an adequate method of porous and tile drainage could have been provided, and the reinforcement dispensed with entirely.

With regard to transverse cracks generally in thin slabs it is, in my opinion, during the early curing periods when most of the mischief is done, and although the sprinkler idea is new to me and appears to be an excellent provision for curing in this case I would suggest that beneficial results could easily be obtained by using the burlap covering as a shade over the whole canal being concreted for fourteen days after concreting and allow the sprinklers to operate as well.

The authors drew attention to the benefits of operating two separate units on either side of the canal simultaneously for lining the sides, claiming that the spirit of competition between the gangs increased production. May I ask whether any of the bonus or differential piece rate systems for payment of labor were employed, by the contractors and if so, what were they? And were there any outstanding results noticeable from it that would be worthy of the authors' comment? Further did the tenderers for this work who appear to have competed keenly, fully understand that rigid control of quality of concrete and method of production would be literally enforced, and if so did it affect the tendering?

I should also like to know whether the rigid enforcement of quality control could always be safely entrusted to the usual job inspector, or had these men to be specially selected for their ability to accommodate their views to the new horizons in concrete work?

I may say I have found it difficult to obtain inspectors who have the necessary practical experience and knowledge of men, together with an aptitude for the learning and application of the new methods of quality control and that many petty deceptions are practiced which are hard to detect and result in false reports.

No doubt these are growing pains we feel here which your older practice of quality control will have outgrown, and I trust the authors may be able to give me an answer which will serve to guide my feet from pitfalls in the path.

AUTHORS' CLOSURE

The comments of Mr. Dibble are gratefully acknowledged by the authors, and are especially appreciated as they radiate a common interest from so distant a center of engineering activity as New Zealand.

In commenting on the transverse cracking between panel joints of the 3-in. concrete lining, Mr. Dibble asks "whether the large amount of steel in so thin a lining, combined with the richness of the mix, would contribute largely to that defect."

The authors have made a further study of the transverse cracking since their original paper was prepared and have arrived at the conclusion that the extent of such cracking can be attributed primarily to the action of the longitudinal reinforcing steel and friction of the subgrade in resisting the contraction of the concrete under falling temperatures and gradual air drying, rather than to any material fault in the fabrication, placing, or curing methods employed. One argument in favor of this conclusion is that the cracks developed progressively. On the south or shaded side slope of the lining, from 20 to 30 per cent of the cracks made their appearance during the first three weeks and the remainder during the following three weeks, while on the north or sunny slope about 60 per cent of the cracks developed during the first 3 weeks' period. Furthermore, lining placed in September was found to have approximately the same number of transverse cracks after six weeks had elapsed as lining placed in the middle of the summer when the maximum atmospheric temperatures were much higher but the daily range was nearly the same. The only evidence of crazing, indicating rapid surface drying of the green concrete, was found in several panels of Hunt-processed lining placed on July 25 when the temperature mounted to 107 deg. F. It does not appear that the richness of the mix used (if a 1:2.4:3.6 dry rodded mix may be classified as rich) has any particular bearing on the development of the transverse cracks if it be assumed, as seems reasonable, that the tensile strength of the concrete and the bond between concrete and reinforcing steel develop proportionally. If the friction of the subgrade, being a relatively minor factor, is disregarded and it is assumed that the average unit bond strength is equal to the unit

tensile strength of the concrete, it may be argued that the ultimate spacing of transverse cracks will be twice the length of steel required to develop a bond equal to the tensile strength of the concrete, or

$$L = 2\left(\frac{A}{\pi d}\right) = 2\left(\frac{\pi d^2}{4p} \times \frac{1}{\pi d}\right)$$

$$\text{or } L = \frac{d}{2p} \qquad (1)$$

in which L = ultimate spacing of cracks, A = cross-sectional area of concrete, d = diameter (or width) of bar, and p = percentage of steel.

For $d = \frac{3}{8}$ in. and $p = .31$ per cent, the values applying to the lining, we have $L = .375/.0062 = 60$ in. or 5 ft. This spacing is in reasonable accord with the average 8-ft. and 6-ft. crack spacings found in the water-cured and Hunt-processed linings respectively, especially when it is considered that additional cracks probably developed subsequent to the time the survey was made, due to increased drying shrinkage and temperature drop.

Inasmuch as equation (1) is obviously predicated on the reinforcing steel remaining intact, it becomes necessary, in investigating the possibility of restricting the cracks to the construction joints at 14 ft. intervals, to consider the question of stresses in the steel.

Assume that the steel takes its own temperature stress in addition to the stress transferred by the concrete after cracking. Then

$$f_s = f_c\,(n + 1/P)$$

in which f_s = unit tensile stress in steel, f_c = unit tensile stress in concrete, n = ratio of moduli of elasticity of steel to concrete, and P = percentage of steel.

Assume further that $n = 10$ and that the unit tensile stress in the steel, of hard grade, should not exceed 100,000 lbs. per sq. in. when the concrete has acquired a unit tensile strength of say 300 lbs. per sq. in. Then

$$100{,}000 = 300\left(10 + \frac{1}{P}\right)$$

$$\textit{and } P = .0031$$

Substituting this value of P in equation (1) we have

$$L = \frac{d}{2\ (.0031)} = 162\ d.$$

If $d = \frac{1}{4}$ in. ($5\frac{1}{4}$ in. spacing), $L = 41$ in. $= 3$ ft.-5 in.
If $d = \frac{3}{8}$ in. (12 in. spacing), $L = 61$ in. $= 5$ ft.-1 in.
If $d = \frac{1}{2}$ in. ($21\frac{1}{4}$ in. spacing), $L = 81$ in. $= 6$ ft.-9 in.

It appears from the foregoing that it is impracticable to design a 3-in. reinforced concrete lining, under the conditions mentioned, to insure an ultimate uniform distribution of transverse cracks at 14 ft. intervals. If steel in the amount of .31 per cent is used, intermediate cracks must be anticipated or the panel length reduced to not over 7 ft. Or if the percentage of steel is reduced to conform to a construction joint spacing greater than 7 ft., ultimate failure of the steel and non-uniform distribution and width of joint openings must be expected.

Mr. Dibble expressed the opinion "that an adequate method of porous and tile drainage could have been provided, and the reinforcement dispensed with entirely." The nature of the country traversed and the variation in soil conditions made the problem of draining the lining one of the most difficult ever encountered by the Bureau of Reclamation and the matter was given very careful attention. With a few minor exceptions the drainage facilities provided appear to have proven adequate and successful to a degree surpassing all expectations.

While the use of plain concrete would undoubtedly have eliminated the intermediate transverse cracks, or at least materially reduced their number, the authors do not look upon omission of the reinforcement with favor, particularly in a region subject to severe frost and unfavorable drainage conditions. The intermediate cracks are not regarded as a serious menace to the integrity of the lining and it is believed that the additional expense for reinforcement (about 10 per cent of the cost of the lining) will prove a judicious investment in providing continuity and increased strength as security against heaving, uneven settlement, undermining, earth or water pressure, flotation, impact from falling rocks, serious washouts, or other conditions which might develop.

With regard to the spirit of competition displayed by the two lining-machine operating crews working simultaneously on both

side slopes of the canal, it may be said that the attitude manifested was apparently spontaneous and not induced by any piecework or bonus system of payment, so far as the authors are aware. The rate of production was held within bounds by the inspector's insistence on proper placement and compacting of the concrete, as well as by the desire of the foreman to avoid reworking and extra finishing.

Although very little trouble was experienced with concrete inspectors, it is the opinion of the authors that rigid enforcement of quality of concrete cannot be safely entrusted to the usual job inspector without apprizing him in all seriousness of the requirements, providing him with the needed implements and information in an understandable and convenient workable form, supplying supervision commensurate with his reactions, and above all instilling an interest and pride in his work. The inspectors were selected from a civil service register of applicants meeting the minimum educational and experience requirements. There were, of course, differences in type and character of the men, but on the whole the inspectors employed proved to be conscientious, trustworthy and efficient. A good many, in fact, developed into enthusiastic control advocates. What few deceptions were practiced were soon detected and obliterated, if necessary by peremptory discharge. It goes almost without saying that wholehearted support and positive backing by the engineer in charge is essential to the complete success of any attempt at rigid concrete control.

In closing, the authors desire to call attention to one feature of the lining not mentioned in Mr. Dibble's discussion but which may be of general interest, because of its practical significance. The original paper stated, in connection with the final adoption of the plain butt type of panel joint, that the use of the edging tool for grooving the top surface of the concrete at the joint was early discontinued upon finding that the groove was not required to insure the development of the crack. Information just received, however, is to the effect that some appreciable spalling has occurred along sharp edges of the cracks and that the edging tool, which provides rounded shoulders, is again being utilized on lining work.

Reinforced Concrete Column Investigation*

Second Progress Report of Committee 105

Committee 105 presented its first progress report at the 1930 convention of the American Concrete Institute in New Orleans. This report was published in the April, 1930 Journal, and is found on pages 601 to 615 of the 1930 *Proceedings*. It contained the program of tests as laid out by the committee, and the results of some of the preliminary investigations on the materials to be used. Since that time, three committee meetings have been held and the investigational work is well under way. In carrying out the tests slight modifications of the program have been found necessary, but in the main the original program has been followed.

At the University of Illinois all the specimens for this program have been made. At Lehigh University all the specimens except the greater portion of those in Series 4 have been made. At both universities many of the specimens have been tested and the work of interpreting the data is under way.

At a meeting of the committee held in December, 1930, at the Bureau of Standards, Washington, D. C., it was decided unanimously, that these participating laboratories, the University of Illinois, and Lehigh University, should be authorized to submit their own progress reports of the tests. Since the tests for Series 1 and 2 had already been completed, it was found advisable to publish the results for these two series in the February Journal of the Institute. These laboratory reports follow the report of the committee. They have been prepared independently by each laboratory, and are intended to present as concisely as possible, the results of the tests to date for future use of the committee and the members of the Institute. These reports do not bind the committee to the expression of any opinion as to their significance.

*For presentation and discussion at the 27th Annual Convention, Milwaukee, Feb. 24-26, 1931.

The work of Series 3 has also been carried far enough to warrant a similar progress report, but it was believed desirable to delay this report slightly in order to include as late data as possible. In conformity with this program it is expected that a further progress report covering Series 3 will be available in preprint at the Milwaukee convention in February.

COMMITTEE 105—REINFORCED CONCRETE COLUMN INVESTIGATION

Readers are referred to the JOURNAL *for March, 1931, for a further progress report, and to the* JOURNAL *for June, 1931, for discussion which may develop. Such discussion should reach the Secretary by May 1, 1931.*

First Progress Report on Column Tests at Lehigh University

BY W. A. SLATER* AND INGE LYSE†

INTRODUCTION

The tentative program and the results of the preliminary tests of the concrete for the reinforced concrete column investigation being carried out under the sponsorship of the American Concrete Institute was published in the Journal for April, 1930[1]. The parts of the report presented herein have been prepared by those having charge of the tests at Lehigh University. The authors accept the responsibility for the statements made. An effort has been made to avoid all generalizations but to present the data as fully as possible at the present time and to point out the important relations indicated in Series 1 and 2.

SERIES 1. STUDY OF END CONDITIONS

1. *Purpose and Program*—The purpose of Series 1 of this investigation was to study the effect of different end conditions on the strength and other properties of the columns, and from the results obtained decide upon the end condition to be used in the remaining series. This series was therefore completed before the others were begun.

The columns included in this series had a diameter of 8 in., an overall length, or shaft length, of 60 in., and were tested at an age of 28 days. All columns contained eight ½-in. square longitudinal reinforcing bars and a $\frac{3}{16}$-in. wire spiral of 1.35-in. pitch. This corresponds to about 4 per cent of longitudinal, and 1.2 per cent of lateral reinforcement. The concrete was designed for a strength of 3500 lb. per sq. in. at 28 days as determined on 6 by 12-in. cylinders at the time of testing the columns.

*Director, Fritz Engineering Laboratory, Lehigh University. Chairman, Committee 105.
†Assistant Engineer, Portland Cement Association, In immediate charge of column tests at Lehigh University.
[1]*A. C. I. Proc.*, Vol. 26, p. 601.

Series 1 included three types of end condition. In the first type there were no capitals, and the ends of the longitudinal reinforcing bars were flush with the ends of the column. The second type had 14-in. diameter capitals. The third type had dowels and no capitals. Two groups of columns of the third type were tested. One group had 13-in. dowels which lapped over the reinforcing bars for a length of 20 diameters. The other group had 18-in. dowels providing for a 30-diameter lap. There was the same number of dowels as of the longitudinal bars, and both were of the same grade of steel. Two columns were included in each group.

2. *The Concrete*—The concrete used in this series was a 1:2.4:3.6 mix by weight. The cement content was 5.4 sacks per cu. yd. of concrete. The nominal water content was 40.5 gal. per cu. yd. of concrete or 7.5 gal per sack of cement. The concrete was mixed in a kettle-shaped mixer of about 2.5 cu. ft. capacity. The dry materials were mixed for one minute. Water was then added and the mixing was continued for three minutes more. Six 6 by 12-in. cylinders were made with each column, three for test at the age of 28 days, and three for test at 56 days.

Table 1 gives information on the properties of the concrete used in this series.

3. *The Reinforcement*—The longitudinal reinforcing bars were donated by the Bethlehem Steel Company of Bethlehem, Pennsylvania. These were plain bars having an average yield-point stress of 48,000 lb. per sq. in. and an average ultimate strength of 76,850 lb. per sq. in. The test results of five coupons taken from five different bars show a good degree of uniformity.

Coupon Number	1	2	3	4	5	Av.
Yield-Point Stress*	47,520	48,800	48,040	47,560	48,120	48,000
Ultimate Stress*	76,680	77,000	76,760	76,800	77,000	76,850

*Stresses given in pounds per square inch.

The lateral reinforcement was donated by the American Steel and Wire Company of Chicago, Illinois, and fabricated into spirals by the American System of Reinforcing. It consisted of $\frac{3}{16}$-in. wire spirals having a pitch of 1.35 in. A definite yield point could not be detected for the spiral reinforcement. Therefore only ultimate strength was obtained.

Coupon Number	1	2	3	4	5	6	7	8	Av.
Strength lb. lb. per sq. No in.	Test	89,340	83,570	85,730	83,930	83,570	87,170	77,450	84,390

It will be noted that the lateral reinforcement was less uniform but about 10 per cent higher in average strength than the longitudinal reinforcement.

4. *Fabrication of Reinforcement*—All the reinforcement for each column was assembled into a unit before being placed in the mold. Four of the longitudinal bars had six ½-in. steel cubes welded to the side so as to form a continuous row of five 10-in. gage lengths. The end cubes were placed five inches from the ends of the column or ends of the shaft.

The spirals had three spacers which were placed approximately 120 degrees apart. Eight longitudinal bars were fastened with wires to the inside periphery of the spirals approximately 45 degrees apart.

5. *Making Columns*—In Group 1 the longitudinal bars were flush with the ends of the column. This provided for transferring the load from the machine directly upon both the concrete and the steel. In making all columns, the concrete was filled to the top of the molds. A settlement of about $\frac{1}{16}$-in. took place during the setting, due to the consolidation of the mass. Neat cement paste having a water-cement ratio of 0.3 by weight, re-mixed

*Broken Cap

FIG. 1—MAKING COLUMNS HAVING CAPITALS

FIG. 2—MAKING COLUMNS HAVING DOWELS

at four hours, was used as capping material. Planed steel plates used for the capping were worked down upon the ends of the longitudinal bars, bringing them flush with the surface of the concrete. The caps were usually about $\frac{1}{16}$-in. thick.

The columns of Group 2 had a capital at each end. The shaft had the dimensions of the plain columns. The capitals were 18 in. long and 14 in. in diameter. The longitudinal bars extended a distance of 30 diameters, or 15 in. into the capital. The spiral extended six inches into the capital. Wire hoops were placed in each capital to prevent its falling apart in case of splitting during the testing. The form used for making the columns of Group 2 is shown in Fig. 1.

The columns of Group 3 had dowels of such a length as to form a 20-diameter splice. The longitudinal reinforcing bars extended to within three inches of each end, and the dowels were flush with the ends. Group 4 was of the same type as Group 3 except

that a 30-diameter splice was used. Screws which passed through the end plates and into the ends of the dowels, held the dowels flush with the surface of the concrete and kept them in position during the placing. Fig. 2 shows the placing of the top plate on a column having dowels. The mold was filled to the top and the dowels were then forced into the concrete until the plate rested on the top of the mold. At the time of capping, the screws were removed and the end plate lifted. The capping was done in the ordinary manner.

In making the columns, the concrete was placed continuously and was rodded into place with ½-in. steel rods. The mold was tapped with a hammer in order to consolidate the mass. At the age of 24 hours the molds were removed, and a ¼-in. diameter by ½-in. steel plug was set in the concrete with neat cement paste beside each lug on the longitudinal bar. The columns were then given three coats of linseed oil and placed in the moist room. One day before testing, each column was removed from the moist room and gage holes drilled in all the plugs and lugs. Five continuous 10-in. gage lengths were thus obtained on both the steel and the concrete on elements 90 degrees apart, around the column. Elements 1 and 3 were at opposite ends of one diameter, and 2 and 4 at opposite ends of the other.

6. *Testing*—The columns were cured in the moist room until they reached an age of 28 days, and then were tested to failure in an 800,000-lb. vertical screw testing machine. For the columns without capitals, an eight-inch spherical bearing block was placed between the head of the machine and the top of the column. The columns with capitals required a larger spherical bearing block and a 17-in. block was used. It was so heavy that it was placed at the bottom instead of the top. The column was plumbed by means of plumb bobs.

Before each column with plain ends was loaded, a complete set of strain-gage readings was taken. For the columns with capitals, a load of 200 lb. was applied before the initial readings were taken. With the spherical bearing block at the base of the column, this load was necessary to hold the column in line.

FIG. 3—COLUMN A OF GROUP 1 AFTER TEST

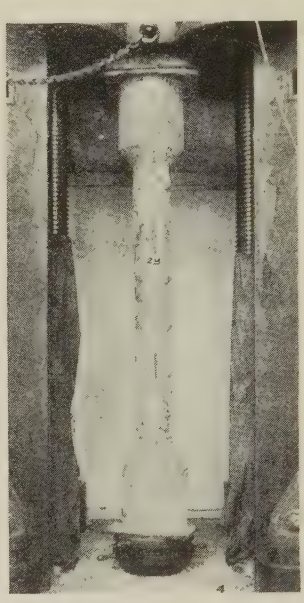

FIG. 4—COLUMN B OF GROUP 2 AFTER TEST

Five 10-in. gage lengths were observed on four rows of lugs on the steel bars with corresponding readings on the plugs in the concrete. This makes a total of 20 gage lengths on the steel, and 20 in the concrete. Each gage length was observed twice, so that 80 observations were made for each set of readings.

The testing crew consisted of two observers and a recorder. The observers took readings on opposite ends of the same diameter simultaneously. The order used in taking the measurements was as follows: Readings were taken from top to bottom on the steel in rows 1 and 3, and then from bottom to top on the concrete. The same order was used for readings on rows 2 and 4. A second set of readings was taken in a similar manner. Ordinarily the maximum variation between the readings of the two sets was 0.0002 in. as read on the dial of the Whittemore strain gage used. If a larger variation occurred a check reading was taken.

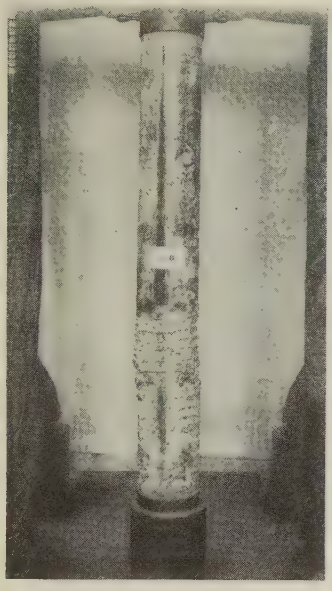

FIG. 5—COLUMN B OF GROUP 3 AFTER TEST

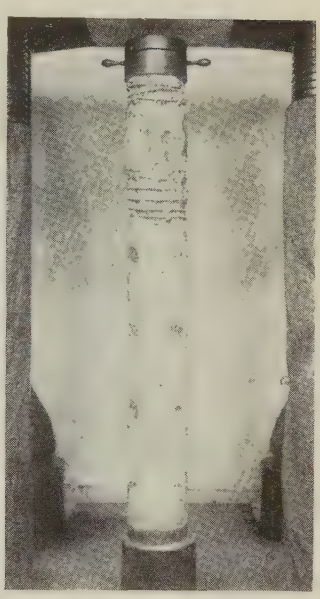

FIG. 6—COLUMN A OF GROUP 4 AFTER TEST

The load was applied in increments of approximately 25,000 lb. A complete set of observations was made for each load. The beam of the machine was rebalanced after the observations so that the load, both at beginning and end of observations, was recorded. This procedure was followed until the deformations went beyond the range of the strain gage on some of the gage lengths.

The time required for each loading, that is, from one application of the load to the next, varied. After some experience, the time for each set of observations ranged from seven to eight minutes.

7. *Strength of Columns*—All columns had 4 per cent of longitudinal reinforcement and 1.2 per cent of spiral reinforcement. The concrete was of the same mix and water-cement ratio throughout the series. Due to minor variations, however, slight differences in strengths were obtained. The test results of the control cylinders are given in section 2. The major difference in

FIG. 7—DETAILS OF FAILURE OF COLUMNS HAVING DOWELS

strength of the columns is, therefore, attributed to the end condition. Table 2 gives the maximum strengths of the columns having different end conditions. Figs. 3 to 7 inclusive, show the types of failure for the groups. The columns of Group 1, shown in Fig. 3, failed near the center. The columns with capitals, shown in Fig. 4, failed about ten inches below the capital. The columns with dowels failed at the ends of the dowels, either at the top or bottom of the column, as illustrated in Figs. 5 and 6. Fig. 7 shows the details of the failure of columns having dowels. After removal of the load a gap was generally found between the end of the reinforcing bar or dowel and the concrete. This is illustrated in Fig. 7. At the ends of the columns also the bars had been pulled back into the concrete slightly. This was true in the columns with continuous bars as well as in those with dowels. It appears that for some reason the concrete elongated more than did the bars on removal of the load. The cause of this phenomenon has not been explained, but it may have been

TABLE 2—STRENGTH OF COLUMNS AND THEIR CONTROL CYLINDERS

Group No.	Maximum Load, lb.			Strength of Control Cylinders lb. per sq. in.		
	Col. A	Col. B	Av.	Col. A	Col. B	Av.
1	252,800	265,000	258,900	2,920	3,350	3,140
2	260,000	251,000	255,500	3,170	3,420	3,300
3	218,600	245,400	232,000	3,510	3,510	3,510
4	231,000	231,000	231,000	3,120	3,340	3,230

due partly to the buckling of the bars as shown in Fig 3 and partly to the assistance of the spiral reinforcement in maintaining the integrity of the concrete.

In order to make a comparative study of the effect of the end condition on the strength of the columns, the variation in the strength of the concrete must be taken into account.

It is shown in Series 2 that the load carried by the plain columns was very nearly 85 per cent of the strength of the control cylinders regardless of the strength of the concrete. Assuming that the concrete in the core of a spirally reinforced column will carry the same amount of load as in a plain column, the remaining load may be attributed to the presence of the steel, both spiral and longitudinal. In computing the load carried by the concrete the area used in the core area specified by the American Concrete Institute Building Code, that is, "the area within the outer circumference of the spiral hooping." As the outer diameter of the spirals was 7.75 in. and as the sectional area of the longitudinal bars used was 2 sq. in., the net core area of the concrete was:

$$\frac{\pi}{4}(7.75)^2 - 2 = 45.1 \text{ sq. in.}$$

The load attributed to the concrete was then 0.85 x 45.1 f'_c, where f'_c = unit strength of the control cylinders. Table 3 gives the computed division of load between concrete and reinforcement at the time of failure. The values given in this table have been plotted in Fig. 8. The upper line in this figure represents the proportionate total loads, and the lower line represents the proportionate loads attributed to the reinforcement in the different groups. The fact that the curve for load carried by the steel

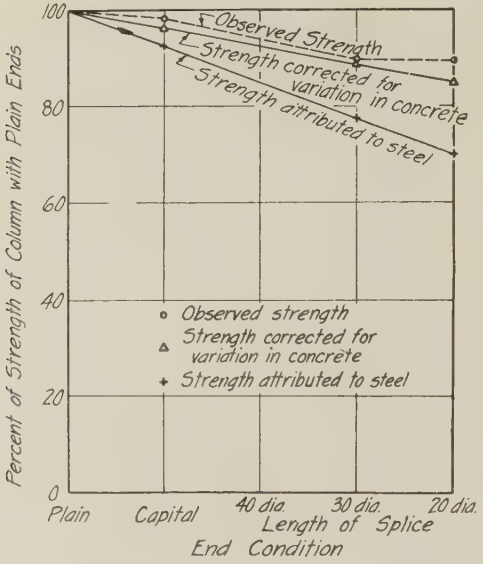

FIG. 8—RELATION BETWEEN END CONDITION OF COLUMN AND STRENGTH

is a straight line is due to a suitable selection of horizontal scale. Fig. 8 indicates that in order to obtain the same effect due to the reinforcement in a column with spliced ends, as in a column with bars flush with the ends, the length of the splice would have to be 60 times the diameter of the bars. The capitals apparently

TABLE 3—DIVISION OF LOAD BETWEEN CONCRETE AND REINFORCEMENT

Group No.	End Condition	Maximum Load		Load Attributed to Concrete	Load Attributed to Steel	
		lb.	per cent	lb.	lb.	per cent
1	Plain	258,900	100	120,500	138,400	100
2	Capital	255,500	98.5	126,800	128,700	93.0
3	(20-dia. splice)	232,000	89.5	135,000	97,000	70.0
4	(30-dia. splice)	231,000	89.2	124,000	107,000	77.4

TABLE 4—COLUMN STRENGTH CORRECTED FOR VARIATION IN CONCRETE STRENGTH

Group No.	Load Attributed to		Total Load	
	Concrete lb.	Steel lb.	lb.	per cent
1	134,500	138,400	272,900	100
2	134,500	128,700	262,200	96.1
3	134,500	97,000	231,500	84.8
4	134,500	107,000	241,500	88.5

gave the equivalent of a splice of 50 diameters.

The load carried by the steel would probably have been no different if the cylinder strength had been exactly 3500 lb. per sq. in. for all groups. Assuming that this is true the strength of the reinforced column for 3500-lb. concrete has been estimated by adding to the load carried by the reinforcement 85 per cent of the assumed cylinder strength of 3500 lb. per sq. in. The computations are shown in Table 4 and the column strengths corrected in this manner are shown in Fig. 8.

Fig. 8 indicates that the columns with the longitudinal steel flush with the ends of the column, developed higher strength than the columns with capitals or spliced reinforcement. The comparative ease of making this type of column makes it less expensive than the columns having dowels and much less expensive than the columns with capitals.

8.—*Deformations*—In order to study the relation between deformations at different elevations, the average deformations for each group of columns have been plotted in Figs. 9 to 12 inclusive.

Fig. 9 shows the average deformations for the columns of Group 1. This figure illustrates that at low loads the uniformity in the elastic properties at different elevations was good. For loads of 100,000 lb. or less, the deformations were practically equal at all elevations of the column. For higher loads, however, the deformations at the center elevation of the column were considerably larger than those at the ends. The most satisfactory explanation of this phenomenon seems to be the possibility of lack of homogeneity of the concrete. At low loads the steel

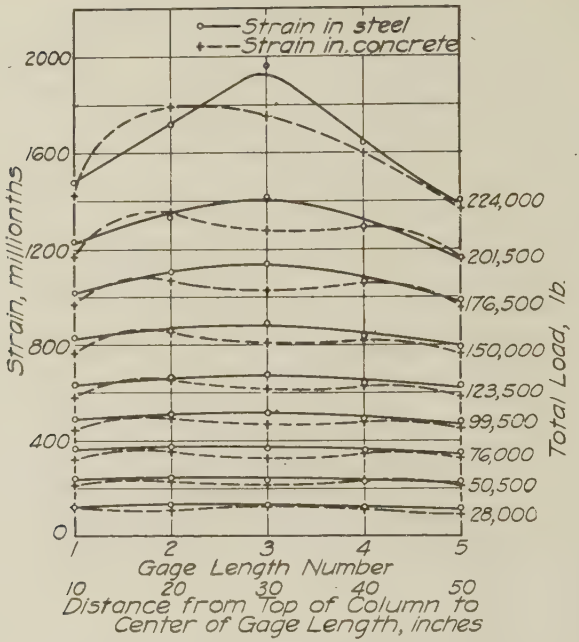

FIG. 9—DEFORMATION AT DIFFERENT ELEVATIONS FOR COLUMNS OF GROUP 1

and the concrete deformed together. At higher loads this equality of deformations continued near the ends, but near the center the deformations in the steel exceeded those in the concrete. The excess of deformation in the steel over that in the concrete increased as the load increased and failure occurred at the center as shown in Fig. 3.

Fig. 10 shows the average deformations of the columns having capitals. It is seen from the figure that the deformation of the steel was nearly equal to that of the concrete for all loads. It is noted, also, that the deformations at different elevations were nearly equal at low load, while for high loads the deformation was much greater at the top than at the bottom.

Fig. 4 shows that the failure occurred near the top of the shaft as would be expected from the behavior described. Slightly

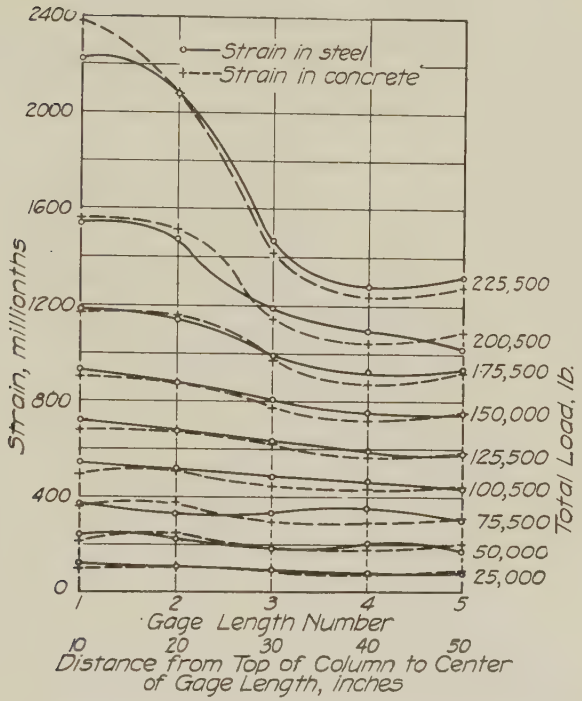

FIG. 10—DEFORMATION AT DIFFERENT ELEVATIONS FOR COLUMNS OF GROUP 2

weaker concrete just below the capital, may have caused the deformations near the top to be larger than those near the bottom. A noticeable eccentricity in the loading (see Fig. 18) probably added to the stresses at the top of the shaft.

Fig. 11 shows the deformations at different elevations for the columns of Group 3. These columns had dowels which provided for a 20-diameter splice. As before, the deformations were nearly equal at different elevations for low loads. In general, the steel and concrete deformed together until a load of about 50 per cent of the maximum strength of the column was reached. At this load the concrete in the bottom section deformed much more than did the steel, indicating that slipping of the bars must have taken place. As the load increased, the slipping between steel and

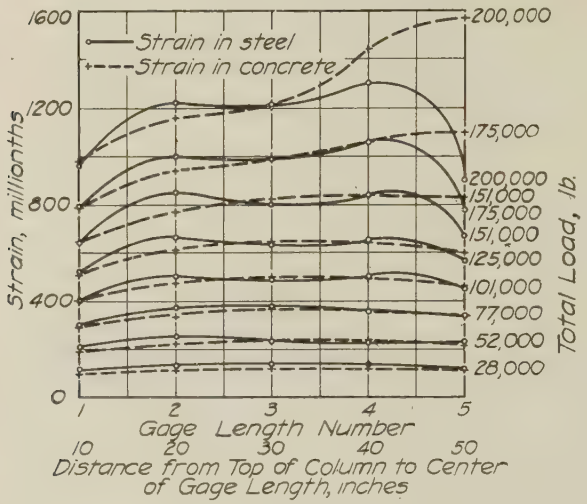

FIG. 11—DEFORMATION AT DIFFERENT ELEVATIONS FOR COLUMNS OF GROUP 3

concrete became more pronounced, and near maximum load it was noted that the concrete had moved away from the lugs on the steel forming a perceptible gap. The concrete spalled at the ends of the dowels and at the ends of the longitudinal bars at practically the same load, indicating that dowels and bars began to slip simultaneously.

Fig. 12 shows the deformations at different elevations for the columns of Group 4. These columns had dowels which lapped over the longitudinal reinforcing bars for a distance of 30 diameters. The figure indicates that the concrete and the steel deformed together throughout the test, for points at the center and below, and also for points above the center, until about 75 per cent of the maximum load had been reached. At this load a slip occurred between steel and concrete near the top of the column, and the deformations of the concrete there became much larger than those of the steel. The concrete deformed very fast while the stress in the steel did not increase materially. The spalling of the columns occurred at the ends of the longitudinal bars and at the ends of the dowels as in Group 3. The failure

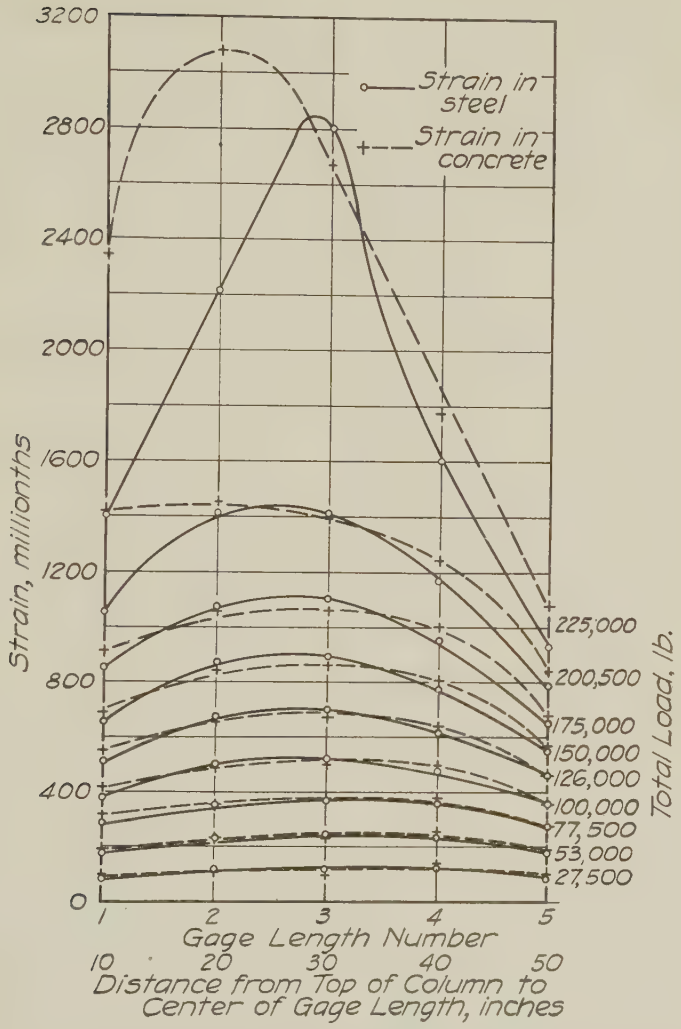

FIG. 12—DEFORMATION AT DIFFERENT ELEVATIONS FOR COLUMNS OF GROUP 4

of these columns was very similar to that of Group 3, except that the columns of Group 4 failed at the top while those of Group 3 failed at the bottom.

For both groups of columns having dowels, the deformations at all loads were smaller near the ends than at the center. This probably was due to the fact that on account of the lapping of the dowels the percentage of steel at the end section was twice the percentage at the center section.

9. *Load Distribution*—In Figs. 13 to 16, inclusive, the average deformations are plotted for the different loads on the columns. In addition, the loads corresponding to the strains in the steel are represented by a broken straight line. This line is carried to a strain of 1600 millionths, corresponding to a yield-point stress of 48,000 lb. per sq. in. within which the modulus of elasticity of the steel was assumed as 30,000,000 lb. per sq. in. No determination of the modulus of elasticity of steel was made in this series of tests. The assumed division of the maximum load carried by the columns is shown on the right-hand side of the diagrams.

Fig. 13 shows the deformation diagram for the columns of Group 1. The assumption has been made that the concrete, the longitudinal steel, and the spiral have jointly contributed to the column strength. The load attributed to the concrete at the maximum load is the product of 85 per cent of the average cylinder strength and the core area of the column, that is, 0.85 x 3140 x 45.1, or 120,500 lb. The load attributed to the longitudinal steel is the product of the yield-point strength and the area of the steel, that is, 48,000 x 2, or 96,000 lb. The sum of the loads attributed to the concrete and to the longitudinal steel (120,500 + 96,000 or 216,500 lb.) has been subtracted from the column strength (258,900 lb.). This difference (258,900 — 216,500 = 42,400 lb.) has been attributed to the spiral.

According to the above assumption, the load attributed to one per cent of longitudinal steel is $\frac{96000,}{4}$ or 24,000 lb. The 1.2 per cent of spiral apparently contributed 42,400 lb., indicating that one per cent of spiral was as effective as 1.47 per

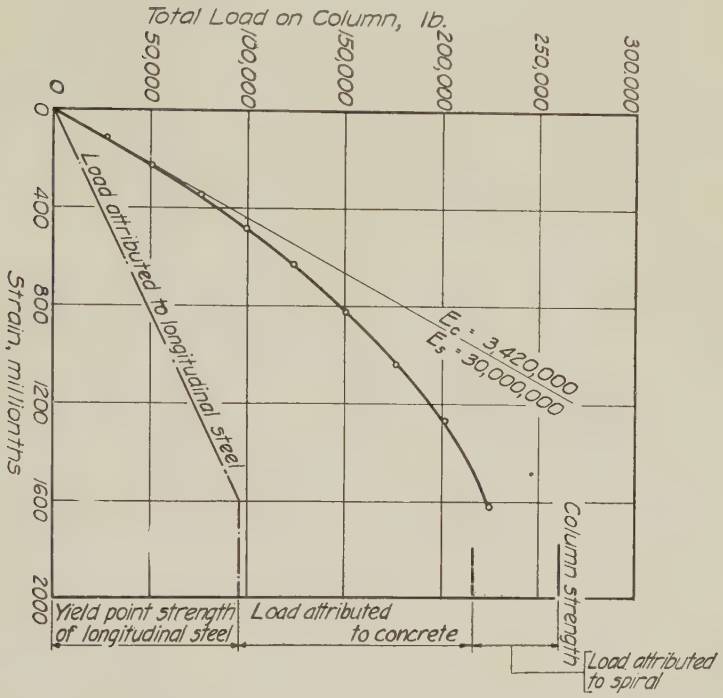

FIG. 13—DEFORMATION DIAGRAM FOR COLUMNS OF GROUP 1

cent of longitudinal reinforcement for the columns of Group 1.

The deformations at top and bottom gage lengths for the columns of Group 2 and the division of load, are shown in Fig. 14. The total load on the column has been distributed between the concrete, the longitudinal steel, and the spiral. It is noted that the load attributed to the 1.2 per cent of spiral is 32,700 lb., or 1.14 times as much as for an equal percentage of longitudinal reinforcement.

Fig. 15 shows the deformation diagram and the division of the load for the columns of Group 3. Here the sum of the yield-point strength of the steel and the load attributed to the concrete is almost equal to the maximum strength of the column. The spiral did not seem to add anything to the strength of the columns,

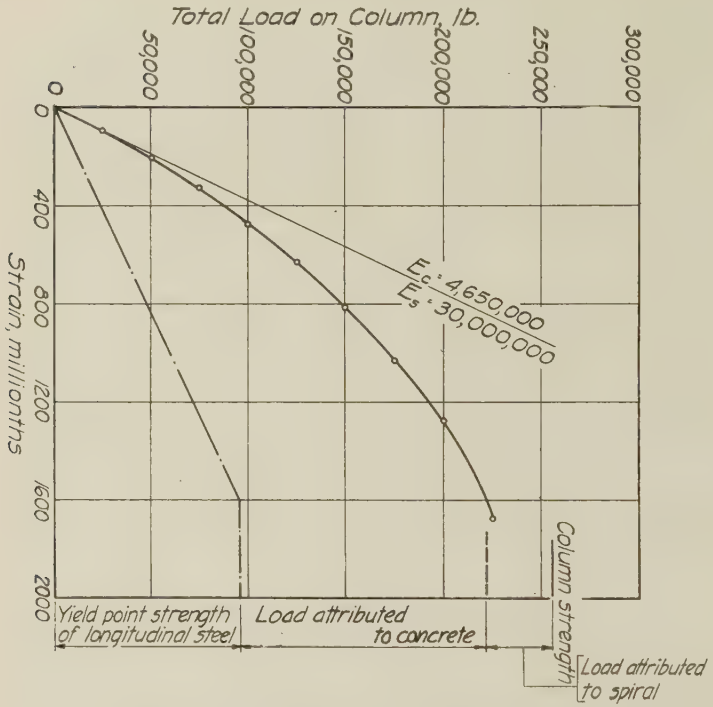

FIG. 14—DEFORMATION DIAGRAM FOR COLUMNS OF GROUP 2

probably because failure was precipitated by the slipping of the dowels before the spirals could come into action.

The deformation diagram and the division of the load for the columns of Group 4 are shown in Fig. 16. In this case the strength of the column was about 11,000 lb. greater than the sum of the yield-point strength of the steel and the load attributed to the concrete. This 11,000 lb. may be attributed to the spiral, but the spiral probably was not fully effective because of slipping of the dowels. It is of interest, however, to point out the fact that the 30-diameter lap was more effective than the 20-diameter lap.

10. *Eccentricity of Loading*—If a plane section remains plane during the loading, the sum of the strains ϵ_1 and ϵ_3 measured at the ends of one diameter, should be equal to the sum of the

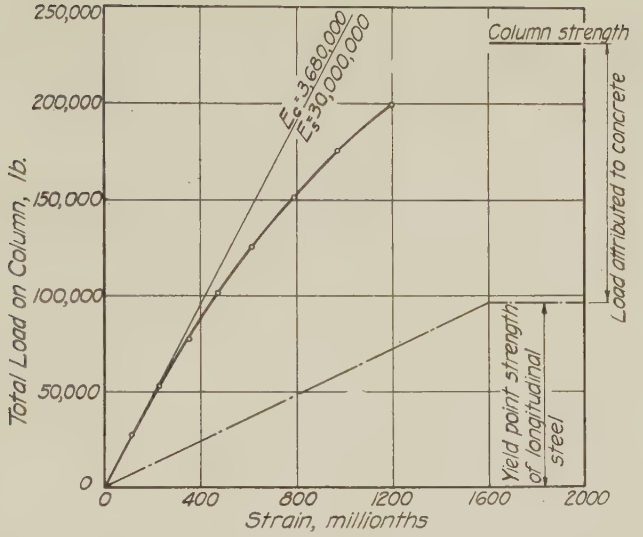

FIG. 15—DEFORMATION DIAGRAM FOR COLUMNS OF GROUP 3

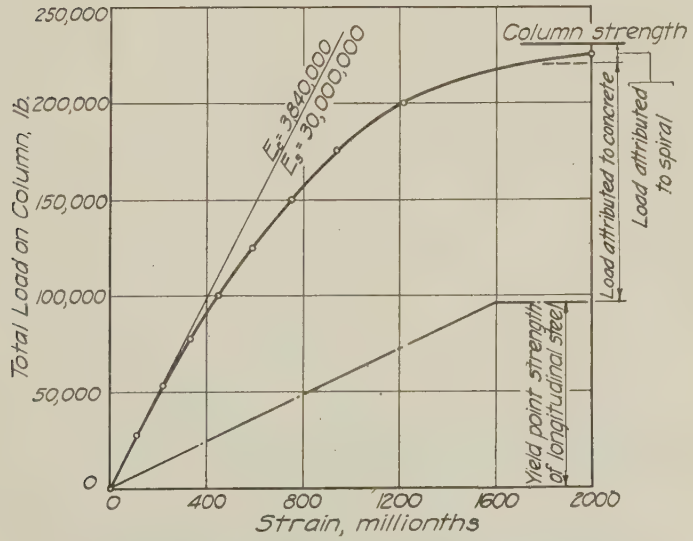

FIG. 16—DEFORMATION DIAGRAM FOR COLUMNS OF GROUP 4

strains ϵ_2 and ϵ_4 at the ends of another diameter. This relation was found to hold approximately true for all the columns. The strain volume is, therefore, a cylinder with ends parallel in the case of centric loading, and non-parallel for eccentric loading. Assuming that the stress is proportional to the strain, this relation may be used to determine the size and shape of the stress cylinder and the distance of the center of pressure from the center of the section, that is, the eccentricity of loading. The center of pressure must pass through the center of gravity of the stress cylinder in order to establish equilibrium.

The following method was used in determining the position of the center of pressure. (See Fig. 17).

The volume of the stress cylinder is:

$$V = \pi r^2 \epsilon E$$

where r = the radius of the cylinder

ϵ = the average strain, that is, $\frac{1}{4}(\epsilon_1 + \epsilon_2 + \epsilon_3 + \epsilon_4)$ and

E = modulus of elasticity

The bending strain, ϵ_b is: $\epsilon_b = r\tan\Theta$, where Θ is the angle between the end planes of the stress cylinder

The bending moment is:

$$M = \frac{\epsilon_b}{c} EI$$

where I = moment of inertia of the cross section

and c = distance from the neutral axis to the point at which ϵ_b is measured

Now

$$I = \frac{\pi r^4}{4} \qquad \text{and } c = r$$

Then

$$M = \frac{r\tan\theta}{r} \; E \frac{\pi r^4}{4} = \frac{\pi r^4}{4} E\tan\theta$$

The distance e from the neutral axis to the center of gravity of the stress cylinder, that is, the eccentricity is:

$$e = \frac{M}{V} = \frac{\frac{\pi r^4}{4} E\tan\theta}{\pi r^2 \quad \epsilon E} = \frac{1}{4} \frac{r^2}{\epsilon} \tan\theta$$

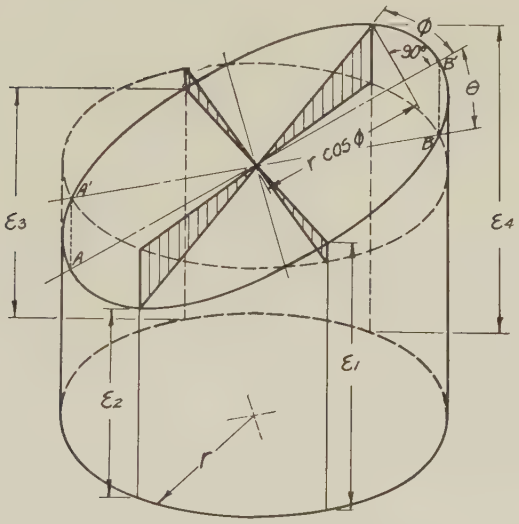

FIG. 17—ILLUSTRATION OF STRAINS USED IN DETERMINING ECCENTRICITY

From the illustration:

$$tan\theta = \frac{\epsilon_4 - \epsilon_2}{2rcos\phi} = \frac{\epsilon_1 - \epsilon_3}{2rsin\phi}$$

where ϕ is the angle between a plane passing through elements 2 and 4 and a vertical plane passing through the line of maximum and minimum stresses. The center of gravity of the stress cylinder will lie in the plane passing through the maximum and minimum strains at a distance, e, from the center line of the cylinder.

The angle ϕ is determined from:

$$\frac{\epsilon_4 - \epsilon_2}{2rcos\phi} = \frac{\epsilon_1 - \epsilon_3}{2rsin\phi}$$

$$\text{or} \quad \frac{2rsin\phi}{2rcos\phi} = \frac{\epsilon_1 - \epsilon_3}{\epsilon_4 - \epsilon_2} = tan\phi$$

$$e = \tfrac{1}{4}\frac{r^2}{\epsilon} tan\phi = \tfrac{1}{4}\frac{r^2}{\epsilon}\frac{\epsilon_4 - \epsilon_2}{2rcos\phi} = \frac{r}{8\epsilon}\frac{\epsilon_4 - \epsilon_2}{cos\phi}$$

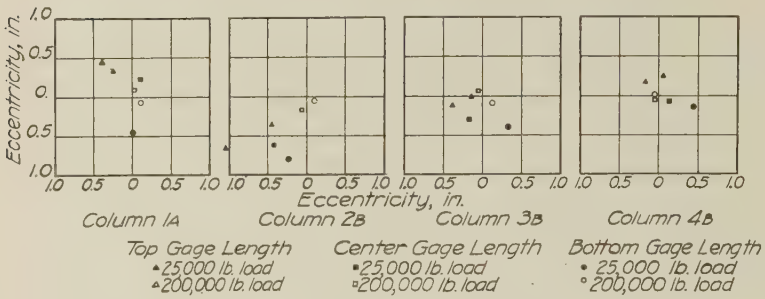

FIG. 18—ECCENTRICITY OF LOAD ON COLUMNS IN SERIES 1

Therefore the eccentricity is given by the formula:

$$tan\phi = \frac{\epsilon_1 - \epsilon_3}{\epsilon_4 - \epsilon_2} \qquad \text{and} \qquad e = \frac{r}{8\epsilon} \frac{\epsilon_4 - \epsilon_2}{cos\phi}$$

Thus the center of pressure may be easily determined from the readings obtained on the four elements 1, 2, 3, and 4. In Fig. 18 the center of pressure is given for top, center, and bottom elevations for loads of 25,000 and 200,000 lb. respectively.

This figure shows that the eccentricity was in all cases considerably less for the load of 200,000 lb. than for 25,000 lb. Also, it was generally less for the center and the bottom than for the top of the column. It may be shown that the ratio of bending stress to total stress is equal to the ratio $\frac{4e,}{r}$ that is, four times the ratio of the eccentricity to the radius of the column. For the columns, without capitals this ratio, $\frac{4e,}{r}$ was always less than $\frac{1}{2}$. For the 200,000-lb. load it was generally much less. For the columns with capitals the ratio, $\frac{4e,}{r}$ was greater than $\frac{1}{2}$ in all cases for the load of 25,000 lb. and at the top it exceeded 1, that is, the bending stress in this case was greater than the average stress, $\frac{P.}{A}$ However, for the load of 200,000 lb. the bending stress had been reduced to about one-half the average stress. For all

the other columns at the load of 200,000 lb. the bending stress was generally less than 20 per cent of the average stress $\frac{P}{A}$. The foregoing analysis has been based upon an assumed constant modulus of elasticity. The fact that in general the modulus is not constant will operate to reduce somewhat the eccentricity and the ratio of bending to average stress.

11. *Summary*—The columns having longitudinal reinforcing bars flush with the concrete at the end of the column (Group 1) appeared to develop the full strength of their component parts and failed near the center without showing local weakness.

The columns with capitals developed high bending stresses and failed near the top.

The columns with dowels showed less strength than did those with continuous bars. Failure occurred at the ends of the bars and at the ends of the dowels.

The superiority of the columns with continuous bars flush with the surface of the concrete and having no capitals, together with the fact that they were the less expensive to make and test, resulted in the adoption of this type of column for the remainder of the investigation.

SERIES 2. EFFECT OF HOLDING THE LOAD FOR FOUR HOURS

12. *Purpose and Program*—The purpose of this series of tests was to ascertain whether the holding of load for a short period such as four hours, would have any effect on the strain and the ultimate strength of the column. There was the added purpose of comparing strengths of columns with three different grades of longitudinal reinforcement, structural, intermediate, and rail steel grades. Variations in percentage of reinforcement, and strength of concrete also were introduced as is indicated in Table 5.

The columns had an outside diameter of 8¼ in., a core diameter of 8 in., and an overall length of 60 in. The longitudinal bars were 60 in. long and the ends were milled, thus insuring direct bearing of both steel and concrete on the end plates. Three like columns were made for each group of plain concrete columns and two like for each group of reinforced concrete columns.

TABLE 5—PROGRAM OF TESTS FOR SERIES 2

Concrete Strength lb. per sq. in.			Reinforcement: Longitudinal Grade	Longitudinal Per cent				Spiral Grade	Spiral Per cent		Method of Loading		No. of Like Columns	Total No. of Columns

													Total	77

13. *Proportioning and Strength of Concrete**—The concrete strength was determined on moist-cured 6 by 12-in. cylinders at an age of 56 days. The concrete designed for a cylinder strength of 2000 lb. per sq. in. was a 1:3.42:5.13 mix by weight of the dry materials. The assumption was made that the amount of water absorbed by the dry aggregates was 0.7 per cent of their weight. The cement content was 4.0 sacks per cu. yd. and the net water content was 39 gal. per cu. yd. of concrete or 9¾ gal. per sack of cement. The test results showed an average cylinder strength of 2280 lb. per sq. in. and an average slump of 2½ in. for all specimens included in this mix.

The concrete designed for a cylinder strength of 3500 lb. per sq. in. was of a 1:2.65:4.00 mix. The cement content was 5.02 sacks per cu. yd. and the net water content 39 gal. per cu. yd. of concrete or 7¾ gal. per sack of cement. The average strength was 3680 lb. per sq. in. and the average slump 3¾ in.

The concrete designed for a cylinder strength of 5000 lb. per sq. in. was a 1:1.98:2.96 mix. The cement content was 6.5 sacks per cu. yd. and the net water content 39 gal. per cu. yd. or 6 gal. per sack of cement. The average strength was 5360 lb. per sq. in., and the slump was 5½ in. It will be noted that the water content was 39 gal. per cu. yd. of concrete for all these mixes. A

*The cement and aggregates used in this series came from the same supplies as those used in the Preliminary Investigation reported in the JOURNAL for April, 1930.

placeable concrete was produced with this water content and only a small variation was noted in the consistency as measured by the slump.

In addition, 11 columns with concrete designed to have a compressive strength of 8000 lb. per sq. in. were made. The mix used for this concrete was 1:½:1 by weight. The cement content was 15.3 sacks per cu. yd. and the water content was 46 gal. per cu. yd., or 3 gal. per sack of cement. This mix was so dry that it could not be properly placed by ordinary methods. It was therefore worked into place by means of an electric vibrator furnished by the Electric Tamper and Equipment Company. The amount of vibration required was quite extreme, and even then small pockets were found in the interior of the cylinders when they were broken. No such pockets were found in the plain columns but no examination was made of the interior of the reinforced columns.

Fig. 19 shows the relation between the strength of the concrete and the water-cement ratio used in the mix. The water-cement strength relation for the plastic mixes was a smooth curve very similar to ordinary water-cement strength curves. The relation between cement content and strength is given by the straight, broken line. In other words, as long as the water content per cu. yd. of concrete was maintained constant with nearly constant consistency of the different mixes, the strength was directly proportional to the cement content.

The strength of the concrete designed for 8000 lb. per sq. in. proved to be only 7000 lb. per sq. in., and it falls below the water-cement strength curve defined by the other mixes. Neither does this strength fall upon the straight line determined by the other mixes when their strengths are plotted against the cement content. This 7000-lb. concrete contained 15.3 sacks of cement per cu. yd. and should have a strength of approximately 12,000 lb. per sq. in. in order to fall upon either of the strength curves shown in Fig. 19.

14. *Modulus of Elasticity of Concrete*—The modulus of elasticity was determined on one control cylinder from each column. The apparatus used consisted of two steel collars, 10 in. apart vertically, attached directly to the cylinders by means

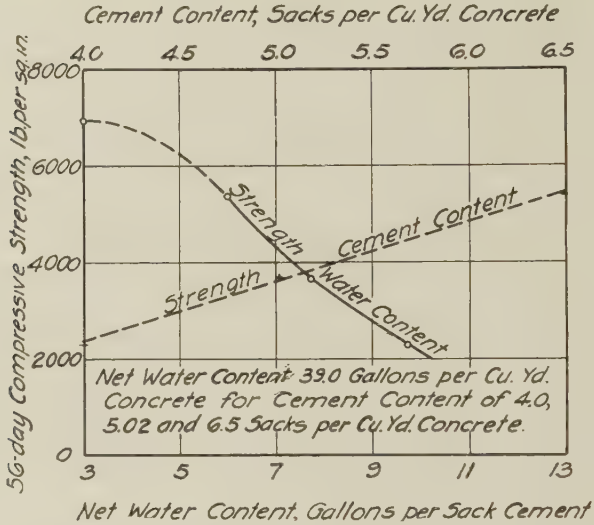

FIG. 19—RELATION BETWEEN STRENGTH AND WATER CONTENT AND BETWEEN STRENGTH AND CEMENT CONTENT FOR CONCRETE IN SERIES 2

of two set-screws 180 deg. apart. Opposite each of the set-screws a 1/10,000-in. Ames gage with its plunger pointing downward was clamped to the upper collar. A steel rod clamped to the lower collar opposite each set-screw extended upward and bore against the plunger of the Ames gage so that a direct reading of the total deformation in 10 in. was obtained. The results thus obtained were averaged for each type of concrete used and these averages are plotted in Fig. 20. The tangent modulus at a stress of 500 lb. per sq. in. was decided upon as the most reasonable value of the modulus of elasticity. In Fig. 21 the moduli of elasticity have been plotted against the strength. For all except the vibrated concrete, the increase in the modulus was very nearly proportional to the increase in strength. Even the value for the vibrated concrete falls not far above the projected straight line determined by the other values.

The results obtained indicate that the method used for deter-

No. 5 (0.207 diam.)	65	Not Determined	82,760

mination of the modulus of elasticity was satisfactory. The simplicity of this method makes it very convenient for determination of modulus of elasticity where greater accuracy is not possible on account of time and expense involved.

15. *Reinforcement*—The longitudinal reinforcement consisted of intermediate, structural, and rail grades of steel bars. The intermediate and structural grades of bars were donated by the Concrete Steel Company of New York, and the rail steel by the Rail Steel Bar Assocation, Chicago. The bars were 22 ft. long when received. At the laboratory they were cut into four 5 ft. lengths and a 2-ft. test coupon. The four 5 ft. lengths were used in the same column. Four ½-in. diameter bars correspond to 1.5 per cent of longitudinal reinforcement, eight ½-in. square bars correspond to 4 per cent, and four ⅝-in. diameter plus four ¾-in. diameter bars correspond to 6 per cent of reinforcement. The coupons from each set of four bars were tested for yield-point stress and ultimate strength. The summary of these tests is given in Table 6. Both yield-point stress and the ultimate strength of the coupons (based upon nominal areas) varied considerably. The variation in weights of bars of the same size indicates that the variation in strength was probably due to the

variation of the cross-section from the nominal size of the bars, rather than differences in quality of the steel.

The yield point and ultimate strength for the structural grade were only slightly lower than those for the intermediate grade steel. The rail steel showed yield point and ultimate strength considerably higher than those for the intermediate grade. The marked influence of this difference will be pointed out later.

The lateral reinforcement consisted of wire spirals. The spiral wire was furnished by the American Steel and Wire Company, Chicago, and fabricated into spirals by the American System of Reinforcing, Chicago. The spirals had an outside diameter of 8 in., and an overall length of 59 in. Three extra turns were provided at each end of the spiral. A No. 5 wire having a 1.35-in. pitch gave 1.2 per cent lateral reinforcement. A test coupon was attached to each spiral. The average tensile strength on these coupons is given in Table 6. It will be noted that the ultimate strength of the No. 5 wire was considerably above that of the intermediate grade longitudinal reinforcement.

The reinforcement for each column was assembled into one unit before being placed in the mold. For the purpose of carrying the strain gage holes, ½-in. steel cubes were welded to four of the longitudinal bars at intervals of 10 in. along their length, thus forming a continuous row of five 10-in. gage lengths on each bar. The end cubes were placed five inches from the ends of the column.

The spirals had three spacers which were placed approximately 120 deg. apart. The longitudinal bars were fastened to the inside periphery of the spiral by means of wires.

16. *Placing and Curing of Concrete*—The mixing was done in a kettle-shaped mixer. The dry materials were mixed for two minutes, the water was then added, and the mixing was continued for four minutes more. One batch of concrete was sufficient for one column and its three control cylinders. For the plastic concrete continuous placing was used in the concreting of the columns. During the placing, the concrete was rodded continuously with a ½-in. steel rod and the mold was tapped with a

hammer in order to consolidate the mass. The concrete to be placed by the vibrator was placed in three equal layers. Each layer was vibrated for about 45 seconds.

About four hours after concreting, the columns were capped with a remixed neat cement paste. At the age of 24 hours the molds were removed, and a steel plug ¼ in. in diameter and ½ in. long was set in the concrete opposite each lug on the longitudinal bars. Neat cement paste was used to embed them in the concrete. The plugs in the concrete and the lugs on the bars were coated with "Cosmic anti-rust preparation," and the columns were placed in the moist room. At the age of seven days the columns were removed from the moist room, holes were drilled in the plugs and lugs, strain gage observation were taken, and the columns were replaced in the moist room to remain until an age of 56 days was reached.

17. *The Testing*—At the age of 56 days the columns were removed from the moist room and placed in the 800,000-lb. screw-power testing machine. The testing crew consisted of two men, an observer and a recorder. Strain gage readings were taken on the entire 40 gage lengths before applying any load and again at each increment of load. About 10 increments were used. The time required for a full set of observations was about seven minutes. With the "fast" loading the weighing beam was re-balanced after completion of each set of readings and a new increment of load was applied immediately.

With the "slow" loading the procedure was similar to that for fast loading up to about 70 per cent of the maximum load. From that time on four hours elapsed between successive increments of load, and readings were taken immediately after completion of one increment and again just before starting of the next one. During the interval between increments the load was kept within about 2000 lb. of that intended. This was done by "bringing up the load" whenever it had fallen off appreciably. The frequency with which the machine had to be operated to maintain the load varied from a few minutes to more than half an hour within any given period between increments. Near the maximum load the frequency with which it was necessary to bring up the load was much greater than for the lower loads. To prevent drying out

during the four-hour period in which the load was held, the column was enclosed in a canvas jacket which was kept moist by sprinkling. All the columns were photographed after completion of the test. A measure of the reliability of the experimental work of this investigation is found in the close agreement of measured strains (1) between the steel and the concrete of the same column, (2) between companion columns of any given group, (3) between

FIG. 22—A PLAIN CONCRETE COLUMN AFTER FAILURE

two groups of the same kind, one of which was used for fast loading and the other for slow loading. This agreement indicates not only good strain gage work but uniformity of making, capping, and curing of the test specimens.

18. *Plain Columns*—The ultimate strengths of the plain columns and of their control cylinders are given in Table 7, also the strengths of the columns stated as a percentage of the strength of the control cylinders. The average strength of the plain columns was approximately 85 per cent of the strength of the cylinders and the uniformity of both the cylinders and the columns was good. The plane of failure generally made an angle of about 30 deg. with the axis of the column as illustrated in Fig. 22. Failure generally occurred within the upper half of

TABLE 7—STRENGTH OF PLAIN CONCRETE COLUMNS UNDER FAST LOADING AND SLOW LOADING

the column, a fact which is consistent with the observation in Series 1, that the eccentricity of loading was largest near the top.

The columns of 8000-lb. concrete failed explosively. Those with 5000-lb. concrete failed less abruptly but almost without warning. The columns of 3500-lb. concrete failed gradually and in some cases it was possible to get them out of the machine whole. The columns with 2000-lb. concrete settled down gradually under the load and were removed from the machine in one piece.

The stress-strain curves for the cylinders and the columns tested with fast loading are given in Fig. 23, 24, 25, and 26, for

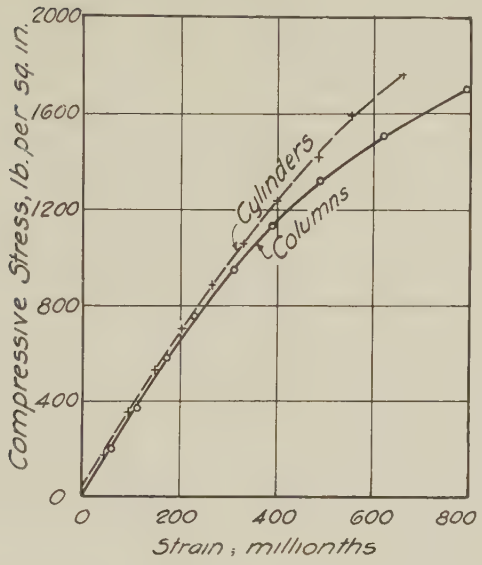

FIG. 23—STRESS-STRAIN DIAGRAM FOR PLAIN COLUMNS AND FOR CONTROL CYLINDERS; DESIGNED CONCRETE STRENGTH 2000 LB. PER SQ. IN.

the four strengths of concrete. Each curve is the average for all the specimens of its kind. The solid lines represent the columns and the dotted lines represent the cylinders. The outstanding features of these figures are the close agreement between the curves for the cylinders and those for the columns within the lower half, and the consistently greater deformation in the columns within the upper half of the curves. Generally the curve for the cylinders lies slightly above that for the columns even at low loads, indicating apparently, that there was some slight delay in getting the strain measuring apparatus used on the cylinders into action.

The modulus of elasticity given by the slope of the stress-strain curves for the columns for a stress of 500 lb. per sq. in. is in close

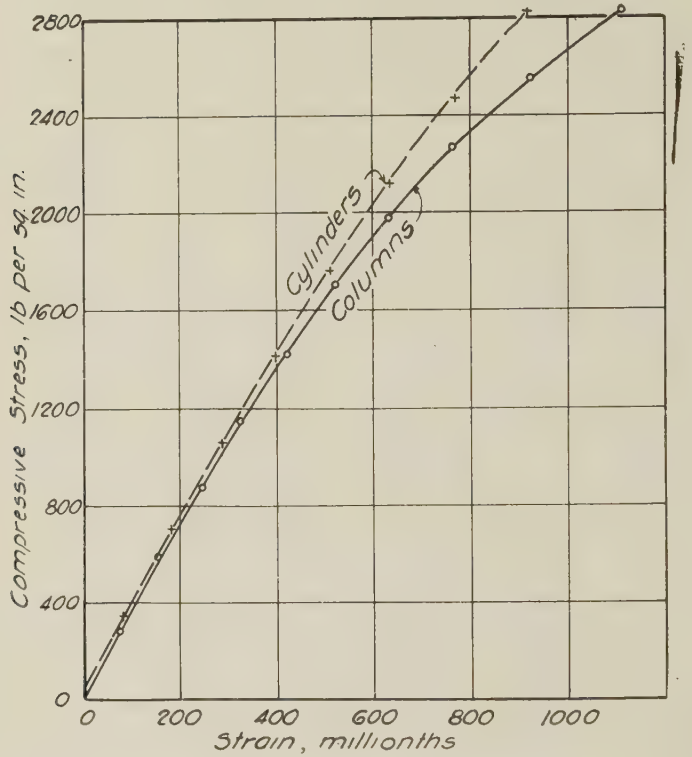

FIG. 24—STRESS-STRAIN DIAGRAM FOR PLAIN COLUMNS AND FOR CONTROL CYLINDERS; DESIGNED CONCRETE STRENGTH 3500 LB. PER SQ. IN.

agreement with that found for the cylinders.

Fig. 27 shows the stress-strain curves for fast and slow loading of columns designed for strengths of 2000, 3500, and 5000 lb. per sq. in. The horizontal portions of the curves represent the deformation which occurred during the four hours under practically constant load. The outstanding feature is the close agreement of those portions of the load strain curves in which the load was applied rapidly.

The horizontal distance between the upper parts of the two curves for the same concrete strength represents the portion of

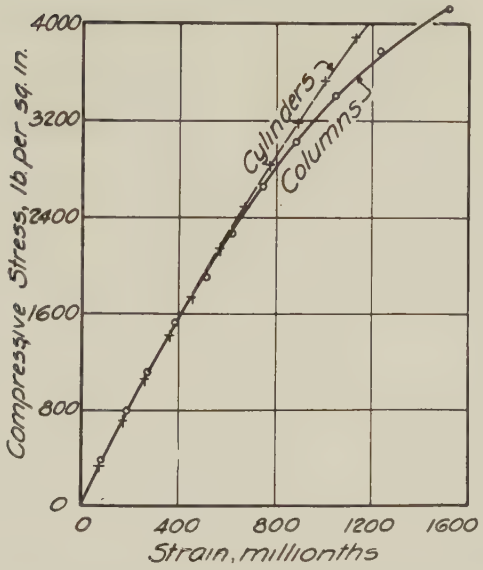

FIG. 25—STRESS-STRAIN DIAGRAM FOR PLAIN COLUMNS AND FOR CONTROL CYLINDERS; DESIGNED CONCRETE STRENGTH 5000 LB. PER SQ. IN

the total deformation which is due to the holding of the load for four hours.

19. *Relation Between Strains and Percentage of Longitudinal Reinforcement*—Figs. 28 and 29 show the stress-strain relations for columns of concrete designed for strengths of 8000 and 3500 lb. per sq. in. respectively. The spiral reinforcement amounted to 1.2 per cent for all the columns, and the longitudinal reinforcement varied from 0 to 6 per cent as indicated. The stress $\frac{P}{A}$ plotted in these diagrams is the load on the column divided by the total area within the outer circumference of the spiral, that is, by 50.3 sq. in., the sum of the sectional areas of the circumscribed concrete and the longitudinal reinforcement. The portion of this average stress that was considered to be carried by the longitudinal reinforcement is indicated by the broken straight lines in the lower part of the diagram. In constructing

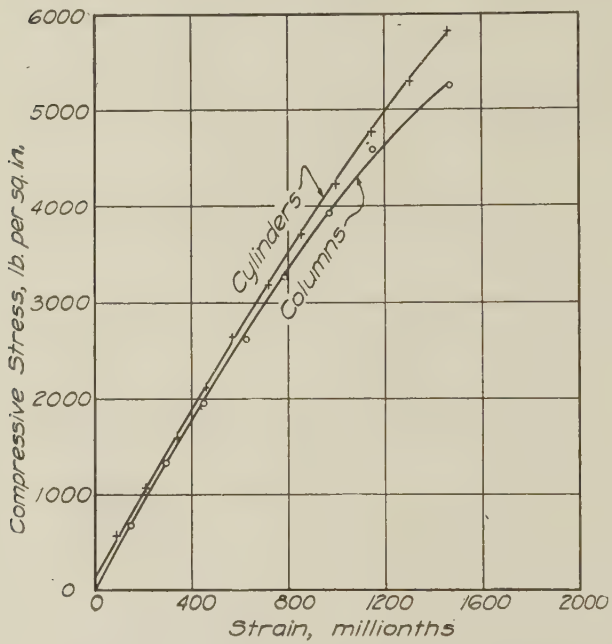

FIG. 26—STRESS-STRAIN DIAGRAM FOR PLAIN COLUMNS AND FOR CONTROL CYLINDERS; DESIGNED CONCRETE STRENGTH 8000 LB. PER SQ. IN.

these lower lines the modulus of elasticity of the steel was taken at 30,000,000 lb. per sq. in. and the stresses were determined from the measured strains. The break in each line comes at the strain corresponding to the yield-point stress of the bars of the size used to secure the percentage of reinforcement indicated.

The stress-strain curves for the control cylinders made with the columns having only spiral reinforcement, have been plotted in Figs. 28 and 29 also. In each figure the curve for the cylinder is a dotted line and its agreement with the curve for the corresponding column is very good. Figs. 28 and 29 indicate much less departure of the strain in the spiraled columns from that in their control cylinders than is shown in Fig. 23 and 26 for the plain columns. The indication is that the presence of the spiral had a slight effect in reducing the longitudinal strain in the

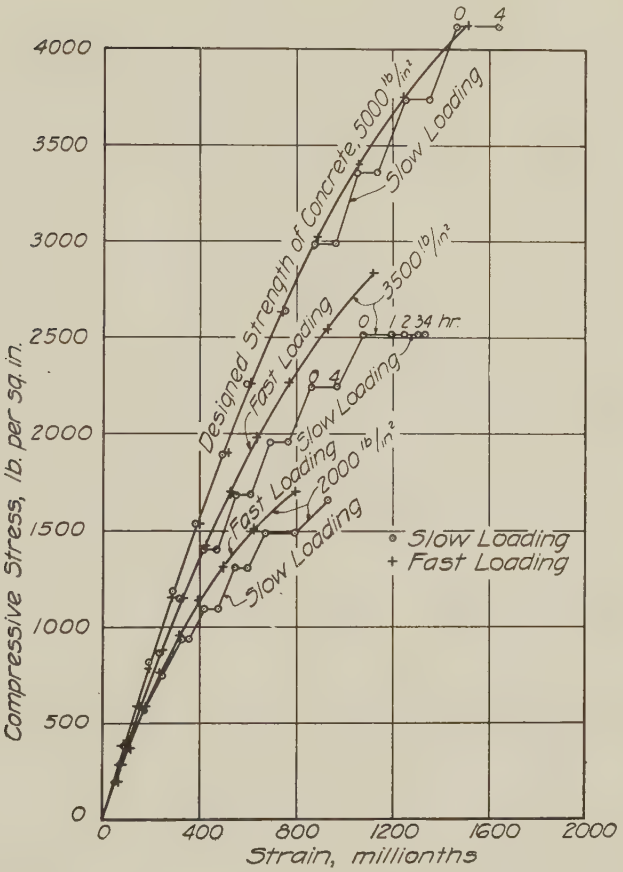

FIG. 27—STRESS-STRAIN DIAGRAM FOR PLAIN CONCRETE COLUMNS, FAST AND SLOW LOADING

columns for stresses above about one-half the cylinder strength, but no effect for lower stresses.

For the concrete designed for a compressive strength of 8000 lb. per sq. in., Fig. 28, the vertical distances between the stress-strain curves for the columns with various percentages of longitudinal reinforcement are very nearly the same as the vertical distances between the corresponding straight lines representing

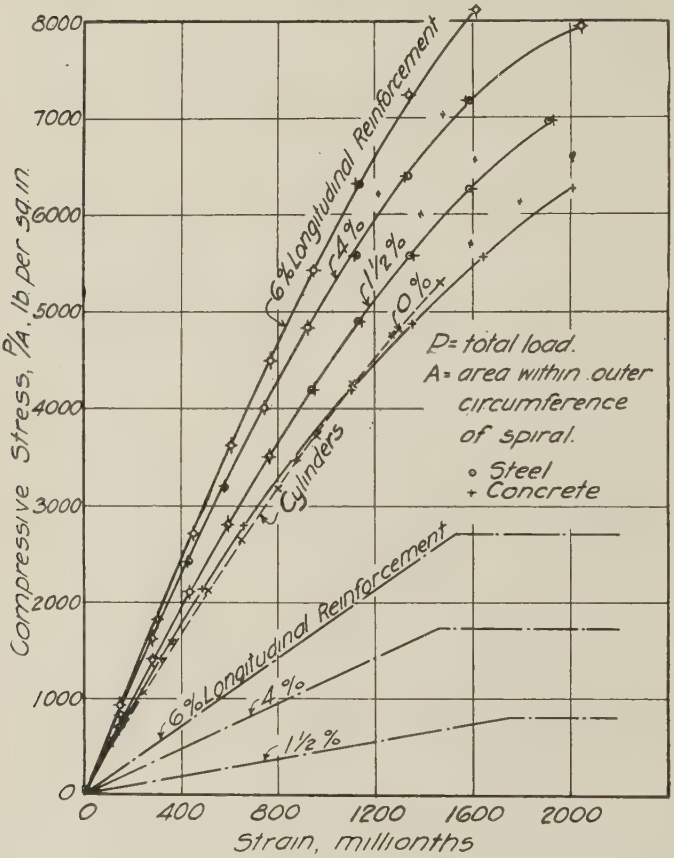

FIG. 28—STRESS-STRAIN DIAGRAM FOR COLUMNS WITH VARYING PERCENTAGES OF LONGITUDINAL REINFORCEMENT; DESIGNED CONCRETE STRENGTH 8000 LB. PER SQ. IN.; 1.2 PER CENT SPIRAL REINFORCEMENT

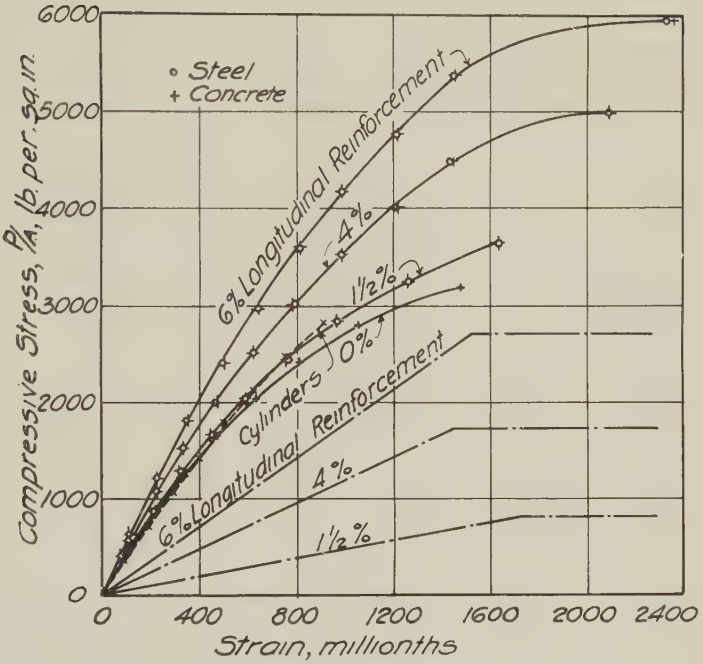

FIG. 29—STRESS-STRAIN DIAGRAM FOR COLUMNS WITH VARYING PERCENTAGES OF LONGITUDINAL REINFORCEMENT; DESIGNED CONCRETE STRENGTH 3500 LB. PER SQ. IN.; 1.2 PER CENT SPIRAL REINFORCEMENT, FAST LOADING

the stresses carried by the reinforcement. That is, if the ordinates to the straight lines (the stresses carried by the longitudinal reinforcement) were subtracted from the ordinates to the stress-strain curves for the columns, the resulting curves would practically coincide with the curve for the column having no longitudinal reinforcement. This indicates that the presence of longitudinal reinforcement had no perceptible effect on the elastic behavior of the concrete designed for a strength of 8000 lb. per sq. in.

With the 3500-lb. concrete shown in Fig. 29 for fast loading and Fig. 30 for slow loading, the case was different. The vertical distances between the stress-strain curves for 0 and 1½ per cent

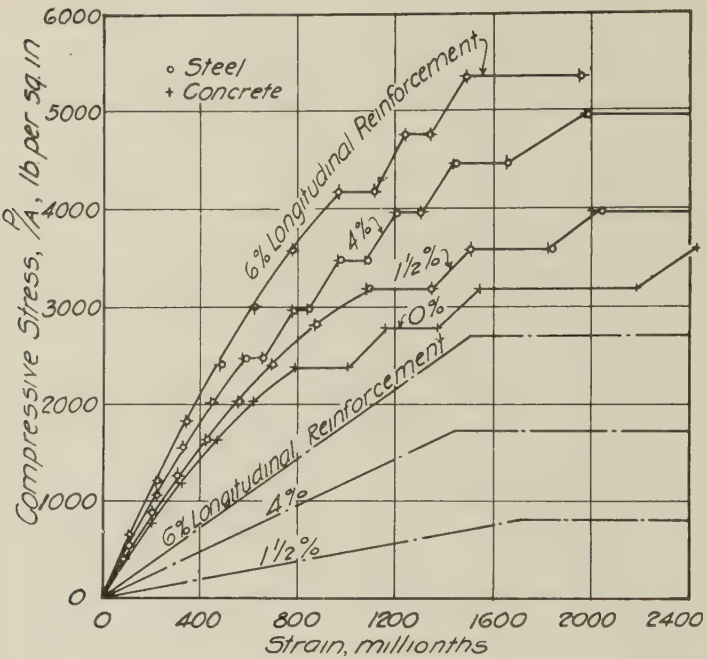

FIG. 30—STRESS-STRAIN DIAGRAM FOR COLUMNS WITH VARYING PERCENTAGES OF LONGITUDINAL REINFORCEMENT; DESIGNED CONCRETE STRENGTH 3500 LB. PER SQ. IN.; 1.2 PER CENT SPIRAL REINFORCEMENT, SLOW LOADING

reinforcement were considerably less than the ordinates of the line representing the stresses carried by 1½ per cent of reinforcement. With this exception, the conditions for the 3500-lb. concrete were about the same as those for the 8000-lb. concrete with the result that if the stresses carried by the reinforcement were subtracted from the total average stresses carried by the corresponding columns the resulting curves for the stresses carried by the concrete for the reinforced columns would practically coincide with each other, but would lie below the curve for the columns without longitudinal reinforcement. The behavior is as though the introduction of the longitudinal reinforcement reduced the effective sectional area of the concrete by a constant amount in

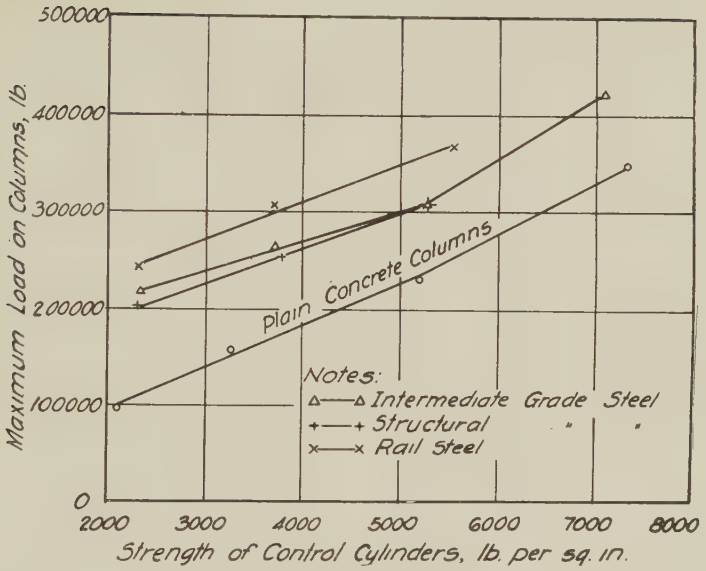

FIG. 31—COMPARISON OF PLAIN CONCRETE COLUMNS WITH COLUMNS HAVING 4 PER CENT LONGITUDINAL REINFORCEMENT OF THREE DIFFERENT GRADES, 1.2 PER CENT SPIRAL REINFORCEMENT OF INTERMEDIATE GRADE

excess of the area of the reinforcement used. The only explanation of the difference in behavior between the 8000 and 3500-lb. concrete which seems reasonable is based upon a possible difference in compactness due to the difference in the methods of placing. The 8000-lb. concrete was vibrated during the placing, and the 3500-lb. concrete was not.

20. *Relation Between Strength of Column and Strength of Concrete*—Fig. 31 shows, as ordinates, the total loads carried by the columns and as abscissas, the strengths of their control cylinders. The lower curve represents the plain columns and the upper curves represent columns having 4 per cent longitudinal and 1.2 per cent spiral reinforcement. The spiral reinforcement was all of intermediate grade; the longitudinal included structural,

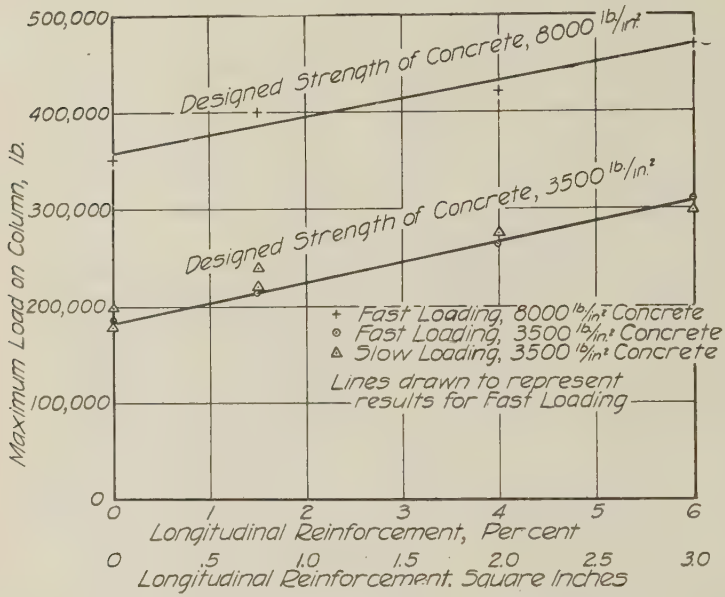

FIG. 32—EFFECT OF VARIATION IN PERCENTAGE OF LONGITUDINAL REINFOFCEMENT ON THE STRENGTH OF THE COLUMNS, 1.2 PER CENT SPIPAL REINFORCEMENT

intermediate, and rail grades of steel. The strengths of the columns increased quite consistently with the increase in strength of the control cylinders. The rate of increase in strength of the reinforced columns seems to have been nearly equal to that of the plain columns when net core areas* of concrete in the reinforced columns are considered. That is, the increase in the strength of the concrete was just as effective in a reinforced column as it was in a plain column. It is shown in a previous section that for a plain column the strength was 85 per cent of its cylinder strength regardless of the strength of the concrete. Therefore the increase in strength of the reinforced columns would be equal to the net area of its concrete times 85 per cent of the increase in strength of its control cylinders, regardless of the grade of longitudinal reinforcement.

*By the term "net core area" of the concrete is meant the area within the outer circumference of the spiral minus the sectional area of the longitudinal reinforcement.

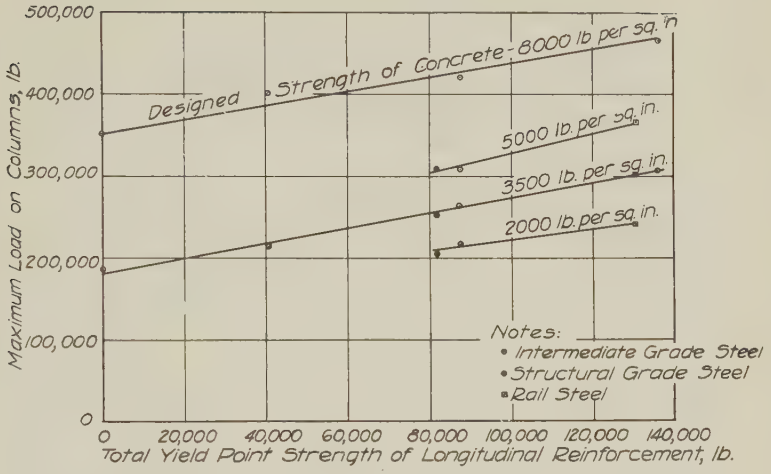

FIG. 33—RELATION BETWEEN TOTAL YIELD-POINT STRENGTH OF LONGITUDINAL REINFORCEMENT AND STRENGTH OF COLUMN, 1.2 PER CENT SPIRAL REINFORCEMENT

In Fig. 32 the maximum loads carried by reinforced columns have been plotted as ordinates and the percentage of longitudinal reinforcement as abscissas. The percentage of spiral was 1.2 for all columns. The straight line representing the relation between the strength of the column and the percentage of reinforcement for a concrete strength of 3500 lb. per sq. in. is parallel to the line representing the same relation for the 8000-lb. concrete. That is, the strength added to a reinforced column due to a given increase in the concrete strength was the same for all the percentages of longitudinal reinforcement used.

Fig. 33 shows the relation between the strength of the columns and the total yield-point strength of the longitudinal reinforcement. This figure is a combination of the previous two figures and shows that the increase in strength of columns due to increased strength of the concrete was practically independent of the yield point strength of the reinforcement used in the columns.

The effect of the strength of the concrete upon the deformation of columns having 4 per cent longitudinal and 1.2 per cent spiral

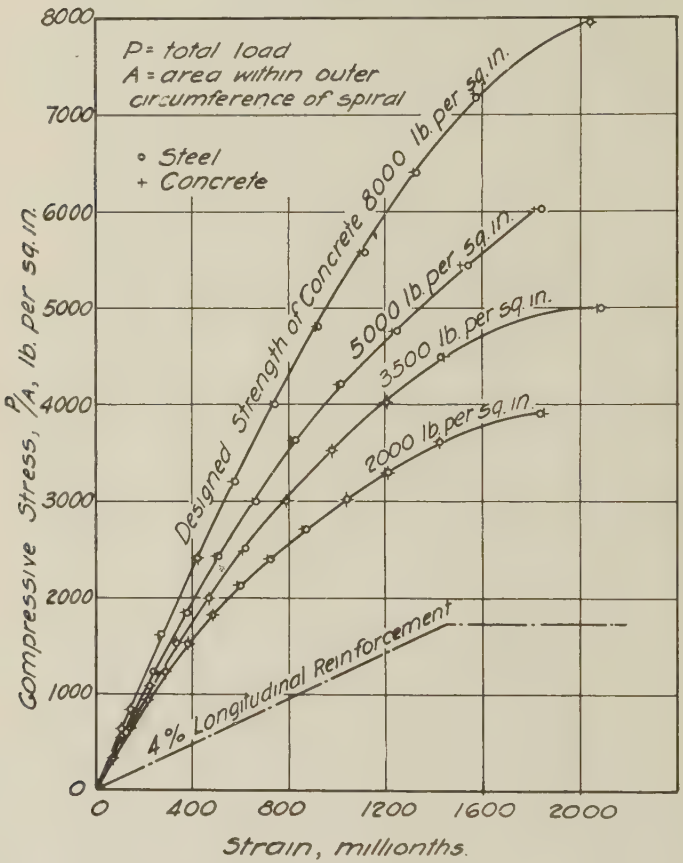

FIG. 34—STRESS-STRAIN DIAGRAM FOR COLUMNS WITH DIFFERENT CONCRETE STRENGTHS, REINFORCEMENT 4 PER CENT LONGITUDINAL AND 1.2 PER CENT SPIRAL

reinforcement is illustrated in Fig. 34. The strains for a given stress decreased quite regularly with the increase in strength of the concrete.

21. *Relation Between Yield-Point Strength of Longitudinal Reinforcement and Strength of Column*—The strength added by the longitudinal reinforcement in the columns may be varied by changing either the percentage or the grade of reinforcing steel.

The effect of various grades of steel upon the strength of columns of a given percentage of reinforcement and strength of concrete is illustrated in Fig. 31. Intermediate, structural, and rail grades were included in these tests, and the column strengths obtained with these grades of longitudinal reinforcement are shown in the three upper lines. The yield-point strength of the reinforcement is given in Table 6. Structural and intermediate grades had nearly equal yield-point stresses (40,840 and 43,560 lb. per sq. in.), but the rail grade had a much higher yield-point stress (65,320 lb. per sq. in.). The lines representing the strengths of the columns having structural and intermediate grades of reinforcement are close together, while the line representing the strength for the columns with rail grade reinforcement lies considerably higher than the lines for the other grades.

In Fig. 33 the strengths of the columns have been plotted as ordinates and the total yield-point strength of the longitudinal steel as abscissas. Straight lines are obtained for each strength of concrete. The increase in yield-point strength was due in some cases to change in grade of steel, and in other cases to increased percentage of reinforcement. Since for a given strength of concrete, all points group themselves along the same line, the strength of the column seemed to be independent of whether the change in yield-point strength was affected by varying the percentage of a given grade of reinforcement or by using different grades of reinforcement. The lines for different strengths of concrete are practically parallel, indicating that the increase in strength due to the higher yield-point strength of the reinforcement was independent of the strength of the concrete. The slope of these lines represents the strength added to the columns for each unit of increase in strength of the reinforcement. The slope is, therefore, a measure of the effectiveness of the longitudinal reinforcement in adding strength to a column of a given concrete strength. The average slope of the curves in Fig. 33 indicate that the reinforcement added 97 per cent of its yield-point strength to the strength of the concrete of the core. The yield-point stress of the steel was determined by the "drop of beam," a method which tends to give values slightly too high. The effectiveness of the longitudinal reinforcement may therefore be

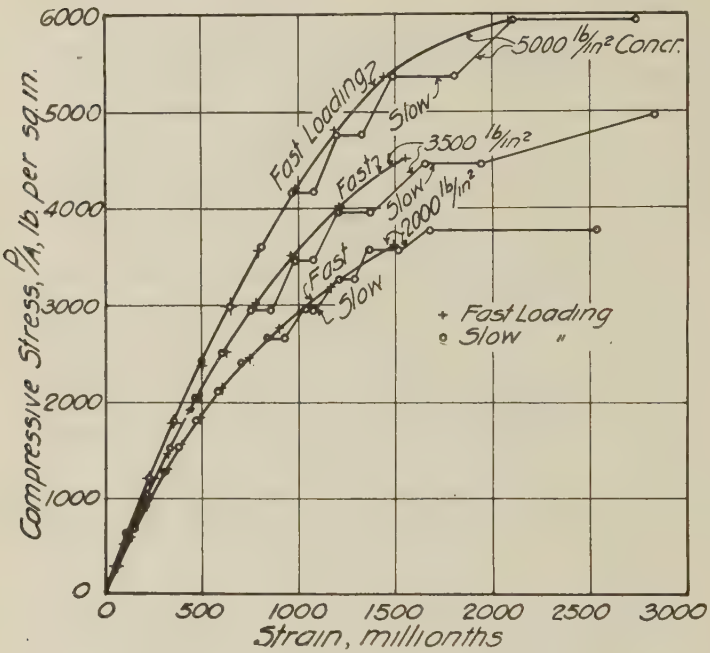

FIG. 35—STRESS-STRAIN DIAGRAM FOR COLUMNS TESTED UNDER FAST LOADING AND SLOW LOADING; 4 PER CENT LONGITUDINAL REINFORCEMENT OF STRUCTURAL GRADE, 1.2 PER CENT SPIRAL REINFORCEMENT

more than 97 per cent of its yield-point strength. In the further discussion in this report the longitudinal reinforcement has been assumed to add its full yield-point strength to the strength of the column. That is, it is considered 100 per cent effective.

22. *Effect of Rate of Loading on Deformation and Strength of Columns*—In Fig. 31 it is shown that the reinforced columns continued to deform during the 4-hour loading intervals. Up to the first load which was maintained for four hours, the deformations of the two sets of columns (designed for "fast" and "slow" loading) were practically equal in all cases, indicating good uniformity in the two sets of columns. The deformation during the first 4-hour interval was generally quite large. The deformation during the succeeding 4-hour intervals was not much different

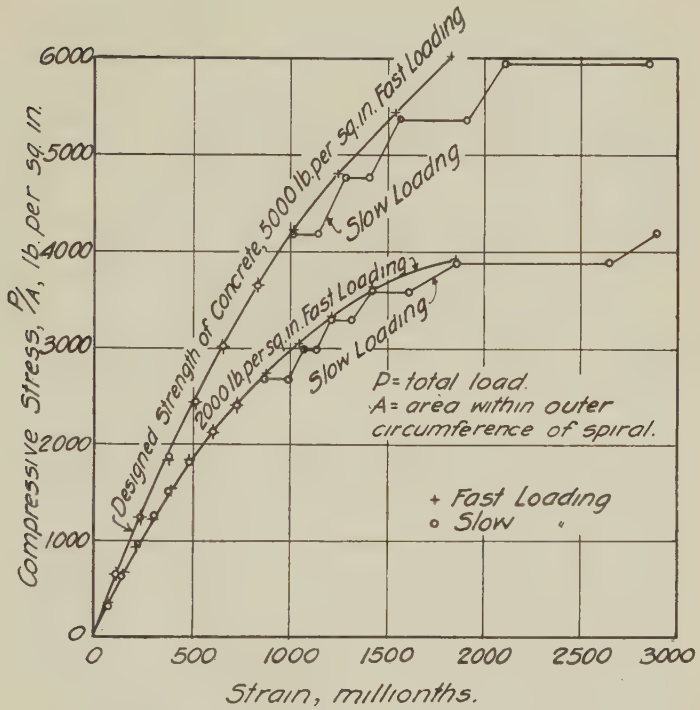

FIG. 36—STRESS-STRAIN DIAGRAM FOR COLUMNS TESTED UNDER FAST LOADING AND SLOW LOADING; 4 PER CENT LONGITUDINAL REINFORCEMENT OF INTEFMEDIATE GRADE, 1.2 PER CENT SPIRAL REINFORCEMENT

from the first one except near the maximum load, when the deformations became several times as large as during the previous intervals. During the application of an increment of load, the rate of deformation was so much lower than that for fast loading that the stress-strain curve was brought very nearly back to the curve for the fast loading.

Figs. 35, 36, and 37 show the deformation for fast and slow loading on columns reinforced with structural, intermediate, and rail grade longitudinal reinforcement. The grade of reinforcement had no effect upon the deformation up to a load near the yield-point strength of the steel. The agreement between de-

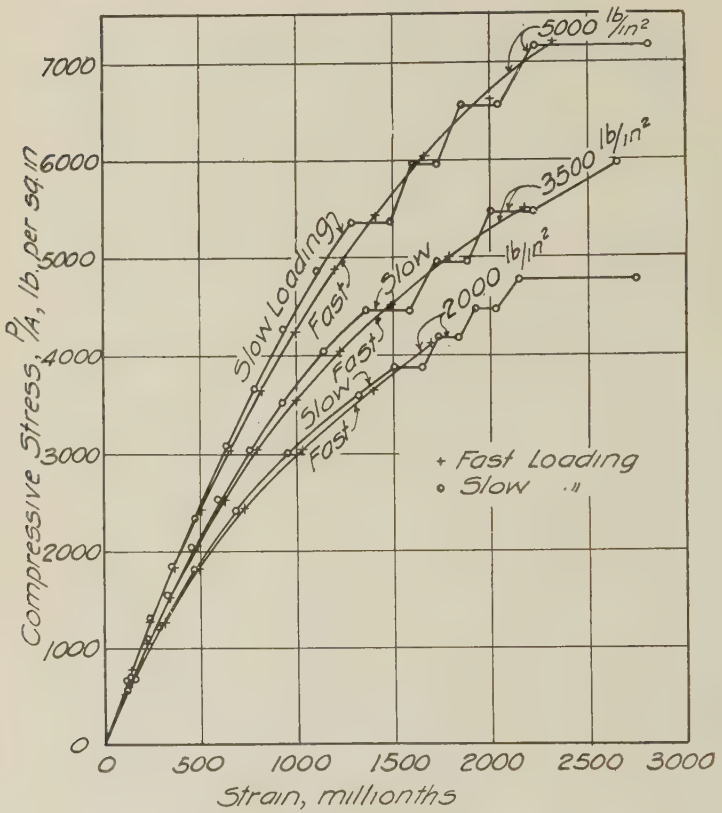

FIG. 37—STRESS-STRAIN DIAGRAM FOR COLUMNS TESTED UNDER FAST LOADING AND SLOW LOADING; 4 PER CENT LONGITUDINAL REINFORCEMENT OF RAIL GRADE, 1.2 PER CENT SPIRAL REINFORCEMENT

formations at low loads for the two methods of testing is evident. In Fig. 37, showing the deformation of the columns having rail steel, the agreement between deformations found for fast and slow loadings was not so good as in the other cases.

The strengths of the columns tested with fast loading and slow loading are given in Tables 7 to 10. Table 7 gives the results for plain columns, and Tables 8, 9, and 10 for reinforced columns. The plain columns tested with slow loading generally developed less strength than did the companion columns with fast loading.

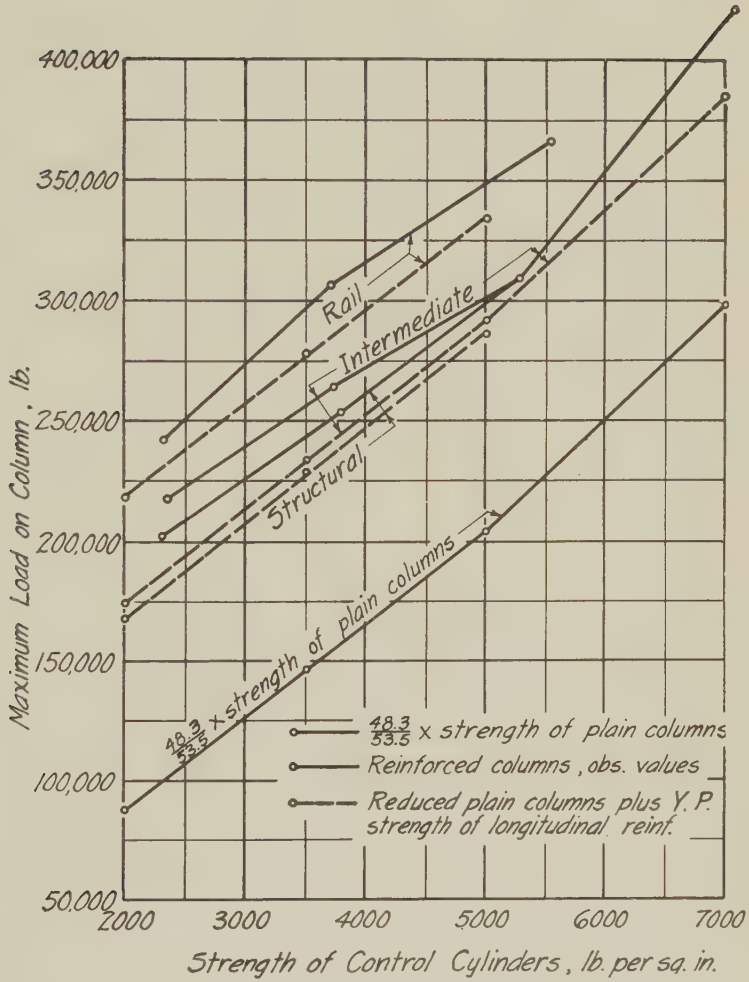

FIG. 38—DIVISION OF LOAD BETWEEN CONCRETE AND REINFORCEMENT

The difference, however, was not very marked. For the reinforced columns the strength obtained with slow loading was very nearly equal to, but generally larger, than the strength obtained with fast loading.

23. *Division of Load Between Concrete and Reinforcement*—Fig. 38 is designed to show the relation between the strengths of the reinforced columns and the sum of the strengths of the concrete and the reinforcement used. All the reinforced columns used in this figure had 4 per cent longitudinal and 1.2 per cent spiral reinforcement. The sectional area of the concrete within the outer circumference of the spiral, that is, the core area minus the sectional area of the longitudinal bars was 48.3 sq. in., and the sectional area of the plain columns was 53.5 sq. in. The plotted values in the lower curve are $\frac{48.3}{53.5}$ times the strength of the plain columns, and represent the strength of the concrete in the reinforced columns. To these strengths have been added the total yield-point strengths of the longitudinal reinforcement. The strengths thus obtained for columns reinforced with structural, intermediate, and rail grades of reinforcement are shown as three distinct dotted lines. In addition, the strengths of the columns so reinforced but having in addition 1.2 per cent spiral reinforcement are shown as solid lines. Based upon the assumption that the longitudinal reinforcement added its full yield-point strength to the column (as indicated in section 21), the vertical distance between the solid and the dotted lines for each grade of steel represents the strength added by 1.2 per cent of spiral reinforcement. The solid line and the dotted line are not far from parallel, indicating that nearly a constant strength was added to the column by the spiral regardless of the strength of the concrete. The average total added strengths so determined were 16,700, 19,000, and 16,000 lb. for longitudinal reinforcement of structural, intermediate, and rail grades of steel respectively. Apparently the strength added by the spiral was not affected by variations in the yield-point strength of the longitudinal reinforcement. The average of the added strengths for the three grades was 17,200 lb. for 1.2 per cent of spiral, or 14,300 lb. for 1

TABLE 8—EFFECT OF GRADE OF LONGITUDINAL REINFORCEMENT ON STRENGTH OF COLUMNS

6.0	3850	3680	3770	305,000	311,900	308,450	Fast
6.0	3690	3790	3740	15 min. 300,000	5 min. 300,000	10 min. 300,000	Slow

per cent. This is 70 per cent of the average strength added by 1 per cent of longitudinal reinforcement of intermediate grade as shown in Fig. 31.

The indication of the foregoing paragraphs is that the strength of the columns having longitudinal and spiral reinforcement was made up of (1) 85 per cent of the cylinder strength times the net area of the concrete within the outer circumference of the spiral, (2) the yield-point stress of the longitudinal bars times their area, and (3) the strength added by the spiral, which amounted to about 70 per cent of the strength added by an equal percentage of longitudinal reinforcement of intermediate grade steel.

24. *Summary of Results*—With the water content of the concrete constant at 39 gal. per cu. yd. the strength of the concrete increased in direct proportion to the increase in the cement content.

For all except the vibrated concrete, the increase in the modulus of elasticity was very nearly proportional to the increase in the compressive strength.

The strains measured on the steel agreed very well with those measured on the concrete for all columns, and the agreement between strains measured on columns of the same kind was good.

The average strength of the plain columns was approximately 85 per cent of the strength of the cylinders and the uniformity of both the cylinders and the columns was good.

The stress-strain curves for the plain columns practically coincided with those for the corresponding control cylinders up to about one-half the maximum load. For higher loads the strains in the columns were somewhat greater than those in the cylinders.

For the 8000-lb. concrete the load at any strain for columns with different percentages of longitudinal reinforcement was equal to the load carried by a column with no longitudinal reinforcement plus the load carried by longitudinal reinforcement having a modulus of elasticity of 30,000,000 lb. per sq. in. With the 3500-lb. concrete the conditions were the same as for the 8000-lb. concrete except that for any given strain the loads for the columns with all the different percentages of reinforcement were a constant amount less than the sum of the load for the column

without longitudinal reinforcement and the load found to be carried by the reinforcement.

For any two columns reinforced in the same manner, the difference in total strength was approximately equal to the difference in strengths of the concrete in the core as determined by the tests of the plain columns.

The increase in total strength due to the use of longitudinal reinforcement was approximately equal to the yield-point stress of the reinforcement times its sectional area, regardless of the grade of reinforcement used.

The strength of the plain columns tested with slow loading was generally slightly less than that of the columns tested with fast loading. For the reinforced columns the strength with slow loading was nearly equal to, but generally slightly greater than that for fast loading.

The indication of the tests is that the strength of the columns having longitudinal and spiral reinforcement was made up of (1) 85 per cent of the cylinder strength times the net area of the concrete within the outer circumference of the spiral, (2) the yield-point stress of the longitudinal bars times their area, and (3) the strength added by the spiral, which amounted to about 70 per cent of the strength added by an equal amount of longitudinal reinforcement of intermediate grade steel.

Progress Report on Column Tests at the University of Illinois

BY F. E. RICHART* AND G. C. STAEHLE†

INTRODUCTION

The Investigation—The following progress report gives results of tests made in the investigation of reinforced concrete columns at the University of Illinois. As stated in a previous report, the investigation is sponsored by Committee 105 of the American Concrete Institute and the experimental work has been divided between Fritz Engineering Laboratory at Lehigh University and the Materials Testing Laboratory at the University of Illinois. The work at the latter laboratory is under the administrative direction of Dean M. S. Ketchum, Director of the Engineering Experiment Station and Prof. M. L. Enger, Head of the Department of Theoretical and Applied Mechanics.

The testing program outlined by the Committee and reported a year ago[1] has been followed quite closely, variations from it consisting principally of the addition of a few columns of plain concrete, and a small group, Series 8, to bring out the effect of long-continued loading on columns in which the reinforcing bars do not end flush with the end of the column. The time schedule followed in the testing program is given in Table 1.

This report contains results of the tests of Series 1 and 2, in addition to general information pertaining to all of the tests. The data of Series 3, in which the columns are being held under design load for one year before being tested to failure, are naturally incomplete; however, the strains measured over a five-months period of continued loading were felt to be of sufficient interest to warrant an early progress report, to appear in the March

JOURNAL of the Institute. A similar report will be prepared soon for Series 5 and 6, while the tests of Series 7 and 8 are still unfinished.

1. *Type of Test Column*—All of the columns tested (except two of Series 1) were cylindrical, with a length seven and one-half times the core diameter. In all but those of Series 6, the fireproofing was omitted and the spiral reinforcement was practically at the column surface. In Series 6, a 2-in. thickness of fireproofing was used. As the result of the tests of Series 1, all columns except those of Series 8 were made with the milled ends of reinforcing bars flush with the concrete bearing faces. In Series 8, the ends of bars were stopped ¼ in. short of the end of the column, so that no bearing was transmitted to the bars.

2. *Materials*—The cement used in making columns was furnished by the Lehigh Portland Cement Co. It was stored in wooden barrels in a dry room until used. The strength, as shown by mortar and concrete tests, was uniformly high. Table 2 gives data of briquet tests made at different times during the season. From other tests made from time to time, the water required for normal consistency of the cement was found to be 23.0 to 24.0 per cent, by weight; the average time of initial set was 3 hr. 40 min.; of final set, 6 hr. 40 min. Tests of fineness showed 12 to 14 per cent retained on a No. 200 sieve after 10 min. in a Rotap sieve shaker. All soundness tests gave satisfactory results.

The torpedo sand used was furnished by the Lincoln Sand and Gravel Co., Lincoln, Illinois, and the gravel was furnished by the Neal Sand and Gravel Co., Mattoon, Illinois. Average sieve analysis and fineness moduli are given in Table 3. The aggregates used in Series 1, which differed from the above, are described in the section referring to that series.

The concrete mixtures used were designed to produce cylinder strengths of 2000, 5000 and 8000 lb. per sq. in. at 56 days, except in Series 1, wherein the tests were made at 28 days. A workability as shown by a slump of 3 to 6 in. was chosen, except in the case of the 8000-lb. concrete, which was designed to be placed with the aid of a high frequency electric vibrator, loaned for the work by the Electric Tamper and Equipment Co., Chicago, Ill. The proportions finally used are given in Table 4. The results of

*Used in 28 and 32-inch columns to reduce ultimate column strength.

56-day tests of companion cylinders made with all columns are reported with the results of the various column tests.

The reinforcing bars were furnished by the Kalman Steel Co., Chicago, Ill., the Truscon Steel Co., Youngstown, Ohio, and the Rail Steel Bar Association, Chicago, Ill. The spiral stock was furnished by the American Steel and Wire Co., Chicago, Ill., and fabricated into spirals by the American System of Reinforcing, of Chicago. While complete tests of reinforcing steel have not been made, average properties of the various lots as determined to date are given in Table 5. It is planned to test coupons which will indicate the properties of the steel in each individual column.

The reinforcement used in Series 1, made before the main stock of steel was received, differs slightly from the remainder in the above list. The spirals of cold drawn wire were intended to approximate the quality to be obtained in a hot rolled rod of intermediate grade. The longitudinal steel was nearly the same as that received later and used in the remaining series.

3. *Details of Reinforcement*—The 8-in. columns were designed to have three percentages of longitudinal steel, 1.5, 4, and 6, and two percentages of spiral, 1 and 2. The larger columns were

Rail steel bars were plain sq., all others deformed.

*No yield point on spiral stock. Values given represent a "useful limit" of the material, and are stresses at a unit elongation of 0.005. This elongation is based upon observations of spiral strains at the ultimate load on columns made with various percentages of spiral reinforcement. (See Bulletin 190, Univ. of Ill. Eng. Expt. Sta.)

designed for 1.5 or 4 per cent of longitudinal steel and 1 per cent of spiral. The commercial sizes chosen to meet these designed values are given in Table 6, to which reference may be made in connection with the tabulated results of all tests. The number of bars selected are in multiples of 4, to facilitate strain measurements on four sides of each column. It is seen that the largest amount of longitudinal steel used in the 28-in. columns was 3.28 per cent. The original design of 4 per cent was reduced in this case to obviate the chance of exceeding the capacity of the 3,000,000-lb. testing machine. Another variation from the design percentage is seen in the 1.24 per cent spirals for 8-in. columns. With the smallest size of hot-rolled spiral rod available this was the smallest percentage possible without exceeding a pitch of one-sixth of the core diameter.

*Percentages of reinforcement based on this core diameter, out to out, of spiral.

4. *Making and Storage of Columns*—The concrete for all columns was mixed in a one-bag batch mixer, the usual mixing time being 4 minutes. For the 8-in. columns all aggregates were reduced to a room-dry condition previous to use. Cement, aggregates and water were proportioned and measured out by weight. The 8-in. columns were made from a single batch, with sufficient excess to permit the making of six companion 6 by 12-in. cylinders. The concrete was wheeled to the forms in wheelbarrows and puddled with the aid of a steel tamping rod and a light air-hammer used on the outside of the form. In pouring the larger columns, each batch was hauled to the form in a bottom-dump bucket mounted on a truck, lifted by a 10-ton crane, and discharged into the form. The largest columns required about 25 batches of concrete and weighed about 8 tons.

The 8 and 12-in. forms were made of steel pipe, split into quadrants and held together with circular clamps. The larger forms were standard steel column forms, loaned by the Kalman Steel Co. for the purpose.

The vertical bars used in all columns were milled to exact length, then wired to the spirals to form a unit or cage. The unit was placed on a machined base plate, the form assembled around it and plumbed. To insure that the ends of bars remained in a plane, a machined 6-in. pipe flange (for the 8-in. columns) was forced and held down against the upper ends of the bars, and the concrete placed in the column through the 6-in. opening in the flange. For the larger columns it was found satisfactory to assemble the reinforcing unit in a vertical position on the base plate before wiring, with the result that the weight of the bars held them in contact at the bottom. In placing the concrete in the columns, the concrete was brought up to about even with the tops of the reinforcing bars. After the concrete had stiffened, a thin layer of neat cement paste or 1:1 mortar was applied to the top and a machined bearing plate pressed down on this cap until it rested firmly on the milled ends of the bars. With this technique it was not difficult to bring the ends of bars into the plane of the cement cap.

Forms were removed from the 8-in. columns the day after moulding, gage lines were prepared by exposing the reinforcing steel and by setting small steel plugs in the concrete with quick-setting cement. Gage holes were drilled for strain measurements with a No. 54 drill. Initial strain readings were taken and the columns were placed in the moist room for the remainder of the 56-day moist storage period. The air of the moist room was kept saturated by humidifying sprays and the temperature was held at 70 deg. F. with an average weekly variation of about one degree. Due to the size and weight of the large columns, it was impossible to place them in the moist room. They were stored in the main crane bay of the laboratory, under burlap which was wet down generally three times a day. The temperature of the room during this curing period—June to September—ranged from about 70 to 90 deg. F. The temperature beneath the wet burlap was considerably lower and the average value did not vary greatly from 70 deg. F.

5. *Testing Methods*—All columns except those of Series 3 were tested to failure in one of four testing machines, a 3,000,000-lb. Southwark-Emery hydraulic machine, a 600,000-lb. Riehle, a

TABLE 7—PRECISION OF STRAIN GAGES

*Based upon general working condition of instrument.

300,000-lb. Riehle, and a 300,000-lb. Olsen screw-power testing machine. A rate of loading was chosen for the hydraulic machine which was comparable with the speeds obtained with the screw-power machines.

Load was applied to the columns through a top spherical bearing block, and in some cases through both top and bottom blocks. With the exception of tests of Series 2, after a small zero load was applied, these blocks were wedged in a fixed position, but it is quite evident that after any considerable load is applied such a block is held against rotation by friction alone. The columns were thus loaded as "flat-ended" columns.

Strain measurements were made by the use of various types of gages. In the majority of the work, longitudinal strains were measured with a 10-in. Whittemore gage at gage lines on four sides of the column on concrete and on steel. The centers of these lines were located 10 in. from the top and bottom of the column, and at midheight. Lateral deformations were measured by use of a "diameter" gage which indicated changes on diametral gage lines. Other gages were a 10-in. Berry gage, 8-in. Berry gages with long legs which were required on the columns having 2 in. of fireproofing, a 50-in. direct reading gage which was used to measure volume changes during moist storage, and a 10-in. direct reading gage for measuring large strains beyond the range of the Whittemore and Berry gages. A summary of the constants of the gages used and their probable precision is given in Table 7.

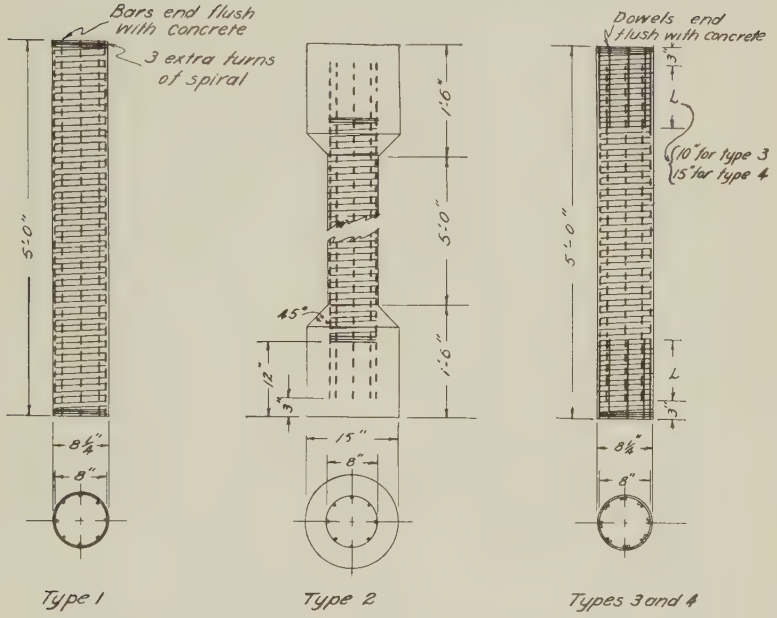

FIG. 1—TYPES OF COLUMN USED IN SERIES 1

SERIES 1—STUDY OF END CONDITIONS

6. *Results of Tests of Series 1*—This group of ten columns was designed to furnish information as to the most desirable type of end condition to be used in the columns of the later series of tests. Four types of end condition are included in the group, two columns of each type, except Type 1 for which there were four. Fig. 1 gives details of the four column types. All of the columns had eight ½-in. square bars (4 per cent) of intermediate grade, and $\frac{3}{16}$-in. cold drawn spirals, 8 in. outside diameter, and 1.35-in. pitch (1.0 per cent). The columns of Type 1 had the ends of reinforcing bars flush with the ends of the concrete. In Type 2, a capital 15 in. in diameter and 18 in. long was added at each end of the column shaft, making the total length 8 ft. The reinforcing bars extended into these capitals to a point 3 in. from the bearing faces, but the spirals were stopped 12 in. from the ends of the

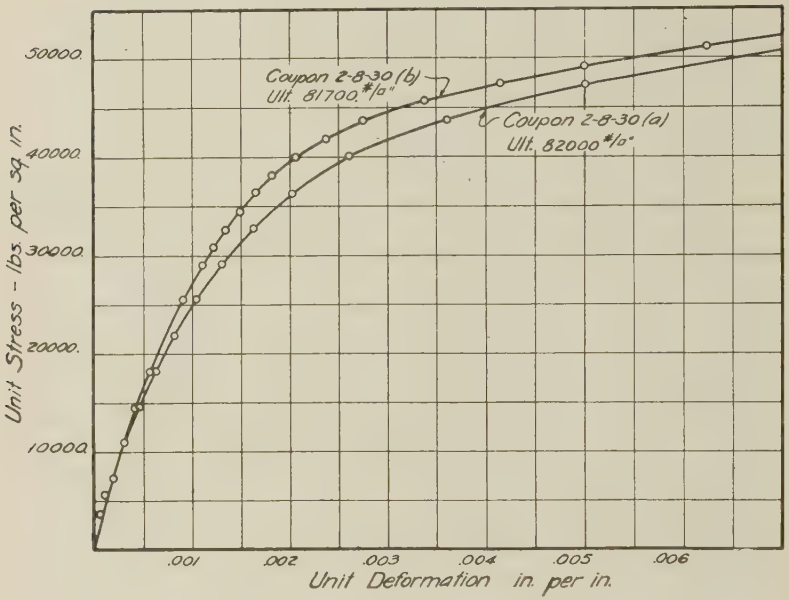

FIG. 2—STRESS-STRAIN CURVES FOR SPIRAL REINFORCEMENT, SERIES 1

column. No other reinforcement was used in the capitals. In Type 3 a 20-diameter splice was made in the longitudinal bars at each end of the column. This was made by stopping the main bars 3 in. from each column end and using 13-in. dowel bars which ended flush with the column ends. Type 4 was like Type 3 except that a 15-in. lap (30 diameters) was used. The dowels were wired to the main longitudinal bars.

Properties of the reinforcing steel are given in Table 5. The cold-drawn wire used in this series did not have a definite yield point; typical stress-strain curves are given in Fig. 2.

The concrete for these columns was intended to have a compressive strength of 3500 lb. per sq. in. at 28 days, but due mainly to the fact that no trial mixtures had been made with the cement used, the concrete obtained gave an average cylinder strength of 5195 lb. per sq. in. The concrete was made with different aggregates from those used in later tests, a torpedo sand from

Attica, Indiana, having a fineness modulus of 3.03 and a ¾-in. Attica gravel having a fineness modulus of 7.21. With the water-cement ratio used, 0.90, slumps of 2.8 to 6.3 in. were obtained. The proportions used, by weight, were 1:2.5:2.8.

The moulds were made from 8-in. steel pipe, cut into quadrants. To accommodate the three spacing bars on the spirals the mould diameter was increased slightly by the introduction of ¼-in. fillers between segments. Leakage of water from the concrete of these specimens led to the practice in later series of tests of sealing all joints with paraffin previous to casting of columns.

Following a procedure outlined by Committee 105, after the forms were stripped, the columns were given two coats of linseed oil before they were placed in moist storage. This was intended to prevent loss of moisture during temporary exposure to the air while gage lines were being prepared and also at the time of testing. However, in the later series this procedure was omitted as unessential and of doubtful value.

The columns were tested when 28 days old, in the 600,000-lb. Riehle testing machine. A spherical bearing block was used at top and bottom of all columns except the two having enlarged ends, with which only the upper bearing block was used. After columns were plumbed and a small initial or "zero" load was applied, the spherical blocks were wedged against further movement. After the initial load of about 6000 lb., a full set of strain readings was taken. The remaining load was applied in about 10 equal increments, and a complete set of strain readings was taken at each increment.

As previously noted, the strain readings were taken at three levels, at middle and 10 in. from each end of the column. In the columns with lap splices in the reinforcement, readings were taken only on the main bars; none on the short dowel bars. Fig. 3 shows views of columns of Types 1 and 2 during testing.

Since the spiral wire was of relatively low strength, approximating intermediate grade hot rolled rod, and since the concrete was of relatively high strength, the one per cent of spiral did not add a very large margin of strength beyond the yield point of any of the columns of Series 1. Little lateral deformation was

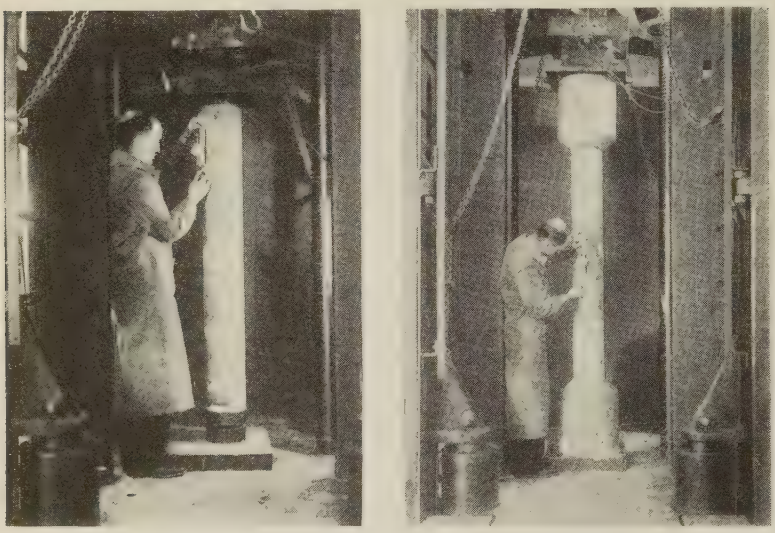

FIG. 3—COLUMNS OF TYPES 1 AND 2 DURING TEST, SERIES 1

noted until the yield point of the column was reached and no appreciable spalling occurred until shortly before the ultimate load was applied. The spiral wire did not break until the maximum load had been passed; then failure occurred by the snapping of one or more wires and outward buckling of the longitudinal bars.

The manner of failure of the two columns of Type 2, with capitals, is noteworthy. Column *g* failed in the shaft in much the same manner as the other columns but breakage of spiral wire after failure was forestalled by splitting of the capital at the top of the column. The strength of this column was equal to that of the strongest column of Type 1. Column *j* failed through the splitting of both capitals, apparently before the full strength of the shaft had been developed.

The principal results of the tests of Series 1 are given in Table 8, together with data on the quality of the concrete used. Both columns and companion cylinders showed unusual uniformity of strength. It is surprising that there was only 5 per cent difference

TABLE 8—RESULTS OF TESTS OF SERIES 1

Reinforcement 8½ in. squares, intermediate grade; Spirals, $\frac{3}{16}$-in. cold drawn wire, 1.35 in. pitch. Spirals 8 in. outside diameter, Core area 50.2 sq. in. Cylinder strengths represent average of three tests. Age of columns and cylinders at test, 28 days.

in average strength between the columns of Type 1, which were the highest, and those of Type 3, which were the lowest of the group. It will also be noted that the average compressive strength for all of the companion cylinders was 5195 lb. per sq. in. and that the variations in the concrete strengths for the four different types of columns did not exceed 1.6 per cent from this average value. Considering that the concrete furnished roughly 60 per cent of the strength of the column, it will be seen that the variations in concrete quality should not produce a difference in the strength of the different types of column amounting to more than 1 per cent. Accordingly no attempt has been made to correct the relative strengths of columns to allow for these minor variations in quality of concrete.

Various attempts have been made to account for the portion of the strength of a column contributed by each of its elements, and most column formulas indicate the share of the load carried on concrete, on vertical reinforcement and on spiral reinforcement. It is evident that the results of Series 1, comprising only 10 column tests and in which variable end conditions were introduced, should not be used to establish any general column formula. The object of the following tabulation is merely to present the results in a form that may easily be studied when the results of the later and more comprehensive series of tests are available. A well-established method of expressing the strength of a column is to consider it made up of three elements, (1) the ultimate strength of the net concrete core area, considered as plain concrete, (2) the load required to stress the compressive reinforcement to the yield point, and (3) the load required to stress the spiral to its limit of effectiveness. It is definitely known that the strength of the concrete in a column seven and one-half diameters in length should be less than that of a 6 by 12-in. cylinder. Tests in this laboratory in 1924 and 1925 showed the strength of 8 by 40-in. and 10 by 40-in. plain columns to be about 85 per cent of that of companion cylinders; the results of Series 2 for 8 by 60-in. plain column (see Table 10, to follow) show a column-cylinder strength ratio of about 0.80. The corresponding tests of Series 2 made at Lehigh University show a ratio of about 0.85 and in the present studies this value will be used. Since no plain columns were included in Series 1, an estimate of the load carried by the concrete portion of the column will be taken at 85 per cent of the companion cylinder strength. The longitudinal steel consisted of 3.98 per cent of intermediate grade, having a yield point of 47,900 lb. per sq. in. There is no definite yield point of the spiral steel; however, an estimate of the useful limit of strength of spiral may be made on the basis of previous tests,[1] in which the spiral strain at the ultimate column load was found to vary from 0.003 to 0.009. Accordingly, the stress in the spiral wire at a strain of 0.005 has been chosen as a rough measure of the useful limit of the spiral reinforcement; the average value found being 48,000 lb. per sq. in. Table 9 gives the distribution

Average		7170	5195	4235	1900	1035

*Concrete section is 96 per cent of core area.

of the strength of the columns of Series 1 on the basis of the above method of calculation. It must be remembered that this calculation has thrown most of the variability of the column strengths into that portion of the strength attributed to the spiral reinforcement, whereas it is much more probable that such variations were due to the different arrangements of the vertical steel.

The longitudinal strains measured on all columns of the series are shown on the load-strain curves of Fig. 4. The strains in concrete and steel at the different elevations are seen to be similar, except for the columns of Types 3 and 4, in which dowels were used. In these columns, the strains measured near the ends of the main reinforcing bars are generally less than those in the adjoining concrete. This is because the gage line is within the lap splice in the reinforcement.

The variation between strains at top, middle and bottom of each column may be seen in Fig. 4. While the point at which high early strains developed usually coincided with the point of failure, no consistent rule may be stated for the location of the point of failure in the columns. In those with dowels, failure occurred within the zone of the reinforcement splice, and in the others the greater number of failures were in the upper third of the column shaft.

The modulus of elasticity of the concrete used in the columns, as found from tests of 6 by 12-in. cylinders, averaged 4,320,000 lb. per sq. in. for the 10 columns. The lower portion of the stress-

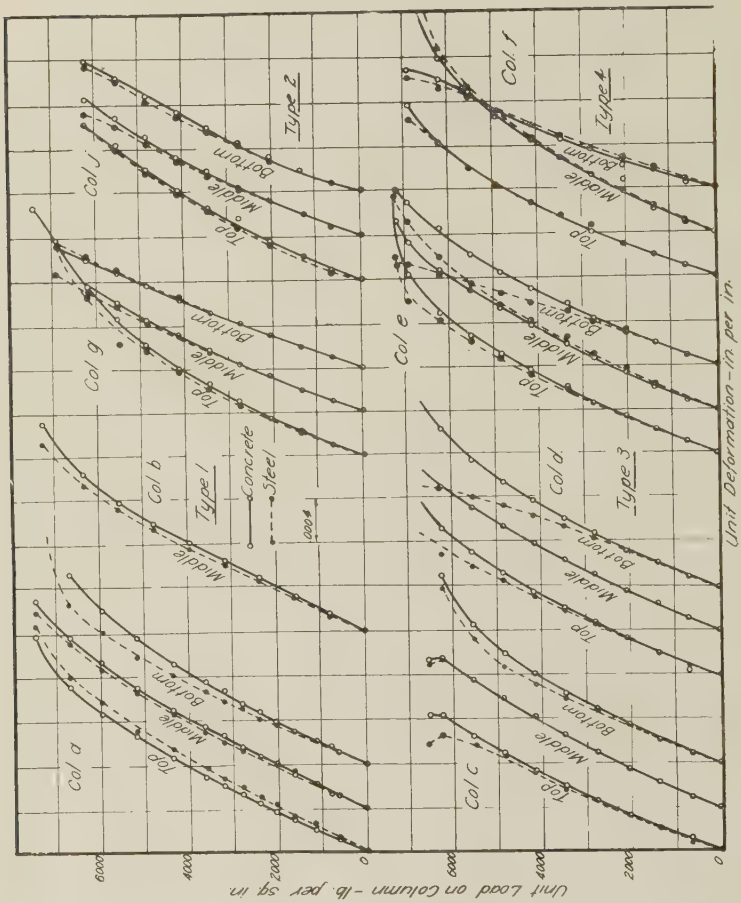

FIG. 4—STRESS-STRAIN CURVES FOR COLUMNS OF SERIES 1

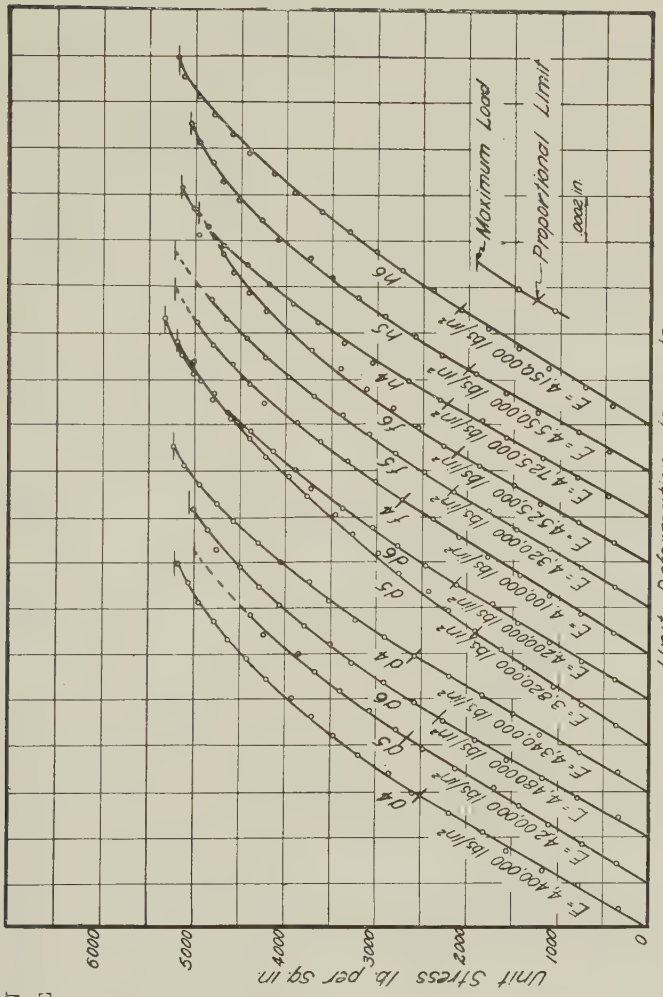

FIG. 5—STRESS-STRAIN CURVES FOR CONCRETE OF SERIES 1

strain curve for these cylinders was a straight line. The limit of proportionality for the concrete was found to be 37 to 54 per cent of the ultimate strength, with an average of 44 per cent. Fig. 5 shows typical stress-strain diagrams for this concrete.

From a consideration of the relative strengths of the columns of the four types given in Table 8, it might be concluded that any one of the four types would give satisfactory results with the possible exception of the type having enlarged ends. However, since there was no apparent advantage with either the type having capitals or those having dowels, economy of material and labor pointed to the selection of Type 1. This type was used in all of the remaining columns of the investigation with the exception of a few columns of Series 8 which were designed to show the effect of long-continued loading on the transfer of stress to the longitudinal reinforcement by bond alone. It might be noted that the amount of material required for the type with capitals was roughly twice as great as for the one finally chosen, and that the labor of making and testing such columns and the moist storage room required for them would be much more than twice as great. The use of dowel bars showed no particular advantage or increase in information to be secured, and an objection to their use was found in the difficulty of securing proper contact of the milled ends against the bearing plates. The wisdom of the choice of Type 1 for the succeeding series of tests has been borne out in the conduct of the later series.

SERIES 2—STUDY OF METHOD OF LOADING

7. *Results of Tests of Series 2*—This series of tests was planned to give information on a number of questions relating to column strength, including different methods of loading, a considerable range in kind and amount of reinforcement and in quality of concrete. The columns were made in general with three grades of concrete, designed to produce 56-day strengths of 2000, 3500 and 5000 lb. per sq. in. In addition a small group was made with concrete designed to produce a 56-day strength of 8000 lb. per sq. in., when compacted into place by the use of an electric vibrator.

Longitudinal reinforcement of three different grades was included in the series and in general three percentages ranging from

1½ to 6 per cent were used. The grades of steel used were specified to meet requirements for intermediate, structural, and rail steel. The spiral reinforcing used was of intermediate grade, hot rolled rod; about 1¼ per cent was used in all columns of this series.

As noted, one of the principal studies embodied in the series was that of rate of loading of the test column. The method used in practically all previous column tests has been to apply the load in increments, allowing only sufficient time between increments for the observation of strains. It was felt that in the range of plastic action of the column a longer period of time between increments would produce a considerable amount of plastic deformation and might quite possibly have a decided effect upon the carrying capacity of the column. Accordingly, two methods of testing were adopted. These will be denoted in the following discussion as "fast" and "slow" loading. Under the "fast" loading the load is applied to the column in 10 or more increments with a time interval between increments of 15 minutes or less, during which strain measurements were taken. In the "slow" loading, a load of approximately ¾ of the estimated yield point strength of the column was applied in 8 to 10 equal increments at the same rate of loading as used in the fast loading method. Subsequent loads were applied in 6 to 10 increments at intervals of four hours. With this procedure, strain readings were taken during each 4-hr. interval immediately before and after the application of an increment of load.

The amount of flow in the test piece during a 4-hr. period naturally caused a certain amount of release of load in the testing machine. To minimize this condition for the tests under slow loading, a special load-holding device was used. This consisted of a bed of coiled springs having a total capacity equal to or greater than the column strength and having a total shortening of approximately 1½ in. The shortening of a column due to plastic yielding of a few thousandths of an inch produced very little difference in the pressure exerted by this bed of springs and hence the load was held nearly constant throughout a full 4-hr. period. A view of a column as tested with one of these devices is shown in Fig. 6. Another feature of the tests with slow loading, which lasted from 36 to 48 hours, was the use of a protective case

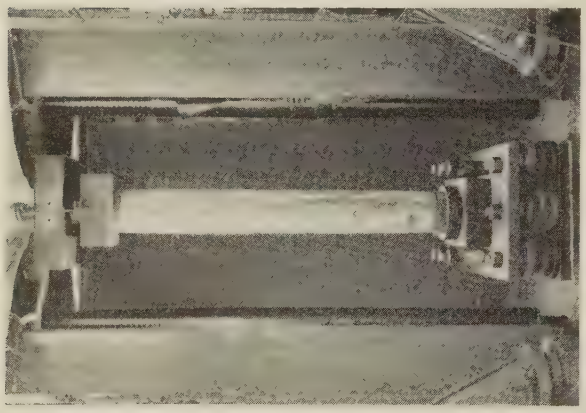

FIG. 7—PROTECTIVE CASE USED WITH SLOW LOADING TESTS, SERIES 2

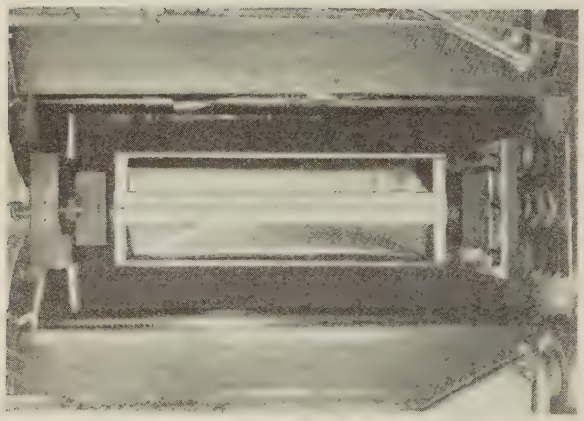

FIG. 6—COLUMN ON TESTING BASE, SLOW LOADING, SERIES 2

which was placed around the column to prevent its drying out. Such a case, lined with wet burlap, is seen in the view of Fig. 7.

The tabulated results of all of the tests of Series 2 are given in Table 10. In all but the tests in which 8000-lb. concrete was used, there were companion specimens tested under both the fast and slow loading, two columns of a kind. In addition to the columns scheduled in the 1930 committee report previously mentioned, 27 plain columns were also made and tested to give further information on the action of the concrete alone under fast and slow loading.

The data of Table 10 indicate that there was not a very marked difference in the carrying capacity of columns tested under the two methods of loading. There was, however, a considerable difference in the amount of deformation measured as indicated by the typical stress-strain curves for corresponding gage lines of columns tested under fast and slow loading, as shown in Fig. 8. From these results it appears that the amount of flow which takes place during a 4-hr. period, while producing quite appreciable changes in length of the test piece, has not produced appreciable changes in strength, except perhaps for the plain columns. The difference in action between plain and spirally reinforced columns is quite readily explained. As has been found in previous investigations, after plain concrete has reached 75 to 85 per cent of its ultimate strength, a decided change in its action takes place wherein lateral bulging develops, internal breakdown of the structure begins, and plastic deformation increases rapidly. The failure of plain concrete may then be expected to take place sooner under the slow loading than under the fast loading. When concrete is restrained within an envelope of spiral reinforcement, it soon reaches a stage of almost entirely plastic deformation wherein the loads carried are in a definite proportion to the lateral pressure exerted by the spiral reinforcement. This proportion is independent of the amount of lateral deformation and hence the column may be expected to carry a given load as long as a definite pressure is exerted by the spiral reinforcement. Failure evidently occurs when the spiral becomes unable to furnish increased lateral pressure with an increase in lateral deformation. Whether it would ever be possible to have sufficient plastic de-

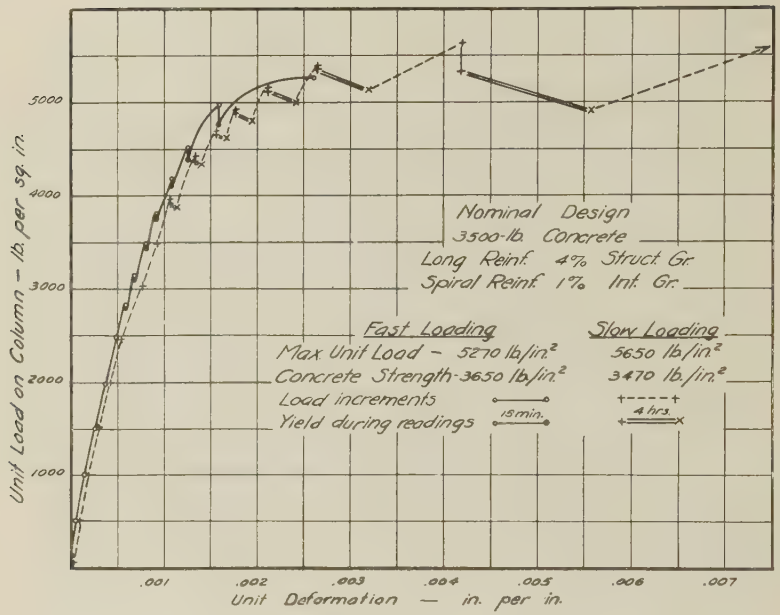

FIG. 8—STRESS-STRAIN CURVES FOR FAST AND SLOW LOADING, SERIES 2

formation or flow of the concrete between spiral wires to cause a decrease in the pressure exerted by the spiral reinforcement is problematic. The relation between the deformations of columns under fast and slow loading will be discussed further in a later report.

A comparison of ultimate column strengths obtained under fast and slow loading methods may be made by reference to Fig. 9, in which column strengths are plotted against the strength of concrete control cylinders. The figure contains the results from all columns of the series made with 1.24 per cent of spiral reinforcement and 3.98 per cent of longitudinal reinforcement of the three grades shown as well as the strength of the plain concrete columns. It is seen that there was no consistent difference in the strengths obtained by the two methods of testing; such differences as are found might be considered as within the range of variation

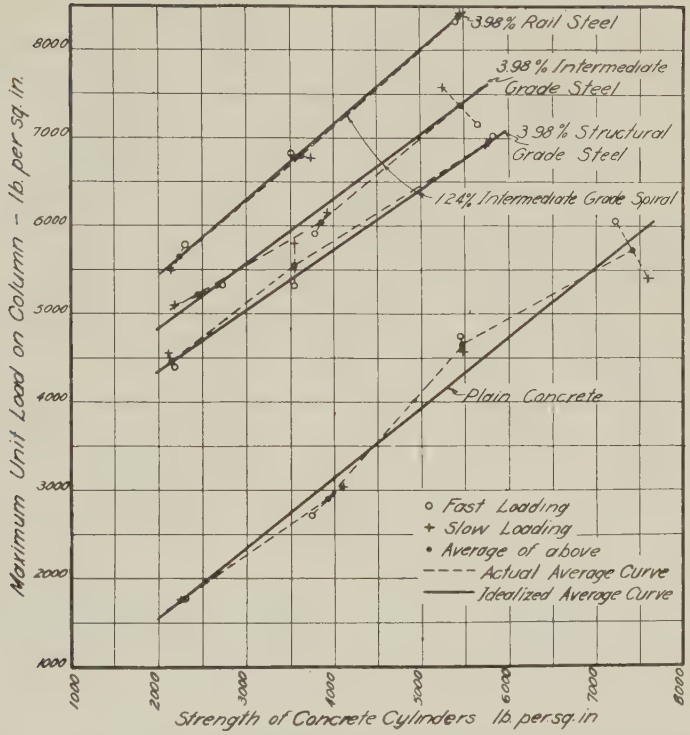

FIG. 9—RELATION BETWEEN COLUMN STRENGTH AND STRENGTH OF CONTROL CYLINDERS, FAST AND SLOW LOADING, SERIES 2

to be met had a single method of loading been used. For this reason, curves have been drawn to represent the average results from the two methods of loading. In plotting these curves the strengths of two individual columns, noted in Table 10 as having shown excessive deflection before failure, have been neglected. One of these columns was thrown clear out of the testing machine at failure, and both appear much weaker than their companion columns.

The curves of Fig. 9 also permit a study of the effect of the three grades of longitudinal reinforcement, and of the three concrete mixtures employed. The points for columns made with rail

steel fall upon a straight line which is practically parallel to the average curve for plain concrete columns in the lower part of the diagram. For columns made with bars of intermediate and structural steel, the plotted points are represented in two ways; the average points are connected by light dotted lines, which represent actual test results; and in addition, heavy solid lines are drawn which fit the respective sets of points reasonably well. In drawing these latter curves, less weight has been given to the points representing 3500-lb. concrete than to the others. It will be noted that the slopes of these two curves are slightly less than the one for plain concrete columns. The average slope for the four curves shown is slightly less than 0.8. This verifies previous tests which indicate that the difference in strength of spirally reinforced columns due to differences in concrete mixtures is equal to the difference in strength of plain columns of these mixtures, times the quantity $(1-p)$. That is, the slopes of the upper three curves might be expected to be 96 per cent of that for plain columns.

The intersections of the solid average curves of Fig. 9 with verticals representing concrete strengths of 2000, 3500 and 5000 lb. per sq. in. have been plotted in Fig. 10, correction being made in this way for variations in actual cylinder strengths from the designed values. Fig. 10 shows column strengths plotted against the average yield point stress for each grade of longitudinal reinforcement. Such a comparison is admittedly inaccurate since there was a considerable variation in the yield point stress for each grade of steel, but corrections for variations in the reinforcement in individual columns cannot be made until the tests of steel coupons are completed. (Test coupons have been saved from the two 22-ft. lengths of bar used in each column of this group.) Fig. 10 shows, however, that the increase in column strength is nearly proportional to the increase in average yield point stress for the reinforcement. With 3.98 per cent of reinforcement, an increase in yield point stress from 40,400 to 68,300 lb. per sq. in. should produce an increase in column strength of 0.0398 times 27,900 or 1110 lb. per sq. in., while the average increase shown for the three curves is 1300 lb. per sq. in. The rate of increase is nearly the same for the columns made with the three different grades of concrete.

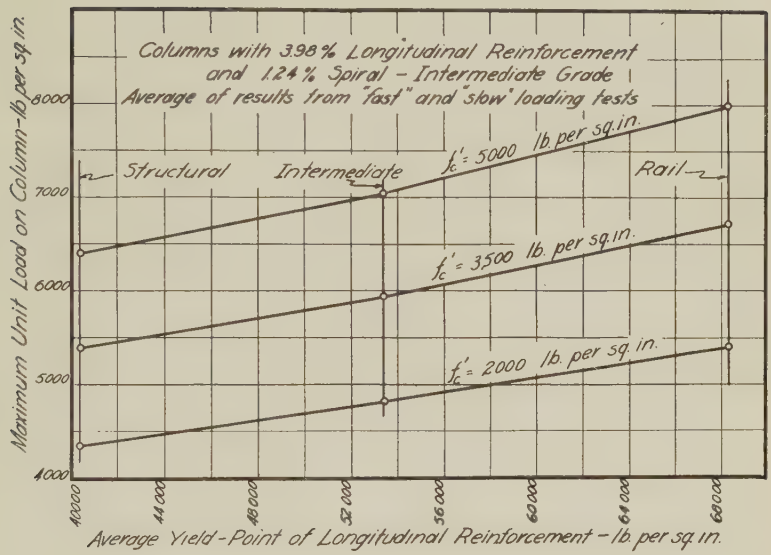

FIG. 10—RELATION BETWEEN COLUMN STRENGTH AND YIELD POINT STRESS FOR LONGITUDINAL REINFORCEMENT, SERIES 2

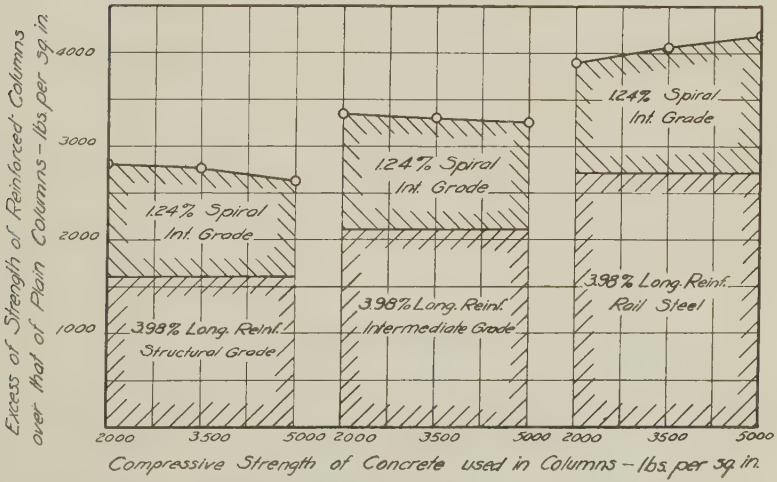

FIG. 11—CALCULATED DISTRIBUTION OF COLUMN STRENGTH BETWEEN LONGITUDINAL AND SPIRAL REINFORCEMENT, SERIES 2

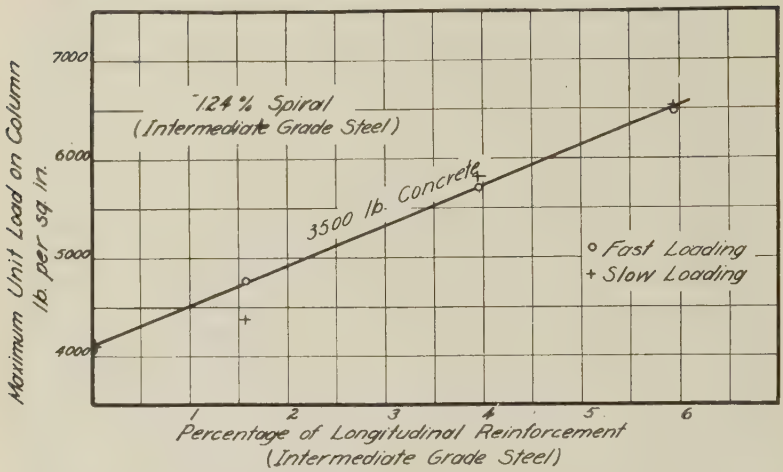

FIG. 12—RELATION BETWEEN COLUMN STRENGTH AND PERCENTAGE OF LONGITUDINAL REINFORCEMENT, SERIES 2

In studying the distribution of column load between the concrete section, the longitudinal steel and the spiral steel, further reference may be made to Fig. 9. Considering that the concrete of the reinforced columns carried a stress equal to the strength of the plain columns on a section 96 per cent of the core area, the portion of the column strength to be attributed to the reinforcement is found, and is shown by the plotted points in Fig. 11. This is distributed between longitudinal and spiral reinforcement, by computing the load on the former, 0.0398 times the yield point stress. The shaded areas indicate the relative portions of the column load attributed to each form of reinforcement. In view of the fact that accidental variations in column strength have thus been thrown into the portion attributed to the spiral reinforcement it is of interest that this portion is so nearly constant for the nine combinations of concrete and longitudinal steel shown.

Another group of columns of this series was made with 3500-lb. concrete, 1.24 per cent of intermediate grade spiral, and 0, 1.57, 3.98 and 5.94 per cent of intermediate grade longitudinal steel. The column strengths found with both fast and slow loading are

plotted in Fig. 12 against percentages of longitudinal reinforcement. Variations in concrete strength as shown by the control cylinders for these columns have been corrected by the use of the average curve for plain columns given in Fig. 9, and the column strengths shown in Fig. 12 correspond to cylinder strengths of 3500 lb. per sq. in. As in Fig. 9, there is little difference in the results for fast and slow loading. The test values are represented by an average curve for the two loadings that is nearly a straight line. Since there is some variation in the quality of the steel used to produce the three percentages, the average curve should not be exactly linear. The increase in strength with increase in longitudinal reinforcement is slightly less than that computed from the percentages and the average yield point stresses as listed in Table 5. The average yield point for the 1.57 per cent steel was 45,600 lb. per sq. in.; that for 3.98 per cent, 53,400 lb. per sq. in.; and for 5.94 per cent, 45,200 lb. per sq. in. On this basis the contribution of the three percentages of longitudinal reinforcement to the column strength should be 715, 2150 and 2685 lb. per sq. in. respectively. From Fig. 9, 3500-lb. concrete should contribute to the column strength about 2750 (1-p) lb. per sq. in. This leaves a remainder which may be attributed to the 1.24 per cent of spiral reinforcement averaging 1165 lb. per sq. in. for the four sets of test values.

Series 2 also included tests of columns made of concrete designed to give a 56-day cylinder strength of 8000 lb. per sq. in. The tests were made by the fast loading method only. The strengths obtained with this rich concrete were quite variable, and since a shortage of reinforcing spirals delayed the testing of part of the group until January, 1931, no analysis of the test results will be given here. The principal results for the group are given in Table 10.

Further analyses of the results of Series 1 and 2, on the basis of more complete information regarding the reinforcement, and in the light of the results of the remaining parts of the investigation, will be made in a later report.

Acknowledgment—The investigation has required the help of a considerable laboratory staff. Especial acknowledgment is made to R. L. Brown, Research Associate, and to L. R. Tucker and T. G. Taylor, Research Graduate Assistants, who have given valuable assistance in the testing program, and in the reduction of the data.

Second Progress Report on Column Tests at the University of Illinois

BY F. E. RICHART* AND G. C. STAEHLE†

SERIES 3—COLUMNS UNDER LONG TIME LOADS

1. *Introduction.*—This report is a continuation of the progress report given in the A. C. I. Journal, February, 1931[1], on the results of the Reinforced Concrete Column Investigation. The previous report described the part of the investigation being conducted at the University of Illinois in cooperation with the American Concrete Institute and Lehigh University, gave details of the methods used in making and testing columns, and included a preliminary report on the tests of Series 1, "A Study of End Conditions of Column," and Series 2, "A Study of Method of Loading."[1] The outline of the entire investigation, prepared by Committee 105 of the Institute is given in the 1930 report of Committee 105[2].

The tests at the University of Illinois have been carried on as a cooperative research project of the Engineering Experiment Station, under the administrative direction of Dean M. S. Ketchum, Director of the Station, and Professor M. L. Enger, Head of the Department of Theoretical and Applied Mechanics. Acknowledgment is made of the assistance given by L. R. Tucker and T. G. Taylor, members of the Experiment Station Staff, in the testing work and the reduction of the data.

Due to the lack of time for consideration of the test results by the other members of Committee 105, this report (like the previous one) has been prepared as an individual report by those

in charge of the tests at the University. However, it is desired to give full acknowledgment of the help of all members of the Committee, who participated in planning the tests, furnished many facilities for the work and advised concerning all phases of the investigation.

2. *Object and Outline of Tests of Series 3.*—It has been realized for many years that the shrinkage of concrete will set up stresses in a reinforced concrete column, and great emphasis was placed on this effect of shrinkage and the similar one of time yield or plastic flow by McMillan[3] in 1921. The purpose of the present series of tests was (1) to make a systematic study of the amount of shrinkage and plastic flow produced in reinforced concrete columns under the ordinary design load, continuously applied, and (2) having induced a redistribution of stresses in a column due to the action of shrinkage and flow over a period of a year, to note the effect upon the strength of the column as found by testing it to failure under the usual method of loading.

The series as outlined included 108 columns, of which 60 are to be held for a year under design load and 48 are duplicate columns held in similar storage but under no load. The design loads have been computed from the column formulas of the A. C. I. Joint Building Code, except for four columns, which have been loaded according to the design formula of the 1916 building code for New York City.

A list of the columns of Series 3, including the design loads used, is given in Table 1. All columns were made and cured in the moist room for 56 days. They were then placed in one of the following four conditions, of loading and storage, to be maintained for a period of one year:

(1) Under design load, in air of laboratory.
(2) Under no load, in air of laboratory.
(3) Under design load, in moist room.
(4) Under no load, in moist room.

The columns stored in air are subject to temperatures of 70 to 90 deg. F., and to relative humidities of 40 to 90 per cent. Those in the moist room are at temperatures of 70 deg. ± 4 deg., in a saturated atmosphere. Systematic strain measurements are

[3]A Study of Column Test Data, by F. R. McMillan, Proc. A. C. I., V. 17, p. 150-181, 1921

TABLE 1. DATA OF COLUMNS OF SERIES 3

Two companion columns of each type, except plain columns. All columns have 8-in. core diameter, 8¼ in. overall diameter, and are 5 ft. long. All columns cured 56 days in moist room, preceding the one-year period of loading and strain measurement. Design loads based on A. C. I. Joint Building code formulas, except for 4 columns indicated by *, which were loaded according to 1916 New York Code formula. All reinforcement is of intermediate grade steel. Columns marked † were loaded in 1931, all others in 1930.

Design Concrete Strength Lb. per sq. in.	Percentage of Reinforcement		Design Load on Column Lb.	Columns Loaded			Columns not Loaded

being made on all of the columns throughout the year using a 10-in. Whittemore strain gage.

Table 1 shows that three grades of concrete were used. These were designed to produce 56-day cylinder strengths of 2000, 3500, and 5000 lb. per sq. in. Three percentages of longitudinal reinforcement, roughly 1.5, 4 and 6, and two percentages of spiral, 1 and 2, were employed in the various columns.

In addition to the 108 reinforced columns originally scheduled 45 plain columns have been made and six of these will be held under constant load for a year. These plain columns were added to provide information on the flow and shrinkage of unreinforced concrete, and to serve as control specimens with regard to the strength of the concrete in the reinforced columns at the end of a year. Four 6 by 12-in. control cylinders were also made with each column, two to be tested at the age of 56 days, and two to be tested a year later when the column is tested to failure.

3. *Materials.*—Details regarding the properties of the concrete and reinforcing steel and a description of the making of columns are given in the progress report published in the A. C. I. JOURNAL, February, 1931.

Average properties of the three concrete mixtures employed are as follows:

Designed strength, lb. per sq. in. (56-day moist curing)	2000	3500	5000
Proportions of mix, by weight	1:4.05:4.95	1:3.27:3.98	1:2.25:2.75
Water-cement ratio, by volume	1.40	1.10	0.80
Average slump, in.	2.9	4.3	5.1

The actual 56-day cylinder strengths are given in Table 1. The materials used in all columns were Lehigh portland cement, Lincoln, Ill. sand and Attica, Ind. gravel. The concrete was mixed 4 minutes in a one-bag batch mixer.

Both the longitudinal and spiral reinforcement were of intermediate grade steel. The selection of bars to provide the three percentages of longitudinal steel was as follows:

1.57 per cent	4 ½-in. round	Yield Point, 45,600 lb. per sq. in.
3.98 per cent	8 ½-in. square	Yield Point, 53,400 lb. per sq. in.
5.94 per cent	4 ⅝-in. round 4 ¾-in. round	Yield Point, 39,300 lb. per sq. in. 51,100 lb. per sq. in.

The reinforcing spirals, of 8-in. outside diameter, were made of hot-rolled rod. The 1.24 per cent spirals were of No. 5 rod, 1.35 in. pitch, and the 2.0 per cent spirals were of ¼-in. rod, 1.19 in. pitch. The stress at which a unit elongation of the spiral rod of 0.5 per cent was produced (in tension tests of coupons) has been taken as a "useful limit" for the material; the average values found were 49,400 lb. per sq. in. for the No. 5 rod and 48,200 lb. per sq. in. for the ¼-in. rod. The respective ultimate tensile strengths were 79,500 and 74,200 lb. per sq. in.

4. *Making and Curing Test Columns.*—Preparatory to making columns, the reinforcing bars were milled to exact length and wired to the spirals or ties to form a unit. The columns were cast in tight steel forms. A tamping rod and a light air hammer were used in placing the concrete. Precautions were taken to bring both ends of the reinforcing bars into the planes of the concrete bearing faces of the columns.

Forms were removed 24 hours after a column was cast. Due to the fact that the forms were water-tight and the top of the column had been covered by a metal capping plate, the column surfaces were damp when the forms were removed and there had evidently been little or no loss of moisture from the column. Shortly after the removal of forms steel plugs were set to form gage lines on which to measure concrete deformations, and gage lines were laid out on the longitudinal steel. The column was then placed in the moist room or stored under wet burlap for one day, when all gage lines were drilled and initial strain measurements were taken. The exposed steel at gage holes was then given a coating of vaseline as a protection against corrosion and the columns were placed in the moist room to complete the 56-day period of moist curing. Strain measurements taken at the end of this period furnished a record of the volume change, usually a slight expansion, produced by about 54 days of moist storage.

5. *Method of Applying Continuous Loads.*—The apparatus for applying and holding a constant load on the columns may be described by reference to Fig. 1. Companion columns, tested in pairs to save apparatus, are confined between bearing plates by four steel tie rods. The desired tension is maintained in these

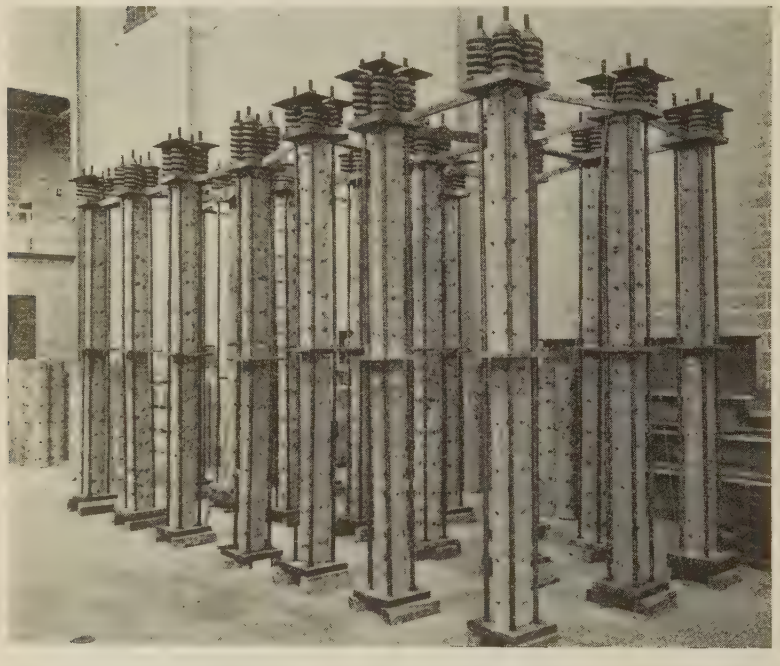

FIG. 1—VIEW OF COLUMNS OF SERIES 3 IN MATERIALS TESTING LABORATORY

rods by four heavy coiled compression springs, to be seen at the top of each rig in the figure. These springs were calibrated, after having been subjected to ten repetitions of their capacity load (for the purpose of relieving localized stresses and thus minimizing the permanent set which might occur under the long continued loading). The desired load was applied to the columns by tightening the nuts on the four tie-rods until the necessary shortening of each spring was reached. This shortening varied from 1.0 to 1.3 in. with the five sizes of springs used, and since errors in measurement on the two gage lengths on each of the four springs would normally be compensating, the design loads are believed to be accurate to within 1 per cent. A complete set of strain measurements was taken on the columns immediately before and after applying the load, and at regular intervals thereafter.

Measurements on gage lines on the springs were made coincident with the reading of strains in the columns. With shrinkage and yielding of the columns a slight decrease in the indicated spring load resulted. One complete adjustment of all loading rigs was made after about three months of loading and since that time there has been little change in the applied load. At the time of the adjustment, several springs were removed and checked, but practically no permanent set of the springs could be detected.

It was anticipated that unequal strains might be produced on opposite sides of a column by eccentricity of load or by variations in the material of the column. To minimize eccentric loading and to stabilize the loading rig, the tie rods were run through holes in a bearing plate between columns at mid-height of the rig. There has been no appreciable evidence of bending or unequal yielding.

The tie-rods and plates shown in Fig. 1 were furnished for the work through the courtesy of the American System of Reinforcing and the Illinois Steel Co., Chicago.

6. *Working Loads.*—As previously noted, the columns were loaded at safe working stresses computed by use of the design formulas for tied and spirally reinforced columns of the A. C. I. Joint Building Code and for spirally reinforced columns of the 1916 New York City building code. This does not imply that the test columns met all of the design requirements of these two codes. For the purposes of the investigation it was considered desirable to use combinations of materials outside the restricted field of either code. Thus most of the columns have a percentage of spiral reinforcement in excess of one-fourth that of the longitudinal reinforcement, as required by the A. C. I. code, and one type of column has a proportion less than one-fourth. None of the columns have an appreciable protective shell of concrete outside the reinforcement. The New York code does not recognize a grade of concrete having a strength of 3500 lb. per sq. in., nor does it permit the use of more than 4 per cent of longitudinal reinforcement. Hence the use of these formulas in determining working loads is not in strict accordance with the apparent intent of the codes, but it is thought that the use that has been made of them has been reasonable and fairly conservative.

The working loads used with all columns are listed in Table 1. The loads for columns without spiral reinforcement were computed by use of the Joint Building Code formula for tied columns. For the plain concrete columns, no formula is applicable. The loads used were chosen to produce concrete stresses comparable with those existing in the reinforced columns in the early stages of loading. It is evident that further tests are needed to determine the flow of the different grades of concrete under various intensities of load.

7. *Flow and Shrinkage During a Period of Five Months.*— The end of the one-year loading period will be reached for the various reinforced columns during June, July and August, 1931. Similar periods for plain columns will extend to March, 1932. However, observations have been taken on all of the reinforced columns and some of the plain ones for five months or more, and it appears that the most rapid development of flow and shrinkage strains has taken place in this period. Figs. 2 to 9 show values of measured strains in the columns, beginning at the end of the 56-day curing period, when the columns were placed under load, and continuing for 5 months. Using a modulus of elasticity of 30,000,000 lb. per sq. in. these strains may be translated into stresses in the longitudinal steel. The curves have been grouped as much as possible according to the class of concrete used in the columns. Generally the time-deformation curves for each pair of companion columns is plotted on the same diagram with similar curves for the corresponding unloaded columns. The storage of columns in the air of the laboratory is designated as "Air Storage" while storage in the moist room is designated as "Moist Storage."

It may be noted that the observations plotted on these diagrams (excepting Fig. 9) represent the strains in reinforcing bars only. The strains on adjacent concrete gage lines have not yet been computed from the original readings, but it may be assumed that they will closely approximate those in the longitudinal steel.

A record was kept of temperatures and relative humidity in both the laboratory and moist rooms when all strain observations were taken. A recording thermometer in the moist room has

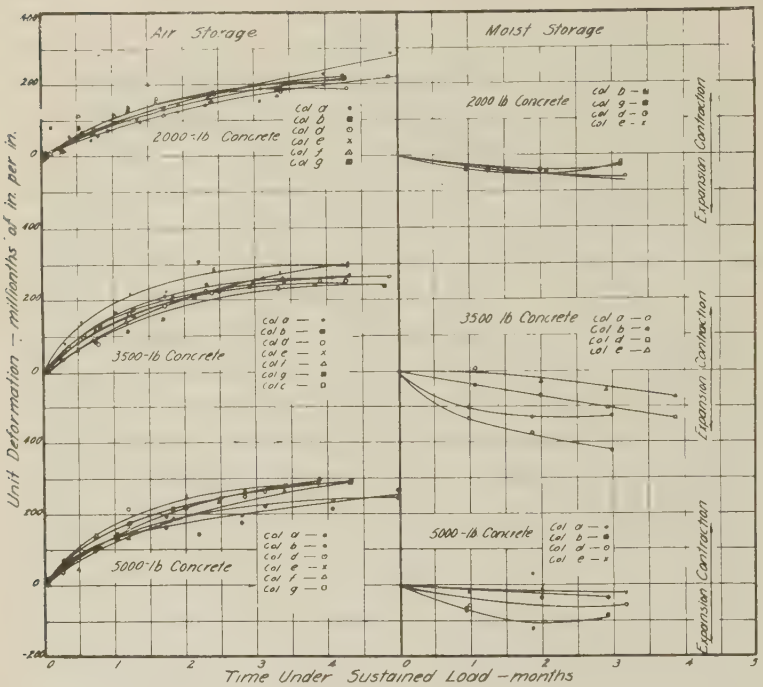

FIG. 9—TIME-DEFORMATION CURVES FOR PLAIN CONCRETE COLUMNS

provided a continuous temperature record over the period of the tests, and a recording psychrometer was installed in the laboratory storage room in January, 1931. Previous to this date, the temperature and humidity records for the laboratory storage room were mainly individual day time observations. In Fig. 10 is shown the record of the average recorded daily temperatures for both dry and moist storage rooms since June, 1930. A similar record of the average relative humidity of the laboratory air is given in the figure. From many observations it is known that the relative humidity of the moist room was maintained at practically 100 per cent, except for short intervals when strain measurements were taken.

The range of temperatures and humidities may be of interest in connection with the curves of Figs. 2 to 9. Knowing from

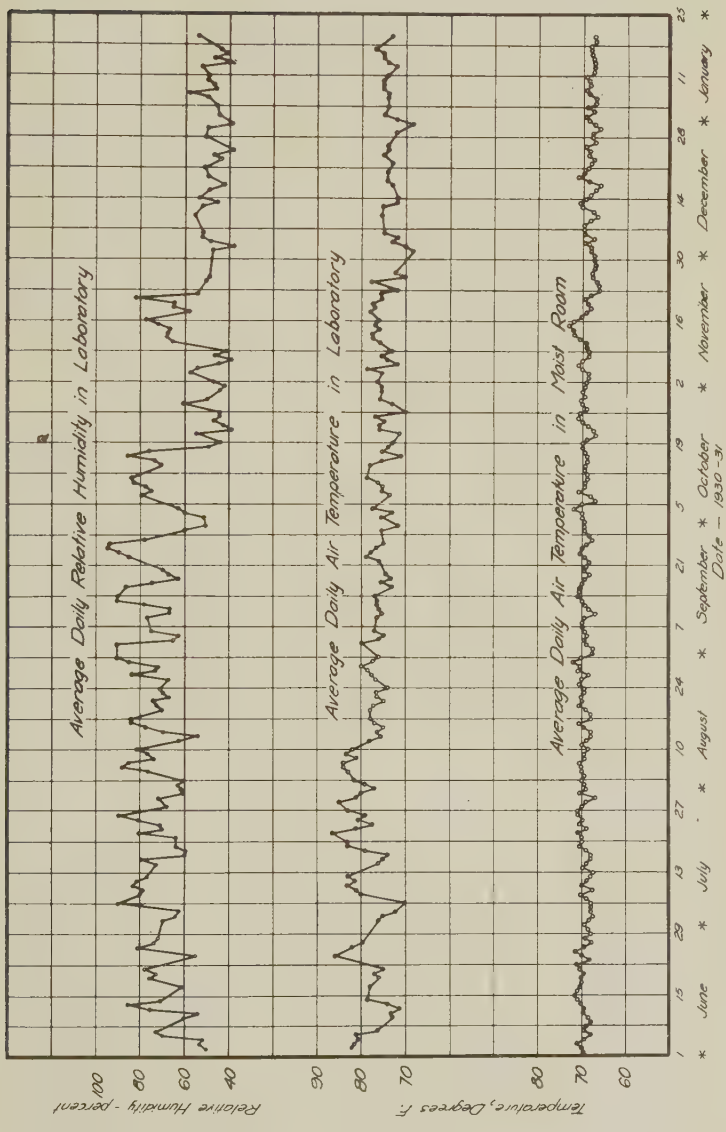

FIG. 10—TEMPERATURE AND HUMIDITY RECORDS FOR PERIOD OF TESTS

Table 1 the date at which loading of any column was started, the trend of temperature and humidity variations thereafter may be traced in Fig. 10, and compared with any unusual variation in the measured strains in the column.

The strains plotted in Figs. 2 to 9 have not been corrected for the effect of temperature changes. For the columns in moist storage such temperature changes were negligible. The air-stored columns are known to have been at very nearly 70 deg. F. when removed from moist storage and placed under spring loading, and subsequent air temperatures of the laboratory are given in Fig. 10; however, it is certain that the effective temperature of any column did not vary as widely or as rapidly as the air temperature of the laboratory. A correction in column strains based on the variation in air temperature might introduce errors as great as if no correction were attempted. It is believed that the uncorrected strains in Figs. 2 to 9 are in no case in error due to temperature effects more than 0.000067 (corresponding to an increase of 10 deg. F. over the initial temperature of the column, and to an indicated tensile stress in the steel of 2000 lb. per sq. in.) and for observations made since August, 1930, the possible error would be much less than this. Any such error is opposite in sense to the effect of shrinkage or flow; if a column has increased in temperature during the loading period, the measured strains attributed to shrinkage and flow are less than the true amount of shrinkage and flow.

The amount of plastic flow, obtained by subtracting the strains of an unloaded column from those of the corresponding loaded one, is unaffected by any temperature changes, since such changes are the same in loaded and unloaded columns.

The strain readings were taken at the time of loading the columns, then generally after 1, 3, 7, 14 and 28 days, and at monthly intervals thereafter. The strain measurements were taken on a total of 16 gage lines, 8 at the middle and 4 each near the top and bottom of column, and included two independent sets of observations. These measurements on a total of 153 columns have required the help of several observers, and in general the strain measurements for any column were taken by two or more observers. The accuracy of the strain gage measurements in this series of tests is therefore considerably less than that obtained

in the other series of the investigation, in which a complete test could be made by one observer in a period of only a few hours, with a definitely established routine for strain measurements.

8. *Elastic Deformations.*—The deformation measured at the time the spring load was applied to any column will be denoted here as an elastic deformation, in contra-distinction to the deformation which resulted from continued loading. Since the concrete stresses were generally well below one-half of the compressive strength, and the steel stress only a small fraction of the proportional limit, it is likely that the strains developed in applying the load were very nearly, if not wholly, elastic. The corresponding steel stresses, which fix the starting point of the curves of Figs. 2 to 8, seem rather erratic from an inspection of the figures. However, a little study of the probable elastic action of the various columns tends to verify the general trend of the measured values. It seems reasonable to assume that the initial stresses due to a load no greater than the design load will be determined by the elastic properties of the two materials; that is, the stresses in concrete and longitudinal steel will be proportional to the respective moduli of elasticity. A large number of extensometer tests of the control cylinders of this series have been made, but not analyzed; however, the average moduli for 10 cylinders, selected at random, of each grade of concrete are as follows:

Designed Strength lb. per sq. in.	Actual Strength lb. per sq. in.	Modulus of Elasticity lb. per sq. in.	Modular Ratio n
2000	2200	2,830,000	10.6
3500	3730	3,800,000	7.9
5000	5460	4,290,000	7.0

These moduli represent the initial slopes of the stress-strain curves, for which the proportional limit was usually 30 to 50 per cent of the ultimate strength. Using 30,000,000 lb. per sq. in. as the modulus for steel, values of the ratio, n, of the moduli for steel and concrete have been computed. This ratio should also represent the ratio of initial steel and concrete stresses. Table 2 gives values of the calculated initial stresses in steel and concrete due to the design loads, based upon the above values of n. The table also shows values of the stresses determined from

TABLE 2. STRESSES IN COLUMNS OF SERIES 3.

The unit stresses, f_s in steel, and f_c in concrete, are in lb. per sq. in. Positive values are compressive stress; negative values, tensile stress.

Nominal Column Design			Design Load lb.	Loaded Columns							Unloaded Columns

**According to N. Y. City Bldg. Code; all others according to A. C. I. Joint Bldg. Code.
*By extrapolation.

strain measurements. It is of interest that although there are a few rather large discrepancies between the two sets of values, the general trend of the two is quite similar. Furthermore, the average values of the ratio of the measured initial steel and concrete stresses, for columns of the three grades of concrete are 10.0, 8.1, and 7.1, as compared with the above values for n (based on cylinder tests) of 10.6 ,7.9 and 7.0.

The design loads which were computed by the A. C. I. formula for spirally reinforced columns are seen to produce relatively high initial concrete and steel stresses in the columns having a large percentage of longitudinal steel. The ratio of initial concrete stress to the concrete strength is not constant, but in general increases with an increase in percentage of longitudinal reinforcement and decreases with an increase in concrete strength.

Table 2 includes data on the stresses in concrete and steel after a 5 months period of observation for both loaded and unloaded columns. The stress in the unloaded columns may be attributed to the effect of volume changes, while the increase in stress in the loaded columns is evidently due to volume change, plastic flow and change in elastic strain. It is interesting to note that the greatest increase in steel stress due to the three combined effects was 14,800 lb. per sq. in., and in most cases with the air-stored columns the increase was from 6000 to 14,000 lb. per sq. in. For the moist-stored columns, the increase was very much less.

9. *Relation Between Strength of Concrete and Column Deformations.*—For further study of the effect of variations in concrete strengths upon column deformations, curves from Figs. 2 to 8 have been replotted in Fig. 11. Each curve represents the average result from a pair of companion columns and each group of curves represents the results from columns that are alike except for the quality of concrete with which they were made. It is difficult to make comparisons as to the relation between concrete strength and the deformation due to flow and shrinkage because the concrete in the three types of column was subjected initially to neither the same stress nor to the same proportion of the concrete strength in the three cases. Furthermore, for air-stored columns, the stress in the concrete gradually decreased as the concrete deformed so that at the end of the 5-month period the concrete stress had lowered considerably, as shown in Table 2. However, the combined effect upon column action is such that there is no great difference apparent in the time-rate of deformation for the columns made with 2000, 3500 and 5000-lb. concrete. It seems probable that there may be a relation between intensity of concrete stress and the corresponding time-rate of deformation

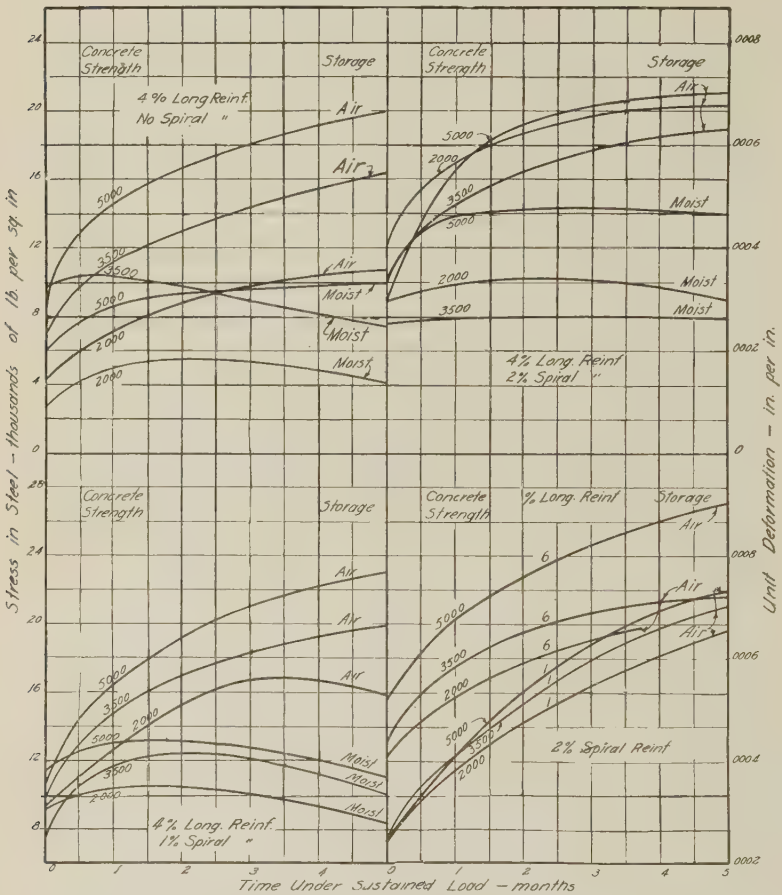

FIG. 11—TIME-DEFORMATION CURVES, VARYING CONCRETE STRENGTHS

at any point on the curves of Fig. 11. Such a relation would be expected to differ for the three grades of concrete.

Fig. 11 also permits a comparison between the deformations found in columns held under load in air and in moist storage. The deformations in the air-stored columns were much larger than those in the moist-cured columns and were increasing at the end of 5 months, whereas in many cases the strains in the moist-stored columns had reached a maximum and were decreas-

ing at the end of the period shown. Such a decrease is also shown by the strain curves for unloaded columns in Figs. 2 to 8 which would indicate that the columns were expanding due to the 5 months storage in the moist room. Since the total deformation of loaded columns is evidently a combination of shrinkage or expansion, plastic flow and elastic deformation produced by the applied load, it seems plausible that the plastic flow after several months of moist storage may be counteracted by the expansion due to the presence of moisture and by an increase in the stiffness of the concrete due to the moist curing. That the elastic strain may decrease due to an increase in modulus of elasticity with age has been shown by Glanville[4] in recent tests of flow of plain concrete under sustained load. This may explain the fact that the flow of plain concrete has been found by Davis[5] and others to be less for specimens in moist storage than for those in dry storage.

10. *Relation Between Percentage of Spiral Reinforcement and Column Deformations*—To permit convenient comparison of time-deformation curves for columns that are alike except for the percentage of spiral reinforcement, Fig. 12 has been drawn. Each pair of curves represents average results for columns with 1.24 and 2.0 per cent of spiral reinforcement, for which the design loads were identical. It was planned to include the results from the tied columns in the comparison, but since the design loads differed from those for spirally reinforced columns, the results did not appear comparable. There is no reason to believe that the presence of spiral reinforcement should have any appreciable effect on the longitudinal strains due to shrinkage, flow or load of the intensity used; this view is supported by the evidence given in Fig. 12. There is no consistent difference in the deformations developed in the presence of the two amounts of spiral, and the differences are of a magnitude which may be explained by errors of observation and differences in the materials and treatment of the columns.

11. *Relation Between Percentage of Longitudinal Reinforcement and Column Deformations.*—Average time-deformation

[5] "Flow of Concrete Under Sustained Compressive Stress." by R. E. Davis and H. E. Davis, Proc. A. S. T. M., V. 30, Part 2, 1930.

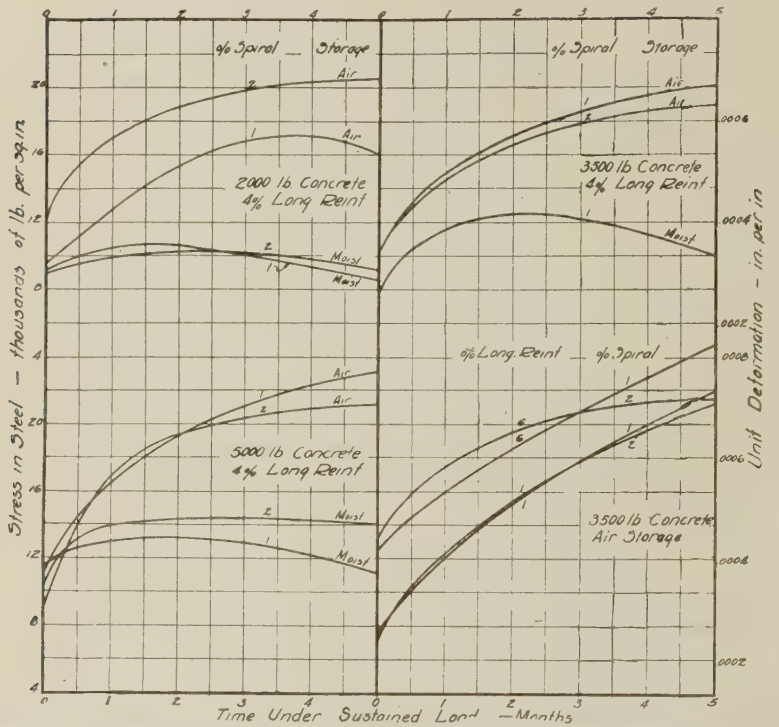

FIG. 12—TIME-DEFORMATION CURVES, VARYING PERCENTAGES OF SPIRAL REINFORCEMENT

curves from Figs. 2 to 8 have been grouped in Fig. 13 to facilitate a study of the effect of variations in amount of longitudinal reinforcement in columns otherwise alike. The three percentages of longitudinal steel were roughly 1.5, 4 and 6. Since all moist-stored columns were made with 4 per cent of longitudinal steel, this comparison is made only between the results from columns stored in air. The figure includes curves for columns made with three grades of concrete and 2.0 per cent spiral reinforcement, also for columns of 3500-lb. concrete with 0, 1 and 2 per cent of spiral reinforcement.

As noted with reference to Table 2, the curves for columns with 6 per cent of longitudinal steel generally start at a higher steel stress than do those for the smaller percentages. This follows from the fact that the A. C. I. formula for spirally rein-

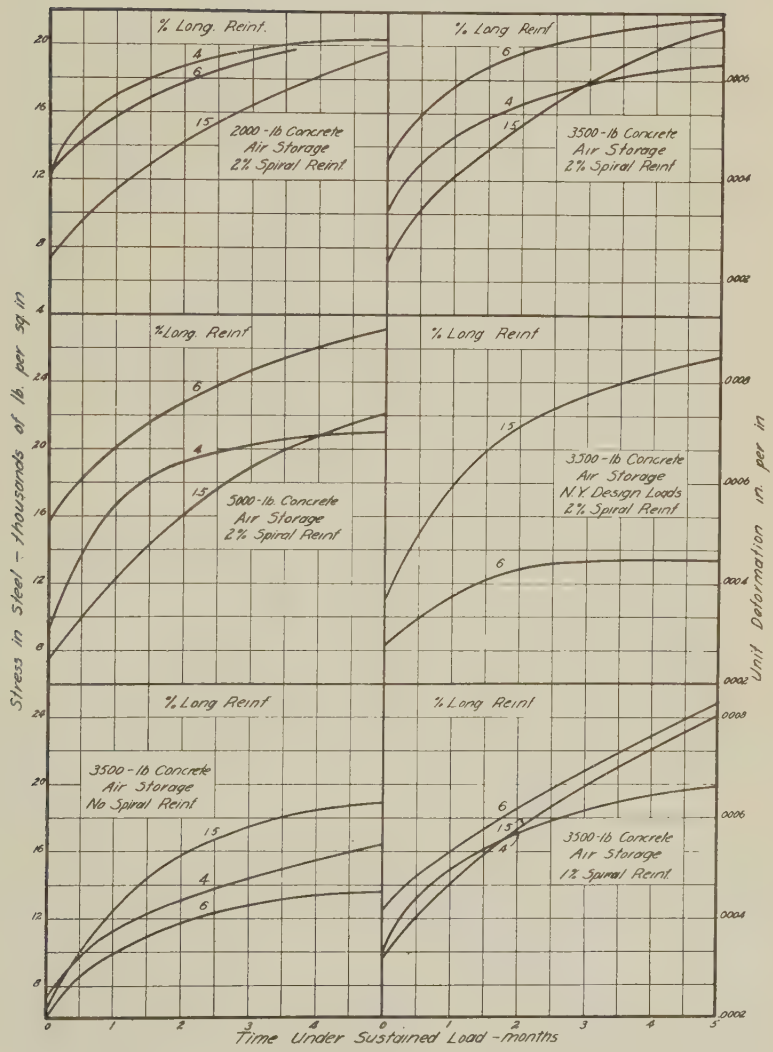

FIG. 13—TIME-DEFORMATION CURVES, VARYING PERCENTAGES OF LONGITUDINAL REINFORCEMENT

forced columns, used in determining the applied loads, permits an increased working stress in both concrete and steel as the amount of longitudinal reinforcement is increased. The elastic strains, therefore were to some extent fixed by the formula used, and by the modulus of elasticity of the concrete.

The change in deformation, and in the steel stresses, in 5 months was generally least for the columns with 6 per cent reinforcement, slightly more for those with 4 per cent and quite obviously greatest for those with 1.5 per cent. This may be due

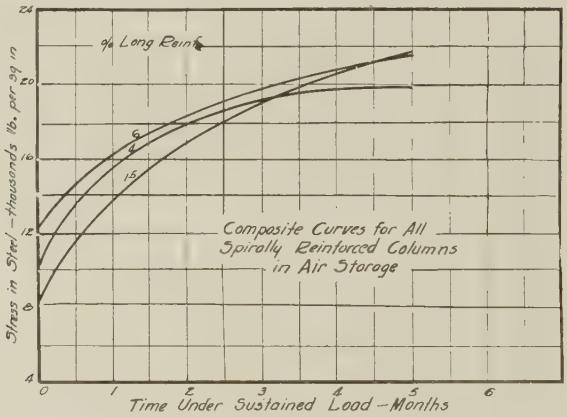

FIG. 14—COMPOSITE CURVES FOR SPIRALLY REINFORCED COLUMNS HAVING VARIOUS PERCENTAGES OF LONGITUDINAL REINFORCEMENT

to the fact that a given amount of yielding or flow decreases the concrete stress much more rapidly in columns with a large amount of longitudinal reinforcement than in those with a small amount. There is no marked difference in the appearance of the curves due to variation in concrete strength or in percentage of spiral reinforcement.

To summarize the relation between longitudinal reinforcement and column deformations, Fig. 14 has been drawn by averaging together the results of all air-stored spirally reinforced columns containing each percentage of longitudinal steel, disregarding the concrete strength and the amount of spiral reinforcement. Each of the composite curves of Fig. 14 thus represents the average

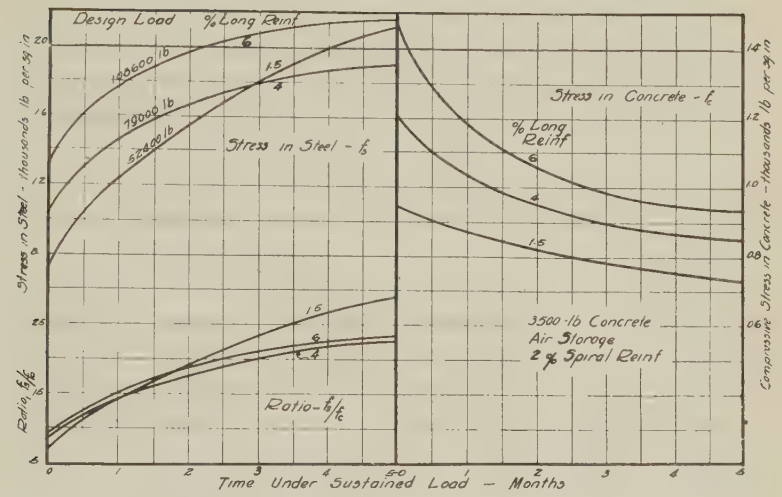

FIG. 15—CURVES SHOWING REDISTRIBUTION OF STRESSES IN CONCRETE AND STEEL DURING A 5-MONTH LOADING PERIOD.

results from ten or more columns. The rate of deformation, and of increase in steel stress during the first two weeks of loading is about equal for the lower two percentages of reinforcement but later on the curve for 4 per cent of reinforcement shows a rapid decrease in rate of deformation as compared to the other two. The curve for 1.5 per cent of reinforcement which started well below the other two, had crossed both of them after 4½ months of loading, and at the end of the 5-month period, shows a much greater rate of increase than the other two curves.

It may be noted that the increase in steel stress during 5 months under load as shown by the composite curves of Fig. 14 were as follows: With 6 per cent of longitudinal reinforcement, 9200 lb. per sq. in.; with 4 per cent, 9700 lb. per sq. in.; and with 1.5 per cent, 13200 lb. per sq. in.

12. *Redistribution of Stresses in Concrete and Steel Due to Inelastic Deformation of Concrete.*—The various time-deformation curves have indicated the increase in the stresses in the longitudinal reinforcement due to shrinkage and flow of the concrete, and it is evident that as the total stress in the steel increased, the total stress in the concrete decreased an equal amount. Table

2 gives a summary of the measured steel stress produced in all columns due to the design load and the increased value of this stress after a 5-months period of loading. From the difference between the applied load and the total stress in the longitudinal steel, the unit stresses in the concrete have also been found, as given in the table.

A conception of the variation in both steel and concrete stresses with time may be aided by reference to Fig. 15. The curves for stress in steel are similar to those of preceding figures, and the corresponding curves showing the concrete stresses at any time during the 5 months have been determined by computation as described above. It is evident that as yielding of the concrete progressed, the concrete stresses fell off rapidly; on the other hand at considerably decreased concrete stresses, yielding was still progressing. Various tests of plastic flow of plain concrete are in agreement on the point that under a constant load the rate of flow gradually decreases with time; if, as in these columns, the applied stress also decreases it would be expected that the plastic flow would progress at a very rapidly diminishing rate. However, tests have been made in which the flow apparently continued for several years, so that it is unsafe to draw any conclusions now as to possible limits in the amount of flow still to be expected.

The lower curves of Fig. 15 show the way in which values of the ratio of steel and concrete stresses varied over the 5-month period. The ratio may be considered equivalent to the modular ratio, n, wherein the modulus of elasticity used is the "sustained modulus of elasticity" and includes the effect of shrinkage, flow and elastic deformation. The curves show no great difference in values of the ratio for the three amounts of reinforcement used, but do show that the values after 5 months of loading average 3 times as great as the initial values. The initial values are in good agreement with the value of n used in computing the elastic distribution of stress in Table 2.

13. *Effect of Initial Strains on Load-Carrying Capacity of Column.*—It is hoped that the completion of this series of tests will furnish information on a number of questions, as yet unanswered, such as: (1) Will the stresses induced in the reinforcing steel reach the yield point of the material, and if so, what will be

the effect upon stresses and deformations, (2) Will the presence of large initial steel strains affect the ultimate strength, or in other words, the factor of safety of the column, and (3) Will the column deformations under continued working loads produce undesirable distortions in a structure?

In the present tests the steel stresses after 5 months are in only one case greater than one-half of the yield point stress for the longitudinal steel, and the rate of yielding is decreasing rapidly. It does not appear probable that the yield point will be reached in any column in the one-year loading period. This is on the assumption that the creep of the reinforcing steel under continued load is negligible at stresses below the yield point as ordinarily defined.

It is known that when a steel bar is stressed beyond the yield point in compression, little lateral force is required to prevent a side-wise buckling if the bar is kept straight. The tests of spirally reinforced columns in the other series of the investigation showed that the longitudinal bars carried load effectively beyond the yield point, though large longitudinal deformations of both concrete and steel took place. The plastic deformation of intermediate grade steel at the yield point is very rapid as compared to the time yields for concrete shown in these tests. Hence it appears that if the yield point of the steel is reached, either due to flow of concrete or to an increase in load, the yielding of the steel will tend to increase the stress in the concrete. Whether, under a constant load, the further yielding of both steel and concrete would be sufficient to bring the spiral reinforcement into action is problematic. However, in the case of the columns which are to be loaded to failure after the end of a year, it seems likely that when the steel reaches its yield point, additional load will be taken by the concrete until it reaches a stress corresponding to the strength of the plain concrete, whereupon the spiral reinforcement will be brought into action. If this is correct, the strength of the column should not be appreciably affected by the initial stresses due to flow and shrinkage.

The deformations in the test columns have not exceeded 0.0009 in. per in., corresponding to a steel stress of 27,000 lb. per sq. in. It does not appear that deformations of this magnitude

should cause any structural difficulties, but if the yield point of the steel were exceeded, the deformations might be of considerable importance.

14. *Summary.*—Little can be stated in the way of conclusions regarding this series of tests, since much of the significance of the results will depend upon the behavior of the columns when tested to failure. It may also be added that in the preparation of this report there has been little time to check up discrepancies in recorded data or to study the results. The following summary may be made as to the foregoing discussion:

1. The stresses in longitudinal reinforcement of columns when initially placed under a working load agree fairly well with the values calculated by assuming the stresses in steel and concrete to be proportional to the respective moduli of elasticity of the two materials.

2. The increase in steel stress in columns held under working loads for 5 months was much greater for columns stored in the air of the laboratory than for those stored in the moist room.

3. The increase in steel stress for the loaded columns was slightly greater for columns with 4 per cent of longitudinal reinforcement than for those with 6 per cent, and much greater for those with 1.5 per cent than for either of the other two.

4. The greatest measured stress in any of the test columns, due to the combined effect of load, shrinkage and flow was 27,100 lb. per sq. in., an increase of 11,600 lb. per sq. in., over the initial stress due to the load alone.

5. The rate of flow does not appear to vary greatly with different grades of concrete or in the presence of different amounts of spiral reinforcement. Any study of the rate of flow is complicated by the fact that the concrete stress decreases as the flow and shrinkage increase.

6. The results thus far obtained in this series of tests indicate that the final results will have a very definite bearing on the question of the proper method of design of reinforced concrete columns.

Readers are referred to the JOURNAL *for June, 1931, for discussion of the Reinforced Concrete Column Investigation of Committee 105. Such discussion should reach the Secretary by May 1, 1931.*

Second Progress Report on Column Tests Made at Lehigh University

BY W. A. SLATER* AND INGE LYSE†

SERIES 3—COLUMNS UNDER LONG TIME LOADS

1. *Introduction.*—The first Progress Report of Committee 105 on Column Investigations was published in the April JOURNAL, 1930.[1] That report gives the program of the investigation and results of the preliminary tests of the materials. The first progress report from Lehigh University on the column tests gives results for Series 1 and 2 and was published in the February, 1931, JOURNAL.[2] The present (second) progress report from Lehigh University gives results for Series 3 on columns subjected to working loads for 20 weeks. Wherever references are made to the results for Series 1 and 2 the information will be found in the first progress report.

2. *Purpose and Program.*—The purpose of Series 3 is to study the effect of sustained working load on the deformation and strength of reinforced concrete columns. The applied working loads were computed according to the formulas given in the present American Concrete Institute Building Code (1928)[3] and the present New York Building Code (1916).[4] The cases to which

[3] $\frac{P}{A} = \left(300 + (0.10 + 4p) f'_c\right) \left(1 + (n - 1)\, p\right)$

[4] $\frac{P}{A} = f_c \left(1 + (n - 1)\, p + \frac{2 f_s n'}{f_c}\right)$

in which P = total load on column

A = total sectional area within outer circumference of spiral
f'_c = ultimate strength of control cylinders
f_c = allowable working stress in concrete. (Foot note continued next page)

each formula was applied are indicated in Tables 1 and 6. The columns in this series did not conform, however, with either code so far as the thickness of the concrete covering of the reinforcement was concerned. The minimum thickness of this covering should be 1½ in. according to the Institute Code and 2 in. according to the New York Code. All columns in this series had an average thickness of the concrete covering of only ⅛ in. A further deviation from the New York Code was made for the columns having 6 per cent longitudinal reinforcement. Even though the New York Code specifies a maximum of 4 per cent longitudinal reinforcement, the load applied to two of the columns having 6 per cent reinforcement was computed from the formula given by the New York Code. The formulas are designed to be used in connection with the 28-day compressive strength of the control cylinders, whereas in computing the working loads for these tests the strength at the time of application of load (56 days) was used instead.

These rather wide divergences from the limits imposed by the Codes are justified by the fact that this investigation is aimed at determining trends, and the applicability of the principles underlying the formulas, rather than the mere testing of columns conforming in every respect to the limitations, within which the Codes are necessarily surrounded. For example, the shell provided outside the spiral is generally intended as fire protection, but to include such a shell on these test columns would, to a certain degree, defeat one purpose of the investigation which is to determine the strength of the spiral core.

The program of tests for Series 3 is shown in Table 1. This does not differ from the program for Series 3 given in the 1930 *Proceedings*, page 611, but is given in more detail for the sake of clarity. Three types of concrete, designed for cylinder strengths of 2000, 3500, and 5000 lb. per sq. in. at 56 days, respectively, were included. The reinforcement was all of intermediate grade

---

f_s = allowable working stress in steel
p = ratio of longitudinal reinforcement
p' = ratio of spiral
n = ratio of moduli

The units used for loads, areas, and stresses are pounds, square inches, and pounds per square inch respectively.

TABLE 1. PROGRAM OF TESTS FOR SERIES 3

Design Strength of Concrete lb. per sq. in.			Reinforcement: Longitudinal per cent			Reinforcement: Spiral per cent			Storage		Method of Test		Number of Columns: Alike	Number of Columns: Total

	3500		1½		6			2		Dry	New York Load		2	4
												Total		108

steel. Three percentages of longitudinal reinforcement, approximately 1½, 4, and 6 per cent respectively, were used. The spiral reinforcement amounted to 0 per cent, 1.2 per cent or 2 per cent of the core area of the column. Some of the columns are stored in the moist room, while the others are stored in the testing laboratory during the period of sustained load. Companion columns under no load are stored with the loaded columns.

The columns have an outside diameter of 8¼ in., a core diameter (outside diameter of spiral) of 8 in., and an overall length of 60 in. The longitudinal bars are 60 in. long and have milled ends, thus insuring direct bearing on both steel and concrete.

Six 6 by 12-in. control cylinders were made with each column, three to be tested when the working load was applied to the column, and three to be stored with the column and tested at the time of loading the column to failure. The working load was applied when the columns were 56 days old. This load is to be maintained for one year and then the columns are to be tested to failure. The first group of columns was placed under load on June 12, and the last on August 15, 1930.

The present schedule calls for deformation readings on the columns immediately before and after the application of the working load, then at 1 day, 1 week, 2 weeks, 4 weeks, 12 weeks, 20 weeks, 32 weeks, and 52 weeks, after the application of the load. Up to the present time this schedule has been adhered to. With each set of observations on the loaded columns, a set is taken on the companion columns stored under no load. This report contains data obtained during the first 20 weeks of the test.

3. *Acknowledgment.*—The success of the work has been promoted by the interested cooperation of the men connected with it. Especial mention is made of C. L. Kreidler, Research Fellow, and of C. C. Keyser, Laboratory Assistant, for their valuable assistance in carrying out the tests and preparing the data for publication.

4. *Proportioning and Strength of Concrete.*—The cement and aggregates used in this series came from the same supply as that used in Series 1 and 2. The mixes used for the different strengths

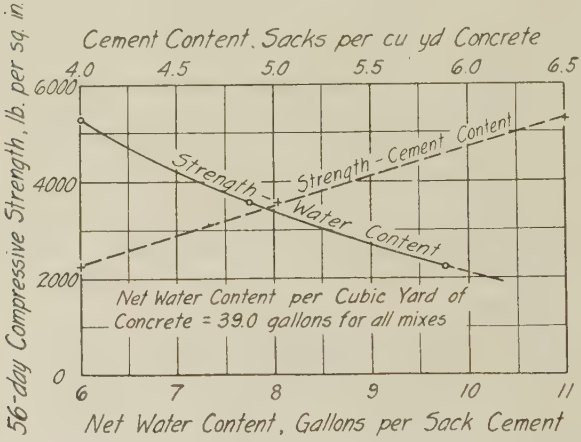

FIG. 1—RELATION BETWEEN STRENGTH AND WATER CONTENT AND BETWEEN STRENGTH AND CEMENT CONTENT FOR CONCRETE USED IN SERIES 3

of concrete were the same as those used in Series 2. Two batches of concrete were required for each column and its six control cylinders. Four minutes mixing was used, one minute dry, and three minutes wet. The two batches were dumped into a metal container and mixed together by hand before placing in the column mold. Table 2 shows the uniformity in strength and slump. The uniformity throughout the series is good, although nearly nine weeks elapsed between the making of the first and the last columns designed to have concrete of the same strength.

Table 3 gives the summarized data of the concrete. A good agreement was found between the strength designed and that secured. The water content was 39.0 gal. per cu. yd. of concrete for all mixes. This produced a placeable concrete and only a small variation was found in the consistency as measured by the slump. Fig. 1 shows the relation between the strength of the concrete and the water-cement ratio used in the mix. The strength-water-content relation was a smooth curve very similar to that obtained for Series 2. The relation between cement content and strength is given by the straight, broken line. This diagram confirms the results of former tests which have indicated that with the same aggregates and a constant water content per cu. yd. of concrete, the slump was approximately constant and

*Assumed 0.7 per cent absorption by weight of dry aggregates.

the strength increased in proportion to the increase in the cement content.

5. *Modulus of Elasticity of Concrete.*—The modulus of elasticity was determined on one control cylinder from each column. The apparatus used was the same as that described in the report of Series 2. The results obtained were averaged for each type of concrete used, and these averages are plotted in Fig. 2. The slope of the tangent at a stress of 500 lb. per sq. in. was taken as the modulus of elasticity of the concrete.

6. *Reinforcement.*—The longitudinal reinforcement consisted of intermediate grade deformed steel bars and came from the same supply as that described in Series 2. The bars were 22 ft. long when received. At the laboratory they were cut into four 5 ft. lengths and a 2-ft. test coupon. The coupons from each set of four bars were tested for yield-point stress and ultimate strength. The summary of these tests is given in Table 4. Both yield-point stress and the ultimate strength of the coupons (based upon nominal areas) varied considerably. The variation in weights of bars of the same nominal size indicates that the principal variation in strength was probably due to the variation of the cross-section of the bars, rather than to difference in quality of the steel.

The lateral reinforcement consisted of intermediate grade wire spirals. The spirals had an outside diameter of 8 in., and an overall length of 59 in. Three extra turns were provided at each end of the spiral for anchorage. A No. 5 rod (nominal diameter 0.207 in.) having a 1.35-in. pitch gave 1.2 per cent lateral reinforcement and a ¼-in. rod having a 1.20-in. pitch gave 2 per cent lateral reinforcement. An identified test coupon accompanied

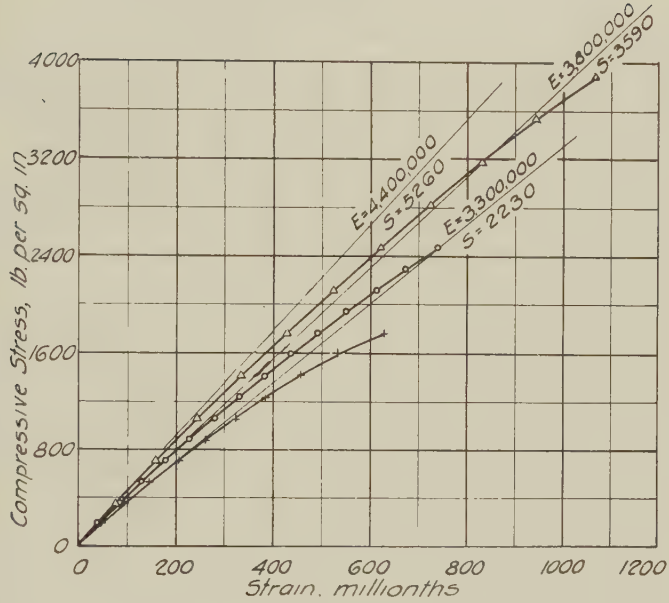

FIG. 2—AVERAGE STRESS-STRAIN DIAGRAM FOR CONTROL CYLINDERS OF SERIES 3

each spiral as received. The average tensile strengths of these coupons were 83,200 and 73,400 lb. per sq. in. for the No. 5 and the ½-in. rods respectively (see Table 5). It will be noted that the ultimate strength of the No. 5 rod was considerably above that of the ¼-in. rod and that of the longitudinal reinforcement.

As described in the report for Series 2, the reinforcement for columns having both longitudinal and spiral reinforcement was assembled into a unit before being placed in the mold.

In the columns having longitudinal reinforcement but no lateral reinforcement, the bars were held in position by tying to five No. 10 wire hoops equally spaced. These hoops did not provide appreciable lateral reinforcement, both because of the large spacing and because in each hoop the ends of the wires were merely hooked together.

7. *Placing and Curing of Concrete.*—The placing and curing of the concrete were the same as those used in Series 2. When

¼-in. diam.	60	73,400

*Based on nominal areas.

four columns of the same mix and reinforcement were concreted on the same day, two were for test under sustained working load. and the two companion columns were for storage under no load, Some of the columns tested under sustained load did not have companion columns stored under no load.

The columns and their control cylinders were cured in the moist room for 56 days.

8. *Working Loads.*—From the standpoint of interpreting the data it would have been desirable to use such a test load as would produce the same initial strain in all columns of the same concrete strength. It was not possible, however, to do this and at the same time to use as test loads the working loads computed from the building codes referred to. The amount of variation of the strain in the concrete at the application of the load is indicated in Table 6.

The formula given by the American Concrete Institute Code for spirally reinforced columns was used in determining the test loads for the columns without, as well as for those with spiral reinforcement. This could be done consistently because there is no term in the formula which represents the amount of spiral re-

*Load according to New York Building Code, remainder according to A.C.I. Building Code
**No sign indicates compression, minus sign indicates tension.

inforcement, and it was desirable to do it because it permitted a direct comparison of the deformations under the same load for columns without as for those with spiral reinforcement.

9. *Applying Working Load.*—At the age of 56 days the columns were removed from the moist room. The design load was applied to the columns scheduled to be held under load for one year. The two columns of the same mix and the same reinforcement were placed one on top of the other so that one loading rig served for

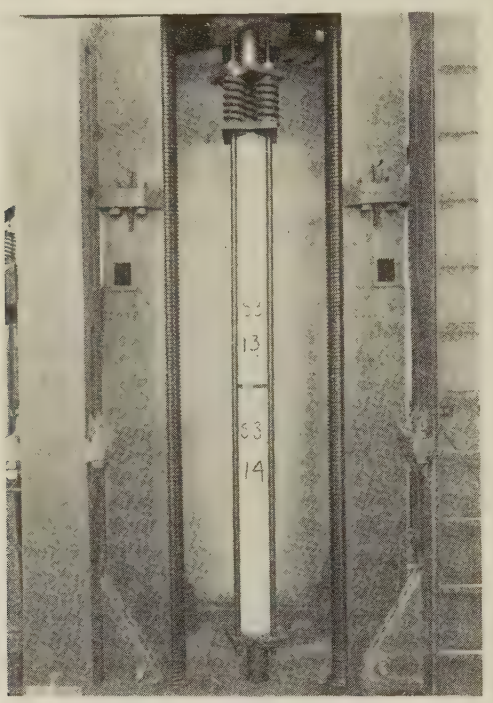

FIG. 3—APPLYING WORKING LOAD TO COLUMNS

both columns. The loading rig and the method used in applying the load to two columns simultaneously are shown in Fig. 3. The load was applied through helical springs held between two loading plates at the upper end of the rig. Steel rods, 1½ in. in diameter and 12½ ft. long, transmitted the load from the springs to the columns. In order to secure a good distribution of the load, planed steel bearing plates were used at the ends of the columns and pieces of beaver board were inserted between the bearing plates and the loading plates. A steel plate, planed on both faces, was inserted between the columns.

The rods and loading plates were donated by the Bethlehem Steel Co. of Bethlehem, Pennsylvania.

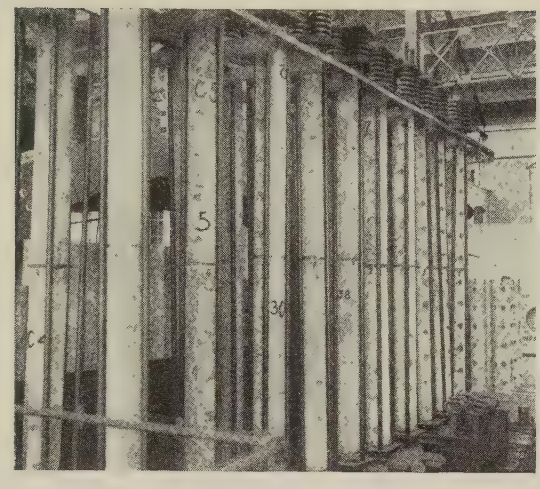

FIG. 4—COLUMNS OF SERIES 3 UNDER SUSTAINED LOAD IN DRY STORAGE

The load was applied to the columns in an 800,000-lb. vertical-screw testing machine. The two columns and the loading rig were assembled on the table of the machine and the design load applied by bringing the head of the machine down upon the upper plate, which bore upon the springs. The length of the springs in their compressed condition under the design load was measured to the nearest 0.001 in. A small excess load was then applied to compensate for the elongation of the rods and deflection of the plates to be expected upon the raising of the head of the testing machine. The nuts were then tightened on the rods, after which all the load exerted by the testing machine was released. The length of the springs was then remeasured, and if it did not agree with that which had been found under the design load, successive trials were made until agreement was secured.

Strain gage readings were taken on all columns immediately before and after the application of the load. The loaded columns and their unloaded companion columns were then stored as scheduled, either wet or dry. The columns stored dry are shown in Fig. 4.

10. *Maintaining the Working Load on Columns in Dry Storage.* —The springs are holding the load fairly well. However, there

is a slight falling off of load, due to the deforming of the columns, and also to permanent set in the springs. The length of the springs was measured after each series of strain gage readings. After 12 weeks under load it appeared that the falling off of the load was of sufficient importance to necessitate readjustment of the springs. The loading rig containing the columns was placed in the testing machine and the correct working load re-applied. The method used for applying the load was also used for the readjustment. The average decrease in 12 weeks was about 7 per cent of the correct working load. Of this, about 4 per cent was due to the deformation of the columns and 3 per cent due to permanent set in the springs.

The columns stored in the moist room showed so slight an increase in deformation during the time under load that it has been unnecessary to readjust the loads.

11. *Data Obtained During the First Twenty Weeks Under Load.*—For purposes of reference the average measured unit deformations for each pair of companion columns of Series 3, are given at the end of this report in Figs. 15 to 44. The agreement between companion columns was very good as is illustrated in Fig. 5. It is not feasible in this report, to include similar results for all columns.

There were 20 gage lines on each column for the measurement of deformation in the steel and 20 for the concrete. Two readings were taken on each gage line with each observation. With some exceptions, the results of 80 readings (40 on each of two columns) therefore were averaged to give each plotted point in Figs. 15 to 44.

The agreement between the deformations observed in the concrete and those in the steel was very good. The most important exception noted is that of columns 81 and 82 (Fig. 38) which show a difference in deformation of about 50 millionths.

The average of longitudinal strains measured at opposite ends of any diameter has been found equal (or nearly so) to the average of the longitudinal strains at opposite ends of the diameter lying at right angles to, and in the same horizontal plane with the former diameter. This applied not only to the elastic strains

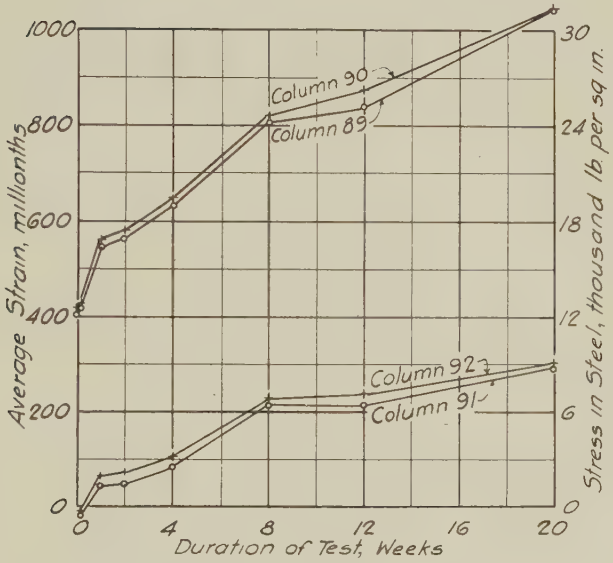

FIG. 5—AGREEMENT BETWEEN DEFORMATION OF COMPANION COLUMNS

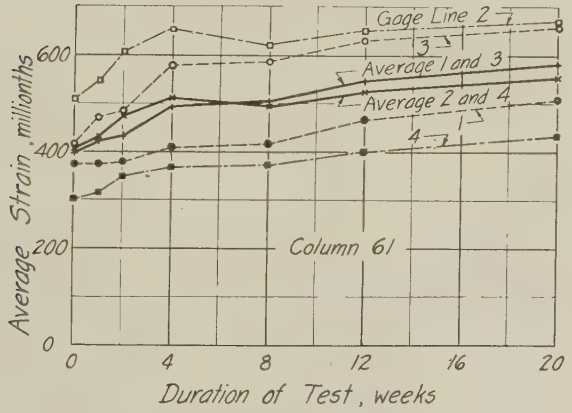

FIG. 6—ILLUSTRATION OF CONSERVATION OF PLANE SECTION

measured at the time of application of load, but also to the shrinkage and increase in deformation during an extended period. An illustration of the relations here pointed out is given in Fig. 6. In the working up of the strain data reliance was placed upon this relation for the detection of error in the computations.

All the columns in dry storage generally showed large increase in deformation during the first two to four weeks under sustained load. From then on the rate of increase in deformation became smaller and more nearly constant as time progressed. The companion columns under no load showed a steady shrinkage for the first 12 weeks of test, but from then on there was little increase in deformation due to shrinkage. The shrinkage deformations of the unloaded columns were subtracted from the deformations of the companion columns under load when both were present. The resulting time-deformation curves so corrected are shown in Fig. 15 to 44 as broken lines. Each corrected curve follows approximately a straight line from about two weeks after the application of the load until the end of the twenty weeks period.

The columns in wet storage showed a much smaller increase in deformation during the loading period than did those in dry storage. The deformation of the unloaded companion columns was quite small throughout the test. As with the columns stored dry each corrected deformation curve for the loaded columns stored wet followed approximately a straight line from about two weeks after the beginning until the end of the twenty weeks under load. It is noted that the increase in deformation due to the load was much smaller for the columns in wet storage than for those in dry storage.

12. *Effect of Variation in Strength of Concrete on Deformation.*—Figs. 7 and 8 give the unit deformations under load for columns made with concrete designed to have strengths of 2000, 3500, and 5000 lb. per sq. in. In Fig. 7 the solid lines and the broken lines represent the deformations of columns having 6 per cent and 1½ per cent longitudinal reinforcement. The spiral reinforcement was 2 per cent in all columns represented in Fig. 7. Each curve in Fig. 8 represents the measured strains for the columns with concrete of a certain designed strength. All the columns rep-

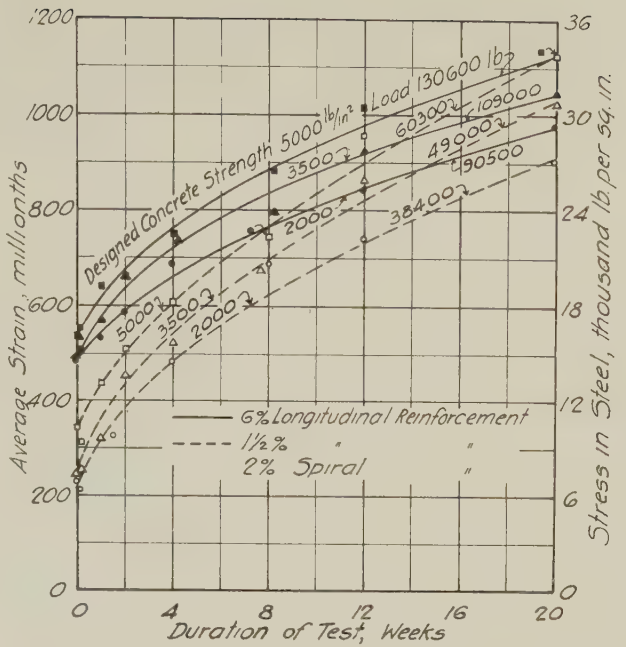

FIG. 7—EFFECT OF VARIATION IN STRENGTH OF CONCRETE ON INCREASE IN DEFORMATION OF COLUMNS HAVING 2 PER CENT SPIRAL REINFORCEMENT AND 1½ PER CENT AND 6 PER CENT LONGITUDINAL REINFORCEMENT, DRY STORAGE

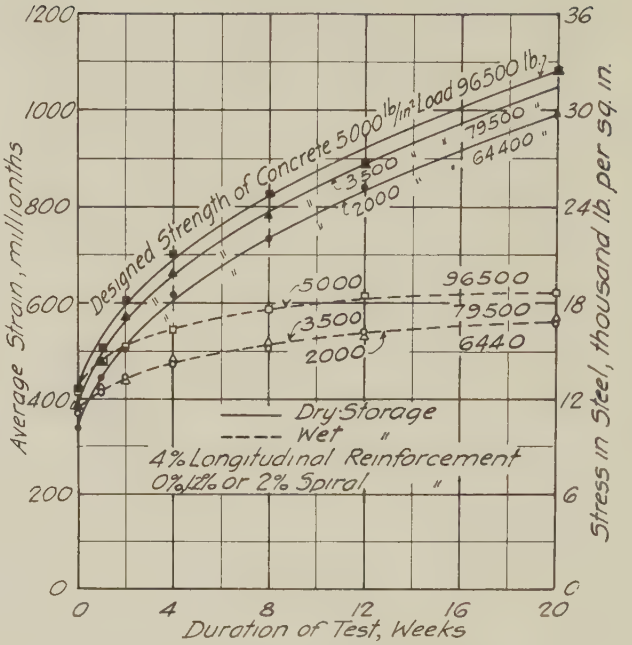

FIG. 8—EFFECT OF VARIATION IN STRENGTH OF CONCRETE ON INCREASE IN DEFORMATION OF COLUMNS HAVING 4 PER CENT LONGITUDINAL REINFORCEMENT AND 0 PER CENT, 1.2 PER CENT, OR 2 PER CENT SPIRAL REINFORCEMENT

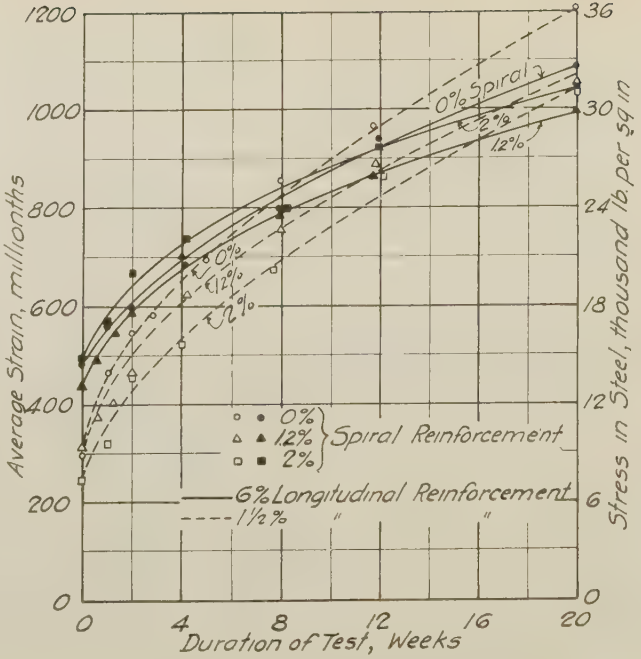

FIG. 9—EFFECT OF VARIATION IN PERCENTAGE OF SPIRAL REINFORCEMENT ON INCREASE IN DEFORMATION OF COLUMNS. DESIGNED STRENGTH OF CONCRETE 3500 LB. PER SQ. IN., 1½ PER CENT AND 6 PER CENT LONGITUDINAL REINFORCEMENT, DRY STORAGE

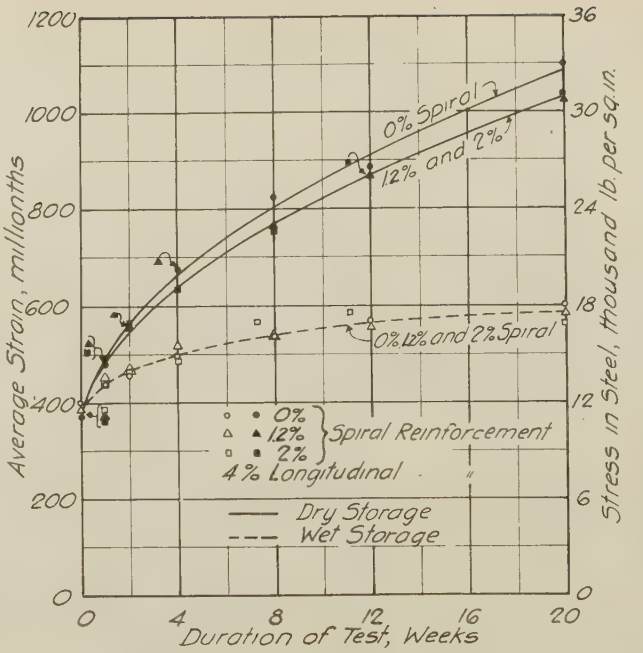

FIG. 10—EFFECT OF VARIATION IN PERCENTAGE OF SPIRAL REINFORCEMENT ON INCREASE IN DEFORMATION OF COLUMNS HAVING 4 PER CENT LONGITUDINAL REINFORCEMENT, DESIGNED STRENGTH OF CONCRETE 2000, 3500, AND 5000 LB. PER SQ. IN.

resented had 4 per cent of longitudinal reinforcement. The spiral reinforcement was either 0, 1.2, or 2 per cent. It is later shown that the strains were practically independent of the amount of the spiral reinforcement, and this fact is used as the justification for averaging the strains indiscriminately regardless of the amount of the spiral reinforcement. The solid lines represent the columns in dry storage and the broken lines those in wet storage. The most striking feature of these figures is that the strain curves for a given type of storage are substantially parallel. That is, within the range of these tests the rate of increase in deformation was everywhere practically independent of the strength of the concrete and of the initial stress. This comment applies to the columns held under load in wet storage as well as to those in dry storage. However, the amount of increase in deformation was very much smaller for the columns loaded in wet, than for those loaded in dry storage. It is probable that the reason for the apparent lack of dependence of the rate of increase in deformation upon the strength of the concrete is the fact that under the code used for determining the working load the concretes of the higher strengths required correspondingly greater loads. In other words, the effect of the higher strengths apparently was offset by the corresponding higher stresses.

13. *Effect of Amount of Spiral Reinforcement on Deformation.*— Fig. 9 and 10 give the time-deformation curves for columns with 0, 1.2, and 2 per cent spiral reinforcement. For all of the columns with a given percentage of longitudinal reinforcement and of a given concrete strength the same load was applied, regardless of the percentage of spiral used. At the time of applying the load the deformations were greatest in some instances for the columns having no spiral and in others for those having 1.2 or 2 per cent of spiral. This indicates that slight variations in the modulus of elasticity of the concrete had more effect on the amount of initial deformation than did the presence or absence of spiral reinforcement. In Fig. 9 the deformations of columns made of concrete having a designed strength of 3500 lb. per sq. in. are shown for 0, 1.2, and 2 per cent of spiral reinforcement and for 1½ and 6 per cent of longitudinal reinforcement. The solid lines represent the columns having 6 per cent and the broken lines those having 1½

per cent longitudinal reinforcement. All columns in this figure were stored dry. Fig. 10 shows the deformations obtained on columns having 4 per cent of longitudinal reinforcement. In Fig. 10 each point represents the average of the deformations of the columns having a given percentage of spiral reinforcement, regardless of the strength of the concrete, which varied between 2000, 3500, and 5000 lb. per sq. in. Since the same variations in strength of concrete enter for one curve as for another in this figure, the curves may be compared in studying the effect of the amount of spiral reinforcement on the deformations. The solid lines represent the deformations of the columns stored dry, and the broken lines those of the columns stored wet.

Within the range of accuracy of the results, except for the columns without spiral reinforcement, the time-deformation curves were either identical or parallel, depending on whether the deformations immediately after applying the load were equal or not. The results indicate therefore, that the rate of increase in deformation was practically independent of the percentage of spiral reinforcement.

14. *Effect of Variation in Longitudinal Reinforcement on Deformation.*—In Fig. 11 are shown the deformations which occurred in the columns during the first 20 weeks of test. To eliminate the irregularities caused by the small number of specimens, an average curve was prepared for all the columns having 1½ per cent longitudinal reinforcement, regardless of the percentage of the spiral, or the strength of the concrete. Similar average curves for 4 per cent and 6 per cent longitudinal reinforcement were prepared and all three are shown in Fig. 11.

The greater the percentage of longitudinal reinforcement, the greater were the applied loads and the initial deformation. This is because under the American Concrete Institute Code (which was used for determining the test loads) an increase in longitudinal reinforcement calls for an increase in the working stress in the concrete. The figure indicates that the rate of increase in deformation with the time under load was greatest for the smallest percentage of longitudinal reinforcement and the least for the largest percentage.

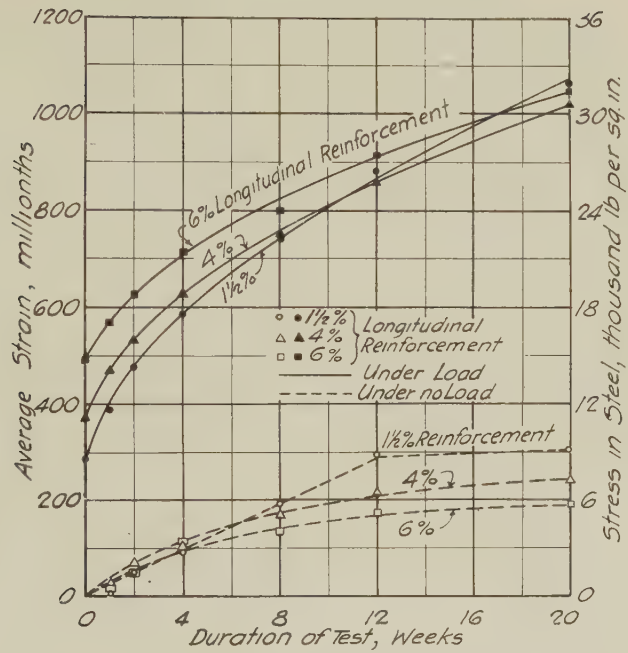

FIG. 11—AVERAGE DEFORMATION OF COLUMNS HAVING VARIOUS PERCENTAGES OF LONGITUDINAL REINFORCEMENT, DRY STORAGE

The broken lines in the lower part of Fig. 11 show the effect of the variation in percentage of longitudinal reinforcement upon the shrinkage of the columns under no load. For the first four weeks of the test, the shrinkage was nearly the same for the three different percentages of reinforcement. From then on, the shrinkage of the columns with the largest percentage of reinforcement was much smaller than the shrinkage of the columns having smaller percentages. After 20 weeks the shrinkage deformations of the columns having 6, 4, and 1½ per cent longitudinal reinforcement were 190, 240, and 300 millionths, respectively. If the shrinkage were subtracted from the companion columns under sustained load, the time-deformation curves would become nearly parallel except for slightly smaller vertical distance between the curves at the end of 20 weeks than at the beginning of the test. Evidently the resistance offered by the added reinforce-

ment offset the effect of the greater initial concrete stress on the rate of deformation for columns having the greater percentages of longitudinal reinforcement.

15. *Comparison Between New York and American Concrete Institute Building Codes.*—Fig. 12 shows the deformations of the two groups of companion columns loaded in conformity with the New York and the American Concrete Institute Building Codes. The solid lines represent the deformations of the columns loaded according to the New York Code, and the broken lines those loaded according to the Institute Code. It is noted that for the former the initial concrete stresses for the columns having 6 and 1½ per cent longitudinal reinforcement respectively, were practically equal. The rate of increase in deformation was much greater for the columns having 1½ per cent reinforcement than for those having 6 per cent. That is, the deformation curves departed continuously from each other as time progressed. At the end of 20 weeks the stress in the steel of the columns having 1½ per cent longitudinal reinforcement was about 14,000 lb. per sq. in. (48 per cent) greater than that for the columns having 6 per cent reinforcement.

The broken lines represent the deformations of the columns loaded according to the Institute Code. Here the curves approached each other as time progressed, and at the end of 20 weeks the deformations of the columns having 1½ and 6 per cent longitudinal reinforcement were nearly equal, even though the columns with 6 per cent had about twice as large initial deformation as did those with 1½ per cent reinforcement.

If, as is present practice, the stress in the longitudinal reinforcement is an important criterion in the design of concrete columns, the American Concrete Institute Building Code gave a better basis for designing reinforced concrete columns than did the present New York Building Code. There are, however, indications that the strength of a reinforced column is equal to the sum of the strength of the concrete and the yield-point strength of the longitudinal reinforcement. If this were to be established as the criterion for the design of columns, the importance of maintaining a fixed stress in the longitudinal reinforcement, regardless of its percentage, would become of less significance.

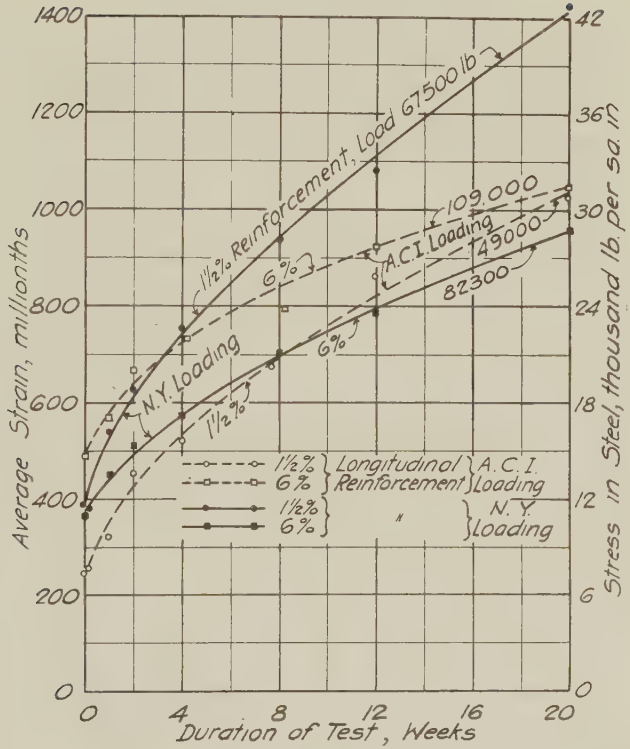

FIG. 12—DEFORMATION OF COLUMNS LOADED IN CONFORMANCE WITH THE NEW YORK AND THE AMERICAN CONCRETE INSTITUTE BUILDING CODES, DESIGNED STRENGTH OF CONCRETE 3500 LB. PER SQ. IN., 2 PER CENT SPIRAL REINFORCEMENT, DRY STORAGE

16. *Shrinkage of Columns Stored Dry.*—Fig. 13 shows the shrinkage for columns stored in the air of the laboratory. The shrinkage of columns having 1½, 4, and 6 per cent longitudinal reinforcement respectively, has been shown for each strength of concrete. Each point represents the average for all gage lines on all columns having concrete of the same strength and the same percentage of longitudinal reinforcement, regardless of the percentage of spiral reinforcement. It is noted that up to four weeks dry storage no marked difference was found for columns of different percentages of longitudinal reinforcement. From then on, however, the shrinkage for the columns having 1½ per cent

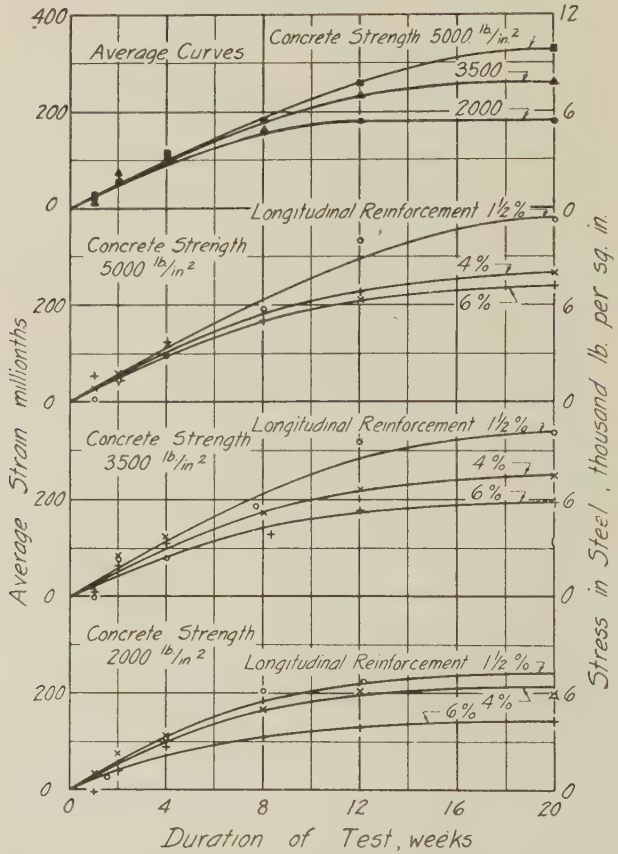

FIG. 13—SHRINKAGE OF COLUMNS WITH VARIOUS PERCENTAGES OF LONGITUDINAL REINFORCEMENT AND OF DIFFERENT STRENGTHS OF CONCRETE

was greater than that for columns having 4 per cent, and the latter in turn was greater than the shrinkage for columns having 6 per cent longitudinal reinforcement. With columns having a given percentage of longitudinal reinforcement, the greater the strength of the concrete the greater was the shrinkage. The effect of the strength of the concrete upon the shrinkage is shown

most directly in the top part of the diagram. Here the average shrinkage for each strength of concrete is shown, regardless of the percentage of longitudinal reinforcement. It was found that after the columns had been under test for more than four weeks the shrinkage was consistently greater with the concretes of the greater strengths.

17. *Summary of Deformations and Stresses*—Table 6 summarizes the deformations and the resulting stresses at the time of application of load and after 20 weeks of test, for the columns included in this series. The table includes the data of both sets of tests, those in which the columns had been loaded with the design load for 20 weeks, and those in which the columns were not loaded but in which the strains due to shrinkage had been measured. It includes also both sets of storage conditions, wet at a temperature of 70 deg. F., and dry at room temperature, which varied between 60 deg. F. and 95 deg. F. during the 20 weeks.

An illustration of how the stress in the steel increased and that in the concrete decreased during the time under sustained load is given in Fig. 14. The curves in the lower half of the diagram represent columns having a concrete strength of 5000, and those in the upper half of 2000 lb. per sq. in. In all these columns the reinforcement consisted of 2 per cent spiral and 1½ or 6 per cent longitudinal. The solid lines represent the stresses in the steel and the broken lines those in the concrete.

It is seen from Table 6 and Fig. 14 that the decrease in stress in the concrete due to the increase in deformation, was greater for the columns with high than for those with low percentages of longitudinal reinforcement. In the cases examined, this decrease was greater proportionately, as well as numerically. For columns 47 and 48 the deformations after 20 weeks of test indicated that a tension of 90 lb. per sq. in. was present in the concrete, that is, apparently the load carried by the reinforcement exceeded the total load on the columns.

Fig. 14 and Table 6 show that the increase in the stress in the steel was large and that it was greatest for the columns with the smallest percentage of longitudinal reinforcement. The highest

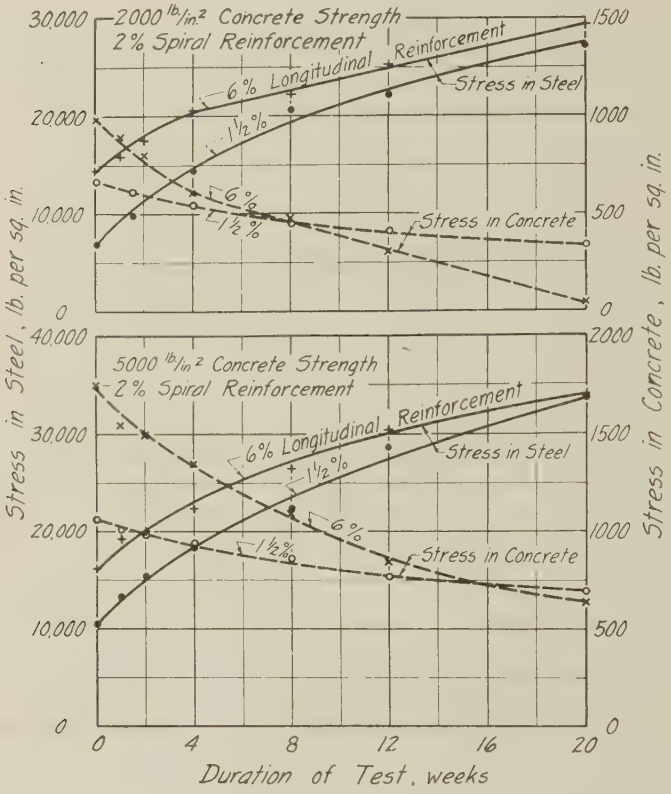

FIG. 14—EFFECT OF DURATION OF TEST ON STRESSES IN STEEL AND CONCRETE

stress reported in this table, 42,660 lb. per sq. in., is practically four times the initial stress. This stress is the average for columns 45 and 46 which have 1½ per cent longitudinal reinforcement. This shows that the steel stress after 20 weeks under the working load was not far from its yield-point stress of 49,500 lb. per sq. in.

For the columns not loaded the shrinkage caused a compression in the steel which resulted in a corresponding tension in the concrete, in spite of the fact that the concrete shortened. The total compressive force found as the product of the measured strain, the modulus of elasticity, and the total area of the steel, must have produced an equal total tensile force in the concrete, since

no external load was applied to the columns. The tensile stresses in the concrete, determined from this relation, are given in Table 6. It will be noted that the average tensile stress in the concrete of columns 107 and 108 was 450 lb. per sq. in. The next lower tensile stress was 370 lb. per sq. in., the average for columns 99 and 100. All four of these columns had 6 per cent longitudinal reinforcement.

A careful examination of all the columns which were stored under no load has recently been made and no cracks have been found. Especial attention was given to the search for cracks on those columns showing the highest tensile stresses. There is no probability that cracks were missed in this visual examination, for their presence would have been plainly indicated in the results of the strain gage measurements which included the total length of the column except for five inches at each end.

18. *Computation of Shrinkage and Flow.*—W. H. Glanville of the Department of Industrial Research, England,[5] has carried out researches on shrinkage and flow in concrete in which tests have been made and theoretical treatments given. The analysis of the problems is so fundamental, and the agreements between the results of the tests and the theoretical treatments are so marked as to make it worth while to include the lines along which the theoretical analysis was carried out. With minor modifications for notations and form of statement, the following are his theoretical analyses of the shrinkage and the flow of reinforced concrete members.

SHRINKAGE

If no slip occurs between the concrete and the steel, the actual change in length of the concrete in a reinforced concrete member is less than the shrinkage of the plain concrete member by an amount equal to the elastic tensile strain of the concrete due to the compressive stress induced in the steel plus the flow of the concrete which has taken place under its tensile stress. Since the increase in load in the steel has to be equal to the decrease in load in the concrete the following equation holds:

$$\Delta f_s \cdot a_s = \Delta f_c \cdot a_c$$

[5]Building Research Technical Papers "Studies in Reinforced Concrete," Technical Paper No. 11, "Shrinkage Stresses," and No. 12, "The Creep or Flow of Concrete Under Load."

where Δf_s and Δf_c are changes in stress in steel and concrete respectively, and a_s and a_c are the areas of steel and concrete respectively.

If c is the flow per unit stress up to the time under consideration the flow occurring during an increment of time Δt is $f_c \cdot \Delta c$, and, since the shrinkage of plain concrete less the flow must be equal to the sum of the strains in the steel and in the concrete, the following equation is derived:

$$\Delta s - f_c \cdot \Delta c = \frac{\Delta f_s}{E_s} + \frac{\Delta f_c}{E_c}$$

$$\text{Since } \Delta f_s \cdot a_s = \Delta f_c \cdot a_c$$

$$\Delta f_s = \frac{a_c}{a_s} \cdot \Delta f_c$$

$$\text{and } \Delta s - f_c \cdot \Delta c = \frac{\Delta f_c}{E_s} \cdot \frac{a_c}{a_s} + \frac{\Delta f_c}{E_c} = \Delta f_c \left(\frac{1}{E_s} \cdot \frac{a_c}{a_s} + \frac{1}{E_c} \right)$$

$$\text{or writing } \alpha = \frac{1}{E_s} \cdot \frac{a_c}{a_s} + \frac{1}{E_c}$$

we have in the limit:

$$ds - f_c \cdot dc = \alpha \cdot df_c$$

This relation can be solved if the relations between shrinkage and time and between flow and time are known. If the flow is neglected in the relation between the shrinkage and induced concrete stresses the formula becomes, by integration,

$$s = f_c \left(\frac{1}{E_s} \cdot \frac{a_c}{a_s} + \frac{1}{E_c} \right) = f_s \left(\frac{1}{E_c} \cdot \frac{a_s}{a_c} + \frac{1}{E_s} \right)$$

Mr. Glanville suggests that this formula be used but that the value of E_c be replaced by fictitious or "effective" modulus of elasticity E'_c in such a manner that the effect of the flow is allowed for.

FLOW

If a reinforced concrete member is under a constant load, the flow of the concrete during a small increment of time, Δt, under a unit stress is Δc. The modulus of elasticity of the concrete is assumed to be constant. Since the total flow is equal to the sum of the resulting strains in the concrete and that in the steel the following equation is derived:

$$f_c \cdot \Delta c = \frac{\Delta f_s}{E_s} - \frac{\Delta f_c}{E_c}$$

The increase in load in the steel must be equal to the decrease in the load in the concrete:

$$\Delta f_s \cdot a_s = -\Delta f_c \cdot a_c, \text{ or } \Delta f_s = -\frac{a_c}{a_s} \cdot \Delta f_c$$

substituting this value for Δf_s in the previous equation gives:

$$f_c \cdot \Delta c = -\frac{a_c}{a_s} \cdot \frac{\Delta f_c}{E_s} - \frac{\Delta f_c}{E_c} = -\Delta f_c \left(\frac{a_c}{a_s} \cdot \frac{1}{E_s} + \frac{1}{E_c}\right)$$

$$\text{or} \quad \Delta f_c = -\frac{f_c \cdot \Delta c}{\frac{a_c}{a_s} \cdot \frac{1}{E_s} + \frac{1}{E_c}}$$

$$\text{As before} \quad \alpha = \frac{a_c}{a_s} \cdot \frac{1}{E_s} + \frac{1}{E_c}$$

$$\text{Then} \quad \Delta f_c = -\frac{f_c \cdot \Delta c}{\alpha} \quad \text{or} \quad \frac{\Delta f_c}{f_c} = -\frac{\Delta c}{\alpha}$$

In the limit:

$$\frac{df_c}{f_c} = -\frac{d_c}{\alpha}$$

When $c = 0, f_c = f_o$ where f_o = stress in concrete immediately after loading. This expression may be integrated between the limits f_o and f_c and the result is:

$$f_c = \frac{f_o}{e^{c/\alpha}}$$

where c is the flow of plain concrete under unit stress from the time of loading to the time under consideration, and e is the base of Naperian logarithms.

The stresses in the steel and in the concrete are found from the following relations:

$$f_s = f_a + f'_s$$

$$f'_c = f_o - f_c = f_o \left(1 - \frac{1}{e^{c/\alpha}}\right)$$

$$\text{and} \quad f'_s = f_a \cdot \frac{a_c}{a_s} \cdot \frac{1}{n} \cdot \left(1 - \frac{1}{e^{c/a}}\right)$$

where:

f_s and f_c are the actual stresses in steel and concrete at the time under consideration (disregarding shrinkage effect), f_a and f_o are the stresses in steel and concrete at the time of application of load, f'_s and f'_c are the changes in stress in steel and concrete due to flow, and n is the ratio, $\frac{E_s}{E_c}$, between moduli.

As shrinkage and flow act independently of each other, the combined result is obtained by adding them.

19. *Review of the Problem.*—The findings reported herewith confirm in a striking manner the results of studies made as long ago as 1916. In that year A. H. Fuller and C. C. More presented a paper dealing with "Time Tests of Concrete." At the same meeting E. B. Smith of the Bureau of Public Roads gave a paper on "The Flow of Concrete Under Sustained Loads." Both papers presented evidence of the flow of concrete under load but did not show the strains in reinforcement embedded in the concrete. F. R. McMillan, however, discussed both papers and described results of measurements which he had initiated on reinforced concrete columns in buildings in service. The observations were begun about two months after the placing of the columns and had been in progress about seven months at the time of the first report. It was already evident that considerable shortening of the concrete and steel was taking place. In the following year (1917) Smith presented to the American Concrete Institute a paper embodying the results of a continuation of his studies. McMillan discussed this paper also, showing that the strains in the columns under measurement had reached a value corresponding, in one instance (designated as column 19), to a stress in the steel as high as 36,000 lb. per sq. in. In 1921 M. B. Lagaard presented as discussion of McMillan's paper "A Study of Column Test Data" further results of the studies initiated by McMillan on columns in service. By that time the measurements had been carried on for approximately six years. The strains had increased so that the apparent stress in the steel of column 19 was 45,000 lb. per sq. in. It is not unlikely that even

then the yield-point stress had been exceeded, especially in view of the fact that the measurements were not started until the columns were two months old. As no comment was made on the appearance of the column it is probable that there were no indications of distress.

R. E. Davis reports that in his investigation of flow the strength of plain concrete was uninfluenced by having been subjected to a long-time load of 800 lb. per sq. in. which caused a final deformation of 900 millionths or three times that with which the test started. Other of his tests confirm these results. If, therefore, the flow in a reinforced concrete column continues to the point at which the steel is stressed beyond the yield point, it is reasonable to expect that the concrete is still capable of carrying its full share of the load.

The only occasion for concern then, must be as to whether the carrying capacity of the steel is reduced by being stressed beyond the yield point. The tests have not yet been carried far enough to give the answer from the experimental end, but the question may reasonably be asked: If the longitudinal steel receives from the spiral and from its embedment in the concrete, sufficient lateral support to prevent buckling under the yield-point stress, how can it escape from continuing to carry its full share of the load?

At the risk of anticipating too far what the final outcome will be, it seems imperative that enough speculation be indulged in to enable us to visualize what must yet be done before the reinforced concrete column problem is solved. First, the strength of the column appears to depend upon the sum of the strengths of the concrete and the longitudinal reinforcement regardless of the ratio of the moduli of elasticity. Second, it seems evident that the basis for the design of reinforced concrete columns must be changed accordingly.

The tests must be carried far enough to determine what is the highest axial load that a reinforced concrete column will carry indefinitely without failure.

Tests must also be carried out on columns subjected to combined bending and direct stress. These tests must be made in such a way that some generalization may be made as to what

redistribution of the bending moment initially present in an indeterminate structure takes place as the concrete shrinks, and flows under long time load.

Readers are referred to the JOURNAL *for June, 1931, for discussion of the Reinforced Concrete Column Investigation of Committee 105. Such discussion should reach the Secretary by May 1, 1931.*

Flow of Concrete under the Action of Sustained Loads

BY RAYMOND E. DAVIS* AND HARMER E. DAVIS†

This paper is here published to encourage discussion at the 27th annual convention at which it will be presented formally in abstract. It represents a part of the work assigned to Committee 109—Summary of Plastic Flow. Professor Davis is Author-Chairman and Harmer E. Davis is a member of the committee. It is solely their joint effort in which the committee as a whole has not participated.—EDITOR

SYNOPSIS

THIS PAPER presents the results of tests on plain and reinforced concrete to determine the effect of loads sustained over a considerable period of time upon the deformations and upon the distribution of stresses in concrete and steel.

Part 1 of the paper describes laboratory tests at the University of California in the interval 1925-1930 on more than 200 cylinder specimens, all maintained under controlled conditions of storage as regards temperature and humidity, to determine the influence of a constant sustained compressive stress upon axial deformations. The deformation due to stress which takes place immediately upon the application of the load is here called the "instantaneous deformation," and that which takes place subsequent to the application of load is here designated as the "flow," a quantity separate from changes in dimensions due to such causes as variations in temperature and moisture conditions. Likewise the ratio of unit stress to unit instantaneous deformation is termed the "modulus of elasticity," and the ratio of the sustained unit stress to the total deformation due to load (instantaneous plus flow), is called the "sustained modulus of resistance."

The tests were made to determine the manner in which flow is influenced by such elements as (1) length of period of sustained load, (2) magnitude of sustained load, (3) age at the time of loading, (4) character of mineral aggregate, (5)

*Professor of Civil Engineering, University of California.
†Instructor in Civil Engineering, University of California.

richness of mix, (6) gradation of aggregate, (7) water-cement ratio, (8) reinforcement, (9) alternately applying and releasing load, and (10) moisture conditions of storage, including variations in humidity of surrounding air.

From these tests, it has been determined among other things that the flow of plain concrete under a constantly sustained compressive stress (1) continues to increase, at first rapidly and then more slowly, for a long time, certainly for several years, (2) is greater for concrete in an atmosphere of low humidity than for an identical concrete in an atmosphere of high humidity or when fully saturated with water, (3) is materially affected by the character of the aggregate, being substantially larger for sandstone concrete than for limestone concrete, (4) is less for rich mixes than for lean ones, (5) is less for concrete having a high modulus of elasticity than for one having a low modulus of elasticity, (6) is greater for a high water-cement ratio than for a low one, and (7) is greater when load is applied at an early age than when it is applied at a later age.

Longitudinal reinforcement in specimens stored in air appreciably reduces both the flow and shrinkage, but under the action of a load long sustained, the compressive stress in the longitudinal steel continues to increase until it becomes several times the stress which existed immediately upon application of the load, even reaching the yield point of the steel.

When after a time the load is released, there is an elastic recovery which is immediate, and a plastic recovery which increases with time, but the plastic recovery is less than the plastic flow which took place under the sustained loading. When concrete has been so loaded and unloaded, the instantaneous modulus of elasticity becomes somewhat greater than that of a concrete alike in all other respects save that it has not been previously stressed.

In time, even at normal working stresses, the flow of concrete may be several times as great as the initial instantaneous deformation, or, putting it in another way, the instantaneous modulus of elasticity is several times the sustained modulus of resistance.

When the load is alternately applied and released for a given time, the magnitude of the instantaneous deformation and the rate of plastic flow and plastic recovery tend to become less as the number of stress cycles is increased.

Part 2 of the paper summarizes the published results of the more important tests reported by other investigators during the last 25 years, in which the phenomenon of "time yield," "plasticity," "time deformation," "plastic flow" or "flow" has been observed and discussed. In general, while the conditions surrounding these early tests are not sufficiently well known nor the tests sufficiently extensive to make the quantitative data of direct value, the results consistently point to a marked time effect, both upon laboratory specimens and upon service structures.

Tests which are here summarized include those reported by Hatt in 1907 on beams; by McMillan in 1915, 1916 and 1921, on beams, slabs, columns; by Fuller and More in 1915, on cylinders and flat slabs; by Goldbeck and Smith in 1914-1917, on cylinders, beams and slabs; by Lord in 1914-16, on flat slabs; and by Faber, 1916-27, on beams.

INTRODUCTION

FOR MORE than a quarter of a century the property possessed by all concrete, to a greater or less degree, of yielding slowly under the action of sustained loads has been known to exist, first through the gradually increasing deflection of beams and slabs and later through measurements of the strains in both concrete and steel of columns, beams and slabs. This property, which is entirely separate from shrinkage due to gradual release of uncombined water when concrete is in air, renders concrete, even within working stresses, not a perfectly elastic material, but a material which when subjected to sustained load continues slowly to yield or deform for a long time. That is, not only does the stress-strain relation of a given concrete vary with the magnitude of the stress, but also with the length of time over which the stress is sustained.

This property of yielding with the passage of time has been designated as "time yield," "time deformation," "plastic deformation," and "plastic flow." In this report, except in quoting the words of other investigators, the term "flow" will be employed, though it is problematical whether there actually occurs in concrete a movement of the particles over one another in the manner commonly associated with the flow of any material.

In many structures where dead load forms a large part of the total load this slow yielding of the concrete with time would seem to bring about a stress distribution quite different from that which would exist under the action of an equivalent live load. In buildings and other structures exposed to drying conditions there also enters further to complicate the problem the added factor of shrinkage of the concrete, which likewise is gradually accumulative over a long period. Take the simple case of a reinforced column, for example; due to dead load, the stress in the concrete may gradually diminish and the stress in the longitudinal steel gradually increase as flow and shrinkage take place, until the yield point of the steel is reached, after which the distribution of stress between steel and concrete may perhaps remain substantially constant. Or consider a simply supported reinforced beam, in which the flexural stress is insufficient to produce cracks below the neutral axis and which is free to contract longitudinally;

due to shrinkage alone the steel is gradually placed in compression, with the top fibers of the beam in compression and the bottom fibers in tension, and due to dead load deformations there may be gradually produced a lowering of the neutral axis tending to increase the tension in the steel and to decrease the compression in the extreme fiber of the concrete. Thus the effect of flow may be to decrease the stress in the concrete and the effect of shrinkage may be to decrease the tensile stress in the steel. In restrained beams, continuous frames, and arches it appears likely that flow acts in some degree to relieve the stresses at sections of large moment and to redistribute the moment in a manner more nearly to equalize negative and positive moments. For example, it might be expected that for a beam fixed at the ends and carrying a uniform dead load, the points of contra flexure would gradually shift position and the elastic curve gradually change its shape until, in the process of time, the maximum positive and negative moments were substantially the same. Or for an arch where there was a gradual rib shortening, due to whatever cause, it appears probable that the moments at crown and spring lines may be substantially less than would be the case were the length of the arch ring abruptly changed by the same amount. And the dead-load moment diagram for a continuous beam with concentrated loads long sustained, instead of being a series of connected straight lines, may be a curved line with summits and depressions rounded.

Many other examples might be cited, but those mentioned are sufficient to indicate the desirability of determining the facts concerning flow and of considering the influence of flow upon structural design. The recognized importance of flow as a factor in stress analysis has prompted the preparation of this paper. Here attempt is made to present quantitative data concerning the phenomenon of flow as determined by tests, leaving to others the task of discussing the significance of flow as related to stresses in structures.

The paper is divided into two parts:

Part 1 describes in considerable detail tests made in the interval 1925-30 at the University of California under the direction of the

authors upon more than 200 compression cylinders under closely controlled conditions. Here the influence of various factors upon flow are discussed.

Part 2 is a summary of some of the more important papers and discussions published in the last 25 years in which the effects of flow, as determined by tests, have been described. These include laboratory tests on cylinders, beams and slabs, and field observations upon the several structural elements. Following the abstracts is a bibliography of articles and papers dealing with flow and shrinkage.

In this paper the term "flow" will be taken to mean that axial deformaton due to stress which takes place subsequent to the application of a sustained load; that is, the flow at the end of any interval of time is the deformation due to the sustained load but not to the instantaneous application of the load. It is the total deformation due to stress, minus the deformation which takes place immediately upon the application of the load. It does not include changes in length due to causes other than stress, such as shrinkage and variations in temperature.

Since concrete under the action of sustained stress is so imperfectly elastic, it seems particularly inappropriate to use the term "modulus of elasticity" as being the ratio of unit stress to unit deformation when flow occurring with the passage of time is included. Consequently in this report the term "modulus of elasticity" will be employed only to designate the ratio of unit stress to unit strain at the time of application of load, and the term "modulus of resistance" will be employed to designate the ratio of unit stress to total unit deformation, this total to include the "instantaneous deformation" occurring immediately upon the application of load, plus the deformation, due to sustained stress, occurring subsequent to the application of load.

Just as concrete instantaneously deforms upon application and continues to deform for a long period if the load is sustained, so upon release of load is there an immediate reduction in deformation, here called the "instantaneous recovery," followed by a further gradual reduction in deformation which extends over a considerable period, here designated as the "plastic recovery."

PART 1—UNIVERSITY OF CALIFORNIA TESTS

Remarks

The tests here reported were conducted in the Materials Testing Laboratory of the University of California to determine the behavior of concrete under long continued compressive stress. From a modest beginning in 1925, the program has been periodically enlarged until in 1930 the number of specimens had reached a total of 217, of which 131 were subjected to sustained stress and 86 were maintained in an unstressed condition, being under observations to determine dimensional changes (shrinkage or expansion) due to causes other than stress. As this paper is written, a considerable number of the specimens have been under observation for more than four years.

All tests have been carried out under closely controlled conditions, the specimens being constantly maintained at 70 deg. F. and the atmospheric humidity being constantly maintained at a desired value. In this manner the uncertainties arising from variable temperature and humidity have been eliminated or the effects of known variations in the humidity have been observed.

For every specimen which has been subjected to sustained stress, there has been a similar specimen maintained under identical conditions except that it has been subjected to no load. These have been designated as "controls," for by means of them it has been possible to determine the *flow* of each loaded specimen by deducting from the total observed deformation, the observed shrinkage or expansion of its *control*.

The specimens have been cylinders varying from 4- to 10-in. diameter and from 12- to 24-in. length. Among the specimens a constant sustained compressive stress as low as 200 lb. per sq. in., and as high as 1200 lb. per sq. in. has been maintained, and the ages at the time of loading have varied from 3 days to 7 months.

Acknowledgments

The tests here described have been made possible through the generous financial support rendered by the Research Board of the University of California, by Engineering Foundation, and by the American Society of Civil Engineers, through its Committee on Arches.

In the years since the tests were started more than a dozen men at one time or another have contributed their services to the work, and to this group thanks are due to the painstaking manner in which the tests have been executed. In particular it is desired to acknowledge the valuable assistance rendered by G. E. Troxell, Associate Professor of Civil Engineering, who supervised many of the earlier tests; J. L. Banville, Assistant in the Materials Testing Laboratory who has been immediately in charge of much of the work since its beginning and who in a large measure is responsible for the design of special instruments and apparatus; and J. S. Hamilton, Assistant in the Materials Testing Laboratory, who has reviewed and assembled many of the data and who has supervised many of the later tests.

Scope of the Tests

The test program has been designed to show the effect upon the time-flow relation of the following:

1. Richness of mix,
2. Gradation of the aggregate,
3. Mineral composition of the aggregate,
4. Age at time of applying load,
5. Condition of storage as regards moisture,
6. Magnitude of stress,
7. Reinforcement,
8. Alternately applying and releasing loads.

Also, tests have been made to determine the effect of flow upon the strength and elasticity.

The tests are divided into seven series, as follows:

Series 1—Inaugurated in 1925 to determine the effect of richness of mix and gradation of the aggregate upon flow. Completed in 1926.

Series 2—Inaugurated in 1926 to determine the effect of magnitude of unit stress, age at time of loading and moisture conditions upon flow. Tests still in progress.

Series 3—Inaugurated in 1928 to determine the effect of humidity upon flow. Still in progress.

Series 4—Inaugurated in 1928 to determine the effect of character of the mineral aggregate upon flow. Still in progress.

Series 5—Inaugurated in 1929 to determine the effect of reinforcement upon flow and flow upon stress in reinforcement. Still in progress.

Series 6—Inaugurated in 1929 to study the effect of alternately applying and releasing a constant sustained load upon flow. Still in progress.

Series 7—Inaugurated in 1929 to study the effect of richness of mix and moisture conditions upon flow and to determine the effect of flow upon the modulus of elasticity and compressive strength. Completed December 1930.

Further details concerning the several series follow:

Series 1

The purpose of these tests was to determine the effect upon flow of (1) richness of mix, (2) gradation of aggregate, and (3) water-cement ratio.

The specimens were 6 by 24-in. cylinders, 16 in number, 12 of which were subjected to a continuous compressive stress of 640 lb. per sq. in. and 4 of which were maintained in an unstressed condition. All specimens were cured for 2 months in water and 5 months in air prior to the application of load. After the beginning of the loading tests, all specimens, including those of the unstressed group, were stored in an atmosphere of 70 deg. F. and 78 per cent relative humidity.

Four concrete mixes were investigated, differing from one another either in regard to richness or to gradation of aggregate, all as indicated in Table 1.

TABLE 1—PROPORTIONS—SERIES 1

Mix	Cement-Aggregate Ratio		Fineness Modulus of Aggregate	Water-Cement Ratio by Volume
	By Volume	By Weight		
1	1:3.4	1:4	6.43	0.81
2	1:3.4	1:4	3.62	1.06
3	1:5.9	1:7	6.43	1.01
4	1:5.9	1:7	3.62	1.42

For mixes of low fineness modulus (mixes 2 and 4) the aggregate was composed of Niles top gravel, a Coast Range sand all of which passed a No. 4 sieve. For mixes of high fineness modulus the fine aggregate was Niles top gravel and the coarse aggregate was a crushed metamorphic sandstone between the sizes ½ and 1½ in. from the local quarries of the Oakland Paving Co. From each mix there were manufactured four specimens, three of which were loaded and one of which maintained without stress.

Series 2

The purpose of these tests was to determine the effect of (1) magnitude of sustained stress, (2) age at time of loading, and (3) air *versus* water storage.

The specimens were 4 by 14-in. cylinders, 58 in number, 40 of which were loaded and 18 of which were unstressed.

The concrete was the same for all specimens, being composed of 1 part cement to 5.05 parts, by weight, of an aggregate composed entirely of crushed granite for which the fineness modulus was 5.03. The proportioning and materials were the same as those employed in the concrete used in the construction of the Stevenson Creek Test Dam of the Arch Dam Investigation of Engineering

Foundation. The water-cement ratio was 1.03 by volume and the average slump was 3.2 in. The mix data are given in Table 2.

TABLE 2—PROPORTIONS—SERIES 2

	Cement	Fine Aggregate	Medium Aggregate	Coarse Aggregate
Proportions by Weight	1	3.01	1.15	0.89
Sieve sizes		Below ⅜ in.	⅜ to ¾ in.	¾ to 1½ in.
Fineness Modulus		3.27	6.72	8.78

In Table 3 are given the storage and stress conditions investigated. Examining the table it will be found that the age at time of loading varied from 2 days to 3 months and that the intensity of sustained stress varied from 200 to 1200 lb. per sq. in. In general, observations were made upon 3 control specimens for each age of loading and storage conditions, and observations were made upon 3 loaded specimens for each age of loading. storage condition and intensity of sustained stress. For those specimens stored in water, the

TABLE 3—STORAGE AND STRESS CONDITIONS OF SPECIMENS—SERIES 2

Curing	Storage After Loading	Age at Loading	Stress, Lb. Per Sq. In.
Water	Water	2 days	200
Water	Water	7 days	300 600
Damp Sand	Water	28 days	300 600 900
Damp Sand	Water	3 months	600 900 1200
Damp Sand	Air at 70 per cent relative humidity	28 days	300 600 900
Damp Sand	Air at 70 per cent relative humidity	3 months	600 900 1200

temperature of the bath was 70 deg. F., and for those stored in air the temperature of the surrounding atmosphere was 70 deg. F. and the relative humidity was 70 per cent.

Series 3

The purpose of these tests was to determine the effect upon flow of variations in the conditions of storage with regard to moisture. The conditions of storage which were included in the investigation were (1) air at 50 per cent relative humidity, (2) air at 70 per cent relative humidity, (3) fog, and (4) under water.

The specimens were 4 by 14-in. cylinders, 20 in number, 12 of which were loaded and 8 of which were used as unloaded controls.

The concrete was the same for all specimens, being composed of 1 part of cement to 5.67 parts by weight of Niles gravel. The mix data are given in the following table. The fineness modulus of the mixed aggregate was 5.61 and the water-cement ratio was 0.89.

TABLE 4—PROPORTIONS—SERIES 3

	Cement	Fine Aggregate	Medium Aggregate	Coarse Aggregate
Proportions by Weight	1.00	2.00	1.67	2.00
Fineness Modulus		3.48	5.99	7.40

The specimens were fog-cured for 28 days when those carrying a sustained stress were all loaded to 800 lb. per sq. in. For each of the four conditions of storage there were three loaded and two control specimens.

Series 4

The purpose of these tests was to determine the effect of the character of mineral aggregate upon flow. The aggregates which were included in the investigations included (1) Niles gravel, containing quartz, sandstones, granites, etc., (2) metamorphic sandstone from Oakland, Calif., (3) quartz, (4) basalt from Napa, Calif., (5) limestone from Santa Cruz, Calif., and (6) granite.

The specimens were 4 by 14-in. cylinders, 30 in number, of which 18 were loaded and 12 were used as controls.

The concrete was of the same richness of mix for all specimens, namely, 1 part of cement to 5.67 parts by weight of mixed aggregate. The water-cement ratio was uniformly 0.89 by volume.

For the gravel concrete, the mix and gradation were as indicated under Series 3. Other aggregates were crushed, screened in a variety of sizes, and then these sizes recombined to give a sieve analysis curve practically the same as that of the gravel. That is, the gradation of one mixed aggregate was the same as for all others. The fineness modulus of each mixed crushed aggregate was 5.75.

The consistency of the fresh concrete for the several aggregates, as determined by slump and flow tests was as shown in Table 5.

The specimens were fog-cured until loaded at the age of 28 days and were thereafter stored in air at 50 per cent relative humidity. For each aggregate, three specimens were loaded to a stress of 80 lb. per sq. in. and two specimens were employed as unstressed controls.

Series 5

The purpose of these tests was to determine the effect of steel reinforcement upon flow. The specimens are 10 by 20-in. cylinders, 4 in number, 2 of which are

TABLE 5—CONSISTENCY—SERIES 4

Aggregate	Slump., In.	Flow
Gravel	4	141
Sandstone	2¼	138
Quartz	4¼	156
Basalt	3	137
Limestone	2	137
Granite	3½	142

plain and 2 of which are reinforced with longitudinal bars and spiral hooping. The reinforcement consists of six ½-in. square deformed bars, and an 8-in. diameter spiral of No. 6 A. S. W. G. of 1¼ in. pitch. The steel is of structural grade and the ends of the longitudinal bars are ground flush with the ends of the cylinders. Considering the core area, the steel ratio for longtiudinal bars is 0.0298 and for spiral is 0.0133. Considering the entire cross-section of the cylinder, the steel ratio for the longitudinal bars is 0.0190.

The concrete is composed of 1 part of cement, to 2.64 parts Niles sand, to 2.32 parts crushed sandstone, all by volume. The fineness modulus of the combined aggregate was 5.22 and the water-cement ratio was 0.86. The slump was 2 in.

The specimens were cured in fog for 50 days and thereafter were stored in air at 50 per cent relative humidity. At the age of 60 days, one plain and one reinforced specimen were loaded. The stress in the plain concrete was 800 lb. per sq. in. and the stress in the reinforced concrete at the time of loading was calculated to have been 775 lb. per sq. in. on the full concrete area.

Series 6

The purpose of these tests was to determine the behavior of concrete under alternations of a maximum and a minimum sustained stress. Observations were made to determine the instantaneous and time yields each time the load was increased from minimum to maximum and the instantaneous and time recoveries each time the load was decreased from the maximum to the minimum.

The specimens are 4 by 14-in. cylinders, 30 in number, 18 of which are subjected to load alternations and 12 of which are unstressed control specimens.

The concrete was the same for all specimens. The mix by weight was composed of 1 part of cement to 5.68 parts of mixed aggregate. The mix data are given in Table 6. The fineness modulus of the combined aggregate was 4.86 and the water-cement ratio was 0.85. The slump was 4 in.

TABLE 6—PROPORTIONS—SERIES 6

	Cement	Monterey Sand	Niles Sand	Niles Gravel
Proportions by Weight.....	1	1.14	1.14	3.40
Fineness Modulus.....		1.74	2.90	6.72

The specimens were fog-cured for 28 days, when load alternations were begun. Thereafter half the specimens were stored in air at 50 per cent relative humidity and the remainder were stored under water.

For all specimens the maximum sustained stress was 800 lb. per sq. in. and the minimum sustained stress was 40 lb. per sq. in. A stress alternation or cycle consisted of a given period at the maximum stress followed by a like period at the minimum stress.

In Table 7 are given the lengths of stress cycle for the several groups of specimens.

TABLE 7—LENGTH OF STRESS CYCLES—SERIES 6

Storage Conditions	Length, Stress Cycle, Days	Group Designation	No. of Specimens	
			Loaded	Control
Air 50% humidity	2	C	3	3
Air 50% humidity	10 to 14	B	3	3
Air 50% humidity	60	A	3	
Water	2	C	3	3
Water	10 to 14	B	3	3
Water	60	A	3	

Series 7

The purpose of these tests was to study the effect of richness of mix and storage conditions upon flow and the effect of flow upon the compressive strength and the modulus of elasticity, that is, it was desired to learn how these properties of a concrete which had been subjected to a sustained stress for a considerable period of time would compare with those of an identical concrete not previously stressed.

The specimens were 6 by 12-in. cylinders, 64 in number, half of which were placed under continuous load at 28 days and the remainder of which were not stressed prior to the strength test.

Two concrete mixes were employed, a rich mix composed of 1 part cement to 3.6 parts by volume of combined aggregate, and a lean mix composed of 1 part cement to 6.3 parts of combined aggregate. For both mixes a constant slump of 3 to 4 in. was used, giving a water-cement ratio which varied slightly for each mix. For the rich mix the fineness modulus of the combined aggregate was 5.70 and the water-cement ratio was close to 0.63 by volume. For the lean mix the fineness modulus of the combined aggregate was 5.55 and the water-cement ratio varied from 0.95 to 1.02 by volume. Table 8 gives the proportions of the separate aggregates.

For the first 7 days all specimens were fog-cured. Thereafter half the specimens were stored under water and the remainder were stored in air at 50 per cent relative humidity. At 28 days, half of those stored in both air and water were loaded to 800 lb. per sq. in. The remainder, as noted above, were left unstressed.

TABLE 8—PROPORTIONS—SERIES 7

Cement-Aggregate, Ratio by Volume	Parts by Weight				
	Cement	Monterey Sand	Top Gravel	Medium Gravel	Coarse Gravel
1:3.6	1	0.66	0.66	1.34	1.34
1:6.3	1	1.26	1.26	2.24	2.24
Fineness Modulus		2.15	2.92	6.88	7.63

At the age of 5 months (a period of 4 months of sustained stress for those specimens which were loaded) half the number of specimens in each condition of storage and of each mix were tested in compression. At the age of 12 months, when the period of sustained stress was 11 months, the remaining specimens of each group were tested. At the ends of these periods the load was removed from the specimens which were subjected to sustained stress, and observations of instantaneous recovery were made. In the 5-months tests, as quickly as possible after unloading, the specimens were tested to failure, in compression, measurement of deformation being made with a compressometer as the loading progressed. In the 12-months tests, after unloading, the plastic recovery was made for four or five days before the elastic compression tests were made.

Testing Apparatus and Methods

Except for the elastic compression tests of Series 7, where an attached dial compressometer was employed, all changes in length have been measured with portable strain gages, those of Series 1 with a 20-in. gage of the multiplying-lever type, and those of all later series with 10-in. gage of the fulcrum-plate type. The latter type has been found particularly satisfactory.

For each specimen observations of changes in length have been made upon three longitudinal gage lines at the third points of the circumference. The reference marks are No. 50 drill holes into which are thrust the points of the strain gage. For Series 1, ½-in. diameter carbon steel plugs were grouted in the proper position into holes drilled in the specimens, the gage distance was punch marked with a templet, and the gage holes were drilled with a hand drill. For all later series ½-in. square brass plugs each threaded to receive a screw, were fastened to the interior of the molds in true position by means of screws passing through the molds. When the concrete had hardened sufficiently the screws were withdrawn and the molds were removed from the cylinders. Later in each brass plug was screwed a rustless steel insert with center hole forming the gage mark. This type of gage marker, consisting of the brass plug with hard-tempered, rustless steel insert, has proven so eminently satisfactory, not only because of its low cost for making and placing, but because of the precision with which the gage holes can be placed and aligned, and because of resistance to wear and corrosion, that attention is invited to its features.

For the specimens of Series 5, in addition to the three longitudinal gage lines with points in the circumferential surface, there are employed two additional

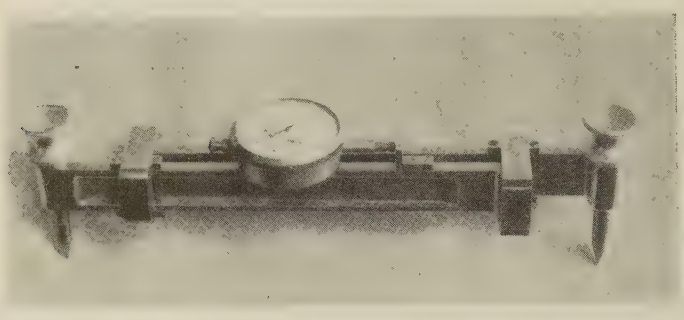

FIG. 1—FULCRUM PLATE STRAIN GAGE

sets of corresponding gage lines, one set of three with plugs set in the concrete at a depth of one inch from the surface, and the other set of three with gage holes in the longitudinal reinforcing bars at 1 in. depth.

In each loaded specimen the load has been maintained constant by means of one or more car springs held in compression by a system of rods and plates between which the specimen is clamped. The desired load is applied by mounting this apparatus in a testing machine with a test specimen in position, the load being indicated by the machine. In order to eliminate the disturbing influence of variable temperature, a small portable machine has been built specially for applying loads to these specimens, and this machine is placed in one of the constant temperature rooms where the specimens are stored. When a specimen is loaded, the nuts on the rods of the load-sustaining apparatus are brought to a bearing against the end plates. The load on the testing machine is then released and the compression in the car spring and in the specimen is maintained by tension in the rods. This method of maintaining stress has proved very satisfactory, since the specimens may be moved about and placed in any position after the load has once been applied, without disturbing stress conditions.

For each group of loaded specimens there is a corresponding group of unstressed or control specimens which is stored in the same conditions as the loaded specimens. Observations made upon these control specimens (made simultaneously with observations on loaded specimens) give changes in length due to causes other than stress, and this makes it possible to determine the flow which has occurred in the loaded specimens as a quantity separate from volume changes due to variations in moisture or temperature.

All specimens have been stored continuously at 70 deg. F. in specially insulated rooms heated by electricity and equipped with sensitive thermostats. Furthermore those stored in air have been placed in rooms where the humidity is controlled as well. Under normal conditions variations from the established standard do not exceed 1 deg. F. in temperature and 1 per cent in relative humidity.

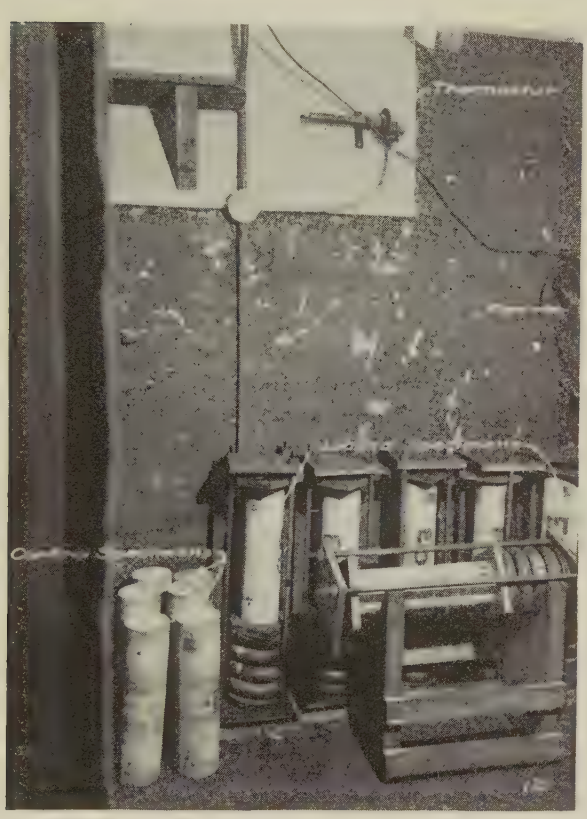

FIG. 2—SPECIMENS IN DRY AIR STORAGE, SERIES 2

Results of Tests

The data of the tests are presented in graphs exhibited as Figs. 4 to 26 inclusive, many of which show the time-flow relation. Each plotted point represents an average value determined by measurements made upon all specimens of a group. Though shrinkage measurements formed a large part of the test data, being taken on all control specimens, they are here eliminated from consideration, except for Series 5 (Fig. 15) in which there are reinforced columns, for which both time-shrinkage and time-flow curves have been drawn.

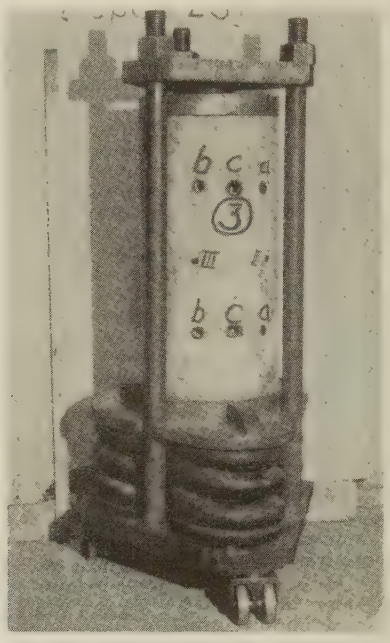

FIG. 3—REINFORCED SPECIMENS UNDER SUSTAINED LOAD, SERIES 5

For the time-flow curves the abscissa represent the time interval in days since the application of load and the ordinates represent flow under the action of sustained load as determined by deducting from the total change in length that due to shrinkage plus that which took place immediately upon application of the load. Examining the figures it will be noted that the flow curves have a characteristic shape, the rate of flow being most rapid immediately after the load is applied and gradually decreasing with time. This indicates that the law governing flow is asymptotic in character, the magnitude of flow gradually approaching a maximum value which depends upon many conditions.

An examination of the diagrams will show that for several conditions the state of flow equilibrium has been reached, but in general it appears that flow is still in progress, even after 3½ years of sustained load.

For several of the figures, in addition to flow curves, there are shown at the left end values of the instantaneous deformations or instantaneous recoveries to the same scale of ordinates as was employed in plotting the flow curves. These deformations and recoveries have been determined by strain-gage observations made immediately before and immediately after the application or release of load.

In Figs. 16 to 19, representing the effect of alternately applying and releasing load, the ordinates to the diagrams give the total deformation due to stress, beginning with the instant before the initial application of the load increment. That is, corrections for shrinkage have been made. The lengths of the full vertical lines represent instantaneous deformations or instantaneous recoveries for the given load increment (760 lb. per sq. in.), i. e., between minimum and maximum or maximum and minimum sustained stresses. The dash lines show the flows under the maximum sustained stress (800 lb. per sq. in.) or the time recoveries under the minimum sustained stress (40 lb. per sq. in.).

Effect Upon Flow of Richness of Mix, Gradation of Aggregate and Water-Cement Ratio—The results of the tests of Series 1 for which the specimens were subjected to a sustained compressive stress of 640 lb. per sq. in. at the age of 7 months, are shown by the diagrams of Fig. 4 and the results of the tests of Series 7, for which the specimens were placed under a sustained stress of 800 lb. per sq. in. at the age of 28 days are likewise represented by the diagrams of Fig. 5. The less precise instruments and methods employed for the earlier series explains the apparent irregularities of the curves of Fig. 4 as compared with those of Fig. 5. Consulting these two figures, it is seen that the general manner in which flow increases with time, as demonstrated by the time-flow curves is characteristically the same for the several groups of specimens represented, the rate of flow being most rapid immediately upon application of the load, and gradually decreasing with time. At the left end of each of the two figures are indicated the magnitudes of the instantaneous deformations which occurred when the load was applied and the instantaneous recovery when the load was released after the period of sustained load which was

approximately 5 months for the specimens of Series 1, and 11 months for the specimens of Series 7.

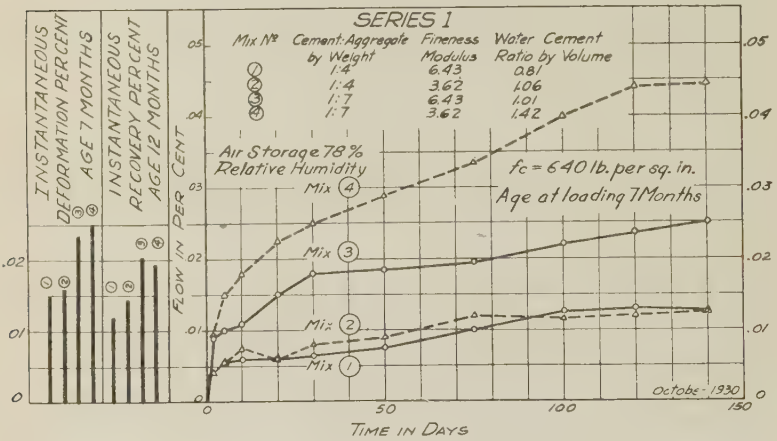

FIG. 4—EFFECT OF RICHNESS OF MIX AND GRADATION OF AGGREGATE UPON FLOW

From a study of the diagrams the following observations are made:

1. Regardless of age, richness of mix, gradation of aggregate, or conditions of storage, concrete subjected to sustained compressive stress plastically deforms for a long time.

2. The rate at which flow takes place under given constant conditions decreases with time, pointing to an eventual state of flow equilibrium.

3. Other things being equal, the leaner the mix, the greater the flow.

4. It appears that the greater the water-cement ratio, other factors remaining constant, the greater the flow, but that the water-cement ratio considered by itself is a lesser factor than is that of the gradation of the aggregate.

5. Other things remaining equal, the better graded the aggregate, or the higher the fineness modulus and the lower the void space, the less the flow.

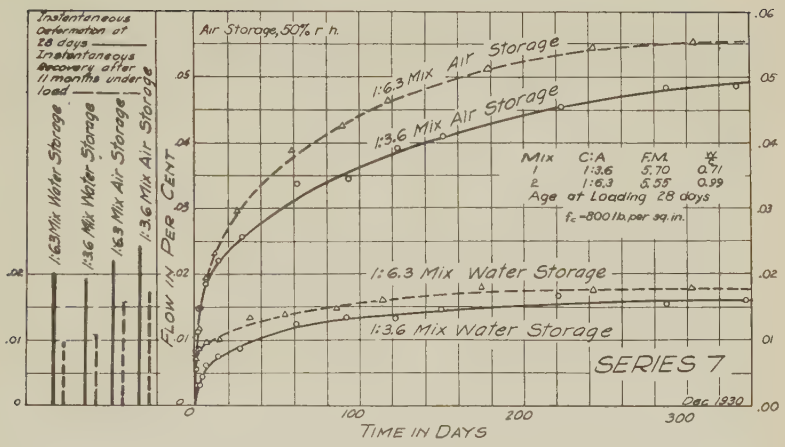

FIG. 5—EFFECT OF RICHNESS OF MIX AND STORAGE CONDITIONS UPON FLOW

6. The instantaneous deformation is less for rich mixes than for lean ones.

7. It is not clear that either the gradation of the aggregate or the water-cement ratio influences the instantaneous deformation to a marked degree.

8. The instantaneous recovery is less than the instantaneous deformation, but this difference in general is not large nor is it clear that the magnitude of the instantaneous recovery is appreciably affected by the duration of the sustained load.

9. Under conditions of dry storage, the flow becomes substantially greater than the instantaneous deformation regardless of richness of mix, gradation of aggregate, or water-cement ratio.

10. It appears that under conditions of dry storage the flow is substantially greater than for the same quality of concrete kept perpetually wet. On the other hand, the instantaneous recovery is proportional to the instantaneous deformation, not being influenced by conditions of storage during the period of sustained load.

11. The total flow at the end of the 5-months sustained load for the lean mix of low fineness modulus of Series 1 (Fig. 4), is more than ½ in. per 100 ft., and for the rich mixes approximately ⅛ in. per 100 ft.

Effect of the Mineral Character of the Aggregate Upon Flow—The results of the tests of Series 4, made to determine the effect of the mineral character of the aggregate are shown by the curves of Fig. 6, one each for limestone, quartz, granite, gravel, basalt, and limestone specimens, and each plotted point representing the average of the given group. The concrete for all aggregates were identical as to richness of mix, water-cement ratio, gradation of aggregate, and conditions of curing. A sustained compressive stress of 800 lb. per sq. in. was applied at the age of 28 days and the specimens were stored in air of 50 per cent relative humidity. The record of flow observations has extended over a period of 2 years.

An examination of the figure shows the following:

12. Regardless of the mineral character of the aggregate, the rate of flow decreases with time, though at the end of two years of sustained load there is no evidence that flow has ceased.

13. The magnitude of the flow is appreciably affected by the character of aggregate, after 2 years being nearly three times as great for sandstone concrete as for limestone concrete, and increasing in the order, limestone, quartz, granite, gravel, basalt, sandstone.

14. As between aggregates of different mineral character, the magnitude of the instantaneous deformation occurring upon application of the sustained load is no criterion to the flow which will eventually take place. The instantaneous deformations for the several aggregates differ but slightly from one another, but the magnitudes of flow differ greatly.

15. The flow after two years of sustained load is 2 to 4 times (depending upon the aggregate) the instantaneous deformation which took place when the load was applied.

16. The rate of flow immediately subsequent to the application of load is generally, though not always, an index to the magnitude of flow after a long period of sustained load. (Among the aggregates investigated, gravel was the exception).

17. The magnitude of the flow produced by the sustained stress of 800 lb. per sq. in. over a period of two years varied from ½ in. per 100 ft. for limestone to 1½ in. per 100 ft. for metamorphic sandstone.

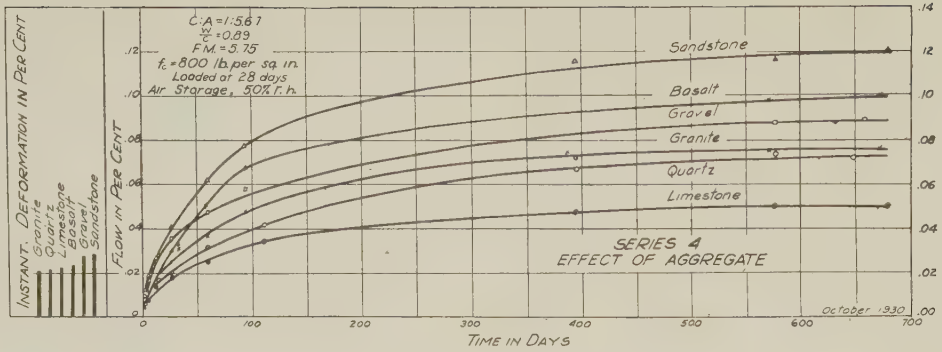

FIG. 6—EFFECT OF MINERAL CHARACTER OF AGGREGATE

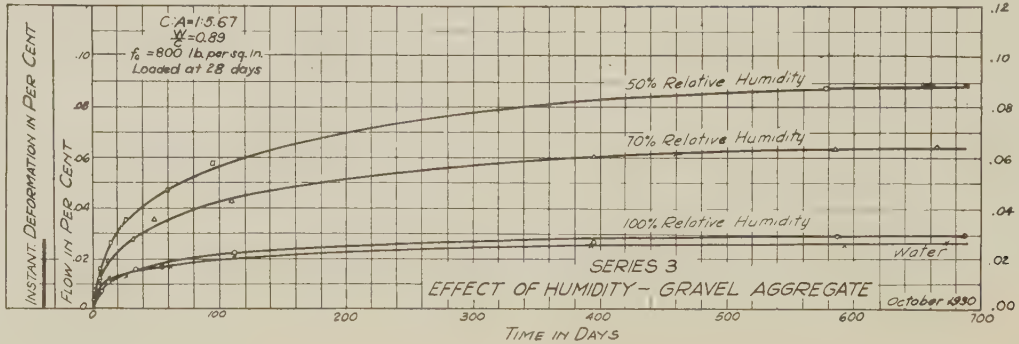

FIG. 8—EFFECT OF MOISTURE CONDITIONS, SERIES 3

Effect of Condition of Storage (As Regards Moisture) Upon Flow—The results of recent tests have demonstrated that the modulus of elasticity of concrete when wet is higher than for the same concrete when dry. In other words, under a given compressive load the instantaneous deformation in a specimen of given concrete saturated with water is less than in a specimen of the same concrete in an air-dry condition, this in spite of the fact that the two specimens may have been moist cured for a long period of time under identical conditions prior to loading.

It has been determined that an analogous condition exists in regard to flow under sustained stress, as is demonstrated by the results of Series 2 and 3, which are shown by Figs. 7 and 8. Further, not only does the analogy hold between fully saturated and air-dry concrete, but also as regards the degree of air-dryness as determined by the humidity of the surrounding air.

Considering Fig. 7, it is seen that there are shown time-flow curves for sustained stresses of 300, 600, 900 and 1200 lb. per sq. in., with ages at loading of 28 days and 3 months, the period of sustained load being about 3½ years. The full lines indicate the flow of groups of specimens stored in air of 70 per cent relative humidity and the dash lines indicate the flow of groups of identical specimens stored under water.

Considering Fig. 8, it is seen that there are shown time-flow curves for nearly two years, a curve for each of four different storage conditions, storage in air at 50 per cent, 70 per cent and 100 per cent (fog) relative humidity and storage under water. For these tests the specimens subjected to a sustained compressive stress of 800 lb. per sq. in. was applied at 28 days. By way of emphasis it perhaps should again be stated that the *flow* is the deformation due to stress alone and does not include shrinkage, which has been eliminated by means of measurements made upon control specimens.

From a study of the diagrams of the two figures the following observations are made:

18. Other things being equal, the flow of concrete stored in air is materially greater than the flow of concrete stored under water.

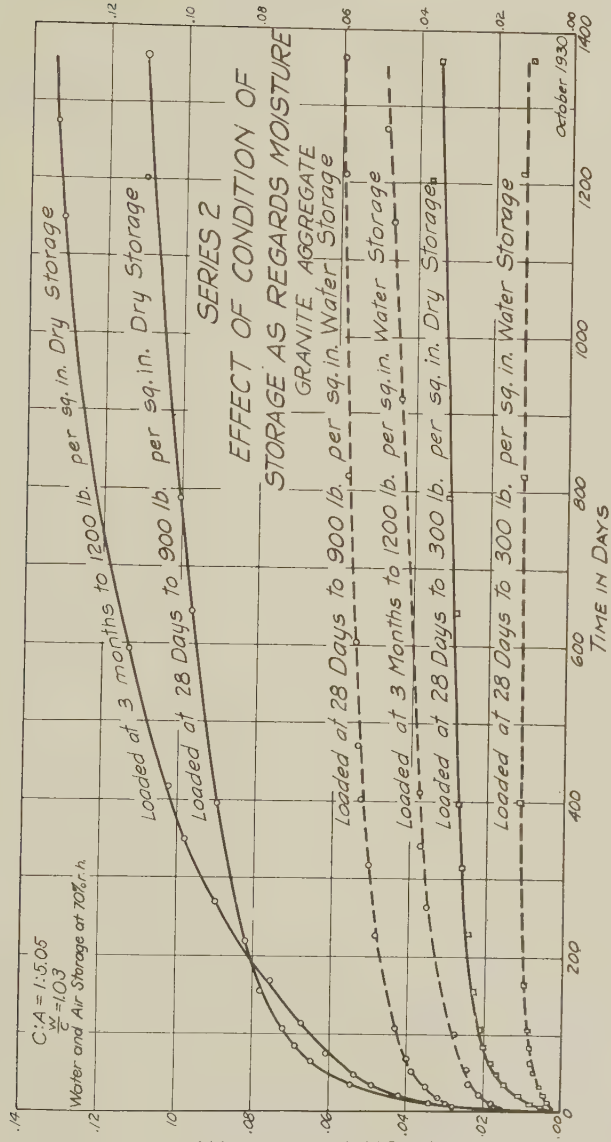

FIG. 7—EFFECT OF MOISTURE CONDITIONS, SERIES 2

and the lower the humidity of the air, the greater the magnitude of the flow. This appears to be true regardless of the intensity or duration of sustained stress and regardless of the age of the concrete at the time of loading.

19. The flows after about 2 years of sustained stress (Fig. 8) at 800 lb. per sq. in. for the several conditions of storage were as follows:

Storage in air at 50 per cent relative humidity	0.089 per cent.
Storage in air at 70 per cent relative humidity	0.063 per cent.
Storage in fog at 100 per cent relative humidity	0.030 per cent.
Storage under water	0.027 per cent.

20. The flow under 800 lb. per sq. in. stress for two years air storage at 50 per cent (Fig. 8) is three times the corresponding flow for concrete stored under water, and three times the instantaneous deformation which took place when the load was applied.

21. The age at loading as well as the intensity of stress and storage conditions as regards moisture has an important influence upon the flow as illustrated by the values of the flow after 3½ years shown on the following table.

TABLE 9—FLOW IN PER CENT AFTER 2½ YEARS, SUSTAINED LOAD—SERIES 2

Storage Condition	Age at Loading, 28 Days			Age at Loading, 3 Months		
	Stress 300 Lbs. per Sq. In.	Stress 600 Lbs. per Sq. In.	Stress 900 Lbs. per Sq. In.	Stress 600 Lbs. per Sq. In.	Stress 900 Lbs. per Sq. In.	Stress 1200 Lbs. per Sq. In.
Air 70% r. h.	0.034	0.069	0.111	0.062	0.081	0.134
Under water	0.012	0.035	0.059	0.018	0.036	0.048

Consulting the table, it is seen that for the range of ages at time loading and the range of sustained stresses represented, the flow in air at 70 per cent relative humidity is 2 to 3 times the corresponding flow under water.

The results of Series 6 and 7 also yield data on the effect of moisture conditions upon the elastic and plastic properties. In Fig. 19 are plotted the residual deformations, due to stress, that remain at the completion of each cycle of certain of the alternating load tests. The maximum stress of each cycle was 800 lb.

per sq. in. and the minimum was 40 lb. per sq. in. A study of the diagrams of this figure results in the following observations:

22. When a sustained compressive stress is alternately applied and released for given periods of time there is left a residual deformation at the end of each stress cycle (no load or low load condition). The magnitude of this residual deformation after a given number of stress cycles is not appreciably influenced by the length of such cycle (high-stress and low-stress periods being of equal duration) but is substantially greater for concrete under conditions of dry air (70 per cent r. h.) storage than under conditions of water storage.

23. After alternations extending over an 8-months period the residual deformation is three times as great for dry as for wet concrete.

In Figs. 20 and 21 are plotted stress-strain diagrams for concrete of two mixes at ages of 5 and 12 months, the ordinates being unit stresses and the abscissae being corresponding unit deformations which took place as the load was gradually applied. The full lines are stress-strain curves for groups of specimens not previously subjected to stress and the dash lines are stress-strain curves for groups which had been previously subjected to a sustained stress of 800 lb. per sq. in. for a period of 5 months for specimens tested at 6 months and for a period of 11 months for specimens tested at 12 months. From these figures it appears that:

24. The ratio of compressive stress to the instantaneous deformation produced thereby, all other conditions remaining the same, is less for a concrete which is dry than for one which is wet (as indicated by the slopes of the curves), regardless of the age of the concrete, the richness of mix, the magnitude of the stress, or whether or not the concrete has been previously subjected to sustained stress.

Effect of Age at Time of Loading Upon Flow—In Fig. 9 are plotted values of flow taking place in the several groups of Series 2 after 3½ years under sustained load. Consulting the figure it is observed that:

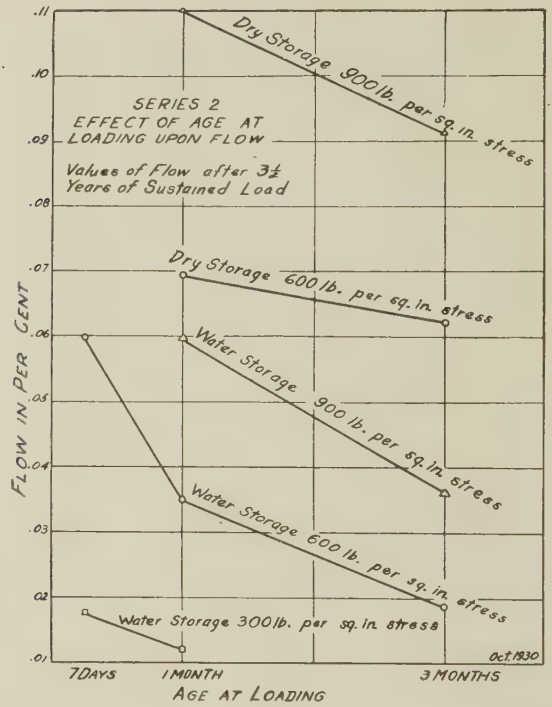

FIG. 9—EFFECT OF AGE OF LOADING UPON FLOW

25. The greater the age at the time of applying the sustained load, the less the flow. Thus the general effect of age is to increase resistance not only to those deformations which take place as the stress is applied but also to the plastic deformations which take place with time.

26. The rate of change in the magnitude of flow under given conditions is greater when the concrete is loaded at an early age than when loaded at a later age.

27. The effect of age at time of loading in reducing the rate of flow is more pronounced for high sustained stresses than for low ones.

Effect of Magnitude of Stress—The effect of the magnitude of the sustained compressive stress upon the flow resulting there-

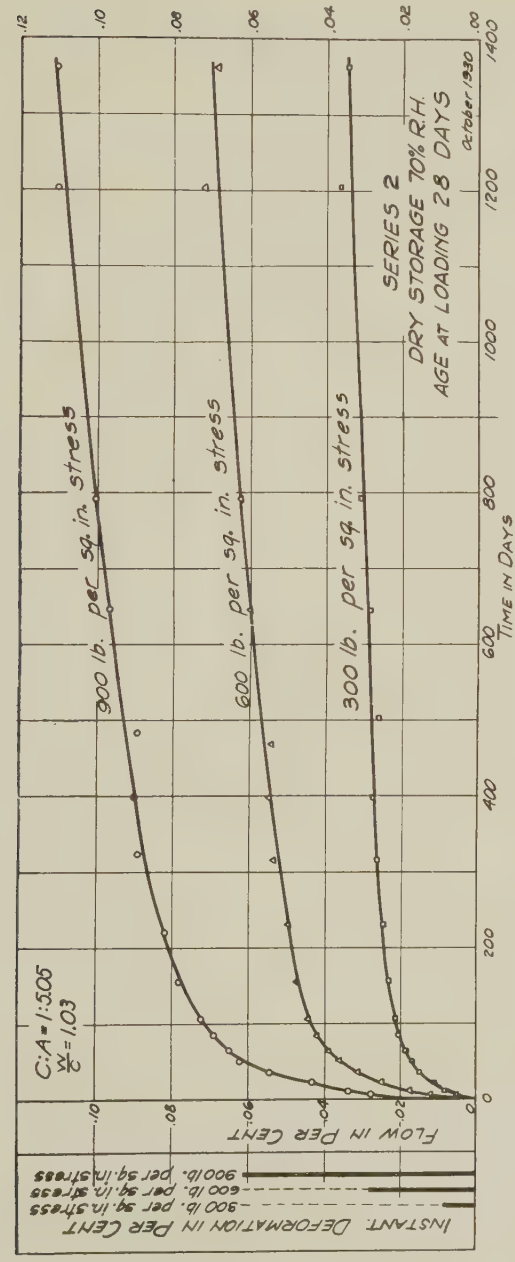

FIG. 10—EFFECT OF STRESS UPON AIR STORED SPECIMENS LOADED AT 28 DAYS—SERIES 2

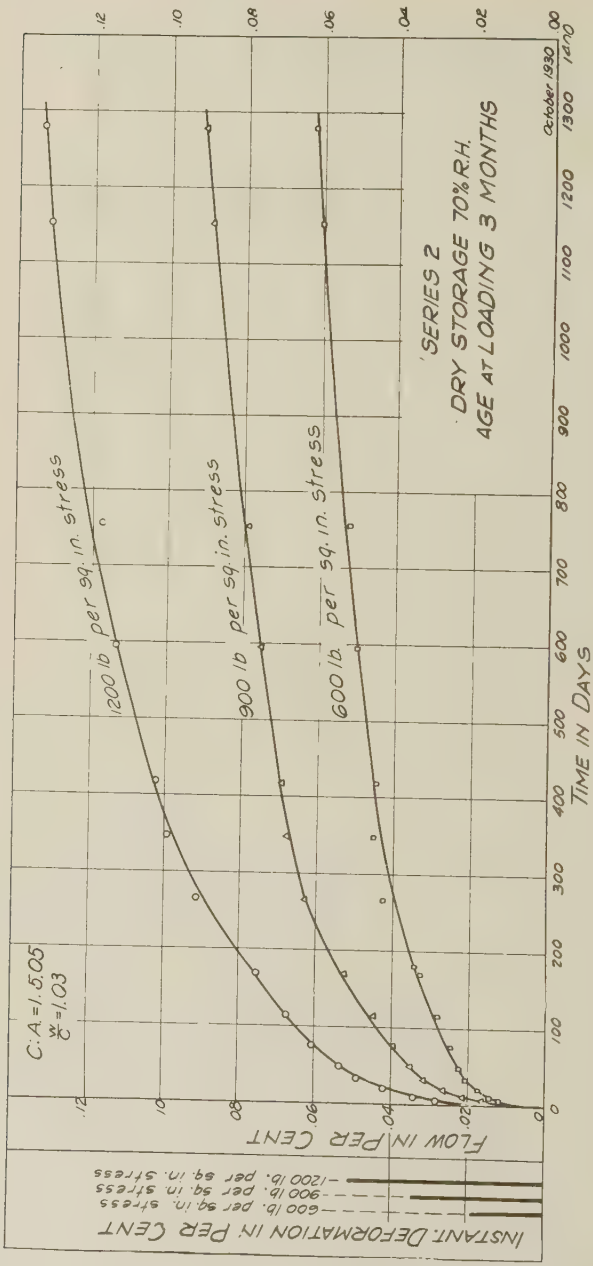

FIG. 11—EFFECT OF STRESS UPON AIR STORED SPECIMENS LOADED AT 3 MONTHS—SERIES 2

from has been determined by the tests of Series 2, where groups of specimens subjected to stresses varying 300 to 1200 lb. per sq. in. have been tested under wet and dry conditions, with loads applied at ages as early as 7 days and as late as 3 months. The results of these tests are shown graphically by the diagrams of Figs. 10 to 14, a separate figure for each condition of storage and age at time of loading. On each figure are shown time-flow curves for the sustained stresses of 300, 600, 900 and 1200 lb. per sq. in., these curves indicating the manner in which flow has taken place over a period of about 3½ years. At the left end of each figure heavy vertical lines show the magnitudes of corresponding instantaneous deformations which took place when the sustained stress was applied.

A study of these four figures results in a number of interesting observations:

28. Under conditions of dry storage, other things being equal, for any given period of sustained load in excess of about four months, the magnitude of the flow proportionally is somewhat greater for high sustained stresses than for low ones, but within the limits of the tests the departure from a linear stress-flow relation is no more marked than is the case for the instantaneous stress-strain ratio or secant modulus of elasticity. It seems reasonable to expect that the sustained stress-flow ratio, as the instantaneous stress-deformation ratio, will become more nearly constant within the range of working stresses as the age is increased.

29. Under conditions of wet storage, including ages of loading of 7 days, 28 days and 3 months, there is marked evidence that the sustained stress-flow relation, at any time after about four months of sustained load, is proportionally greater for high stresses than for low ones, the younger the age of concrete at time of loading, the greater the proportion. Thus by Fig. 12, for an age at loading of 7 days, the flow produced by a stress of 600 lb. per sq. in. is roughly 3½ times that produced by a stress of 300 lb. per sq. in., after any given period of sustained load between 100 and 1300 days. But for a loading age of 3 months (Fig. 14) the corresponding ratio for stresses of 1200 and 600 lb. per sq. in. is roughly 2½.

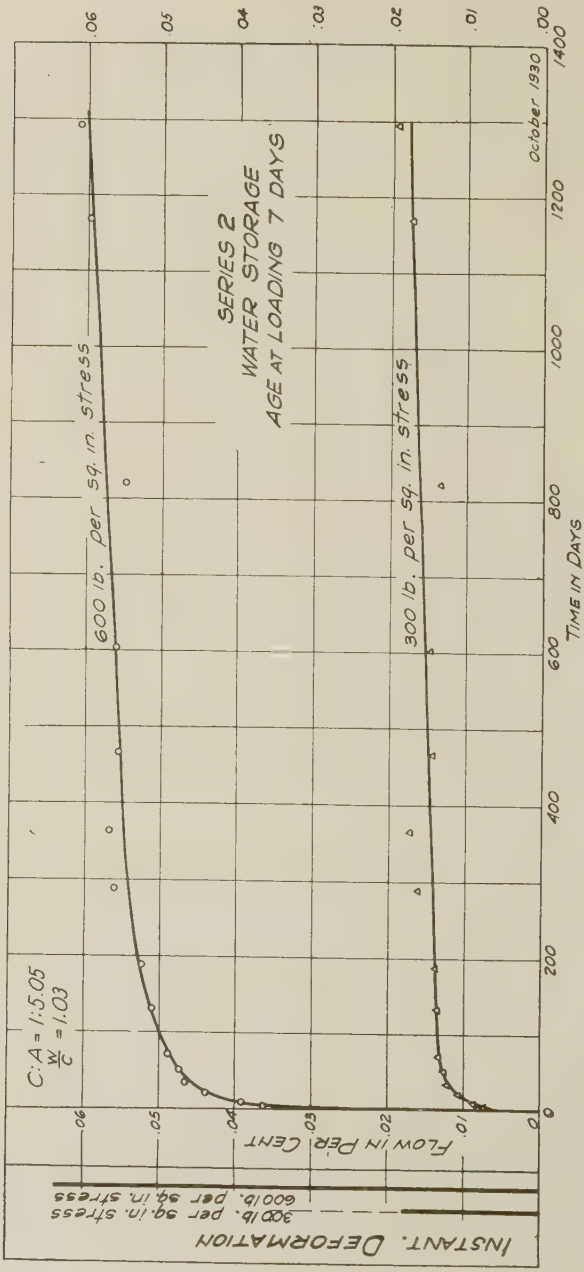

FIG. 12—EFFECT OF STRESS UPON WATER STORED SPECIMENS LOADED AT 7 DAYS—SERIES 2

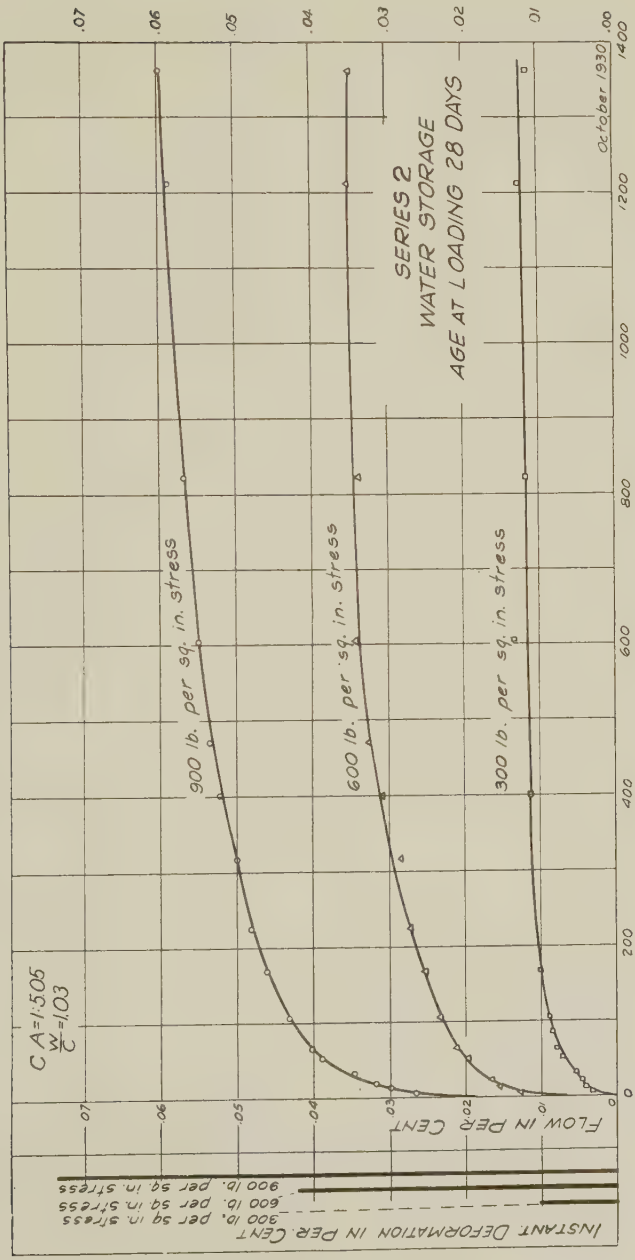

FIG. 13—EFFECT OF STRESS UPON WATER STORED SPECIMENS LOADED AT 28 DAYS—SERIES 2

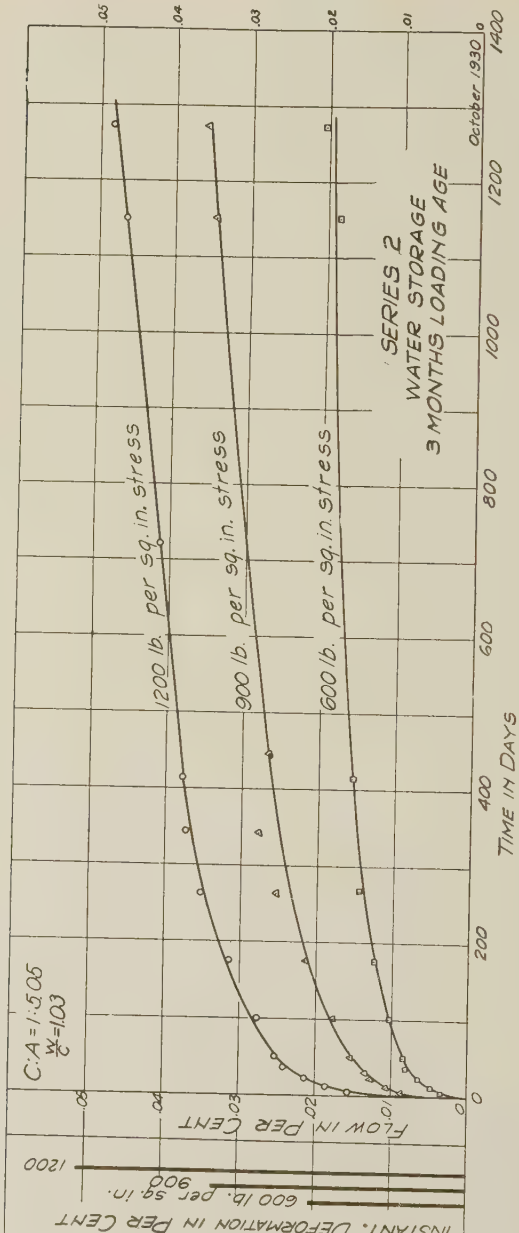

FIG. 14.—EFFECT OF STRESS UPON WATER STORED SPECIMENS LOADED AT 3 MONTHS—SERIES 2

30. For all cases of water storage, regardless of age at time of loading and regardless of intensity of sustained stress, the flow roughly seems to be approaching as a limit the magnitude of the instantaneous deformation. There are some exceptions to this statement, but on the whole, the trend in this direction seems to be rather striking.

31. For all cases of air storage at 70 per cent relative humidity the flow under a sustained stress for 3½ years is substantially greater than the corresponding instantaneous deformation, the ratio of the former to the latter varying between about four for low stresses and about two for high stresses. Since for the higher stresses flow is increasing at a fairly rapid rate even after 3½ years, it would seem reasonable to expect that when flow equilibrium is finally established this ratio of flow to instantaneous deformation may reach a figure as high as four for all stresses. This is, of course, not a general prophecy but merely applies to the conditions of these particular tests.

The data of Series 2 and of Figs. 10 to 14 will be employed in a later discussion of the sustained modulus of resistance, total stress-deformation curves being shown for various periods of sustained loads.

Columns and the Effect of Reinforcement Upon Flow and Stress— The results of the tests of Series 5, made on short plain and reinforced column sections are given by the diagram of Fig. 15, instantaneous deformation being shown at the left and shrinkage and flow curves for plain and reinforced specimens being plotted one above the other.

The tests were begun when the specimens were 60 days old, the previous storage having been 50 days in fog and 10 days in air at 50 per cent relative humidity. The stress was 800 lb. per sq. in. in the plain concrete at the time of loading. The increment of stress placed in the concrete of the reinforced section at the time of loading was 775 lb. per sq. in. (assuming the modulus of elasticity of the steel as 30,000,000 lb. per sq. in.) but the actual stress in both the longitudinal steel and the concrete is not precisely known because observations of shrinkage were not begun upon control specimens until the sustained loads were applied.

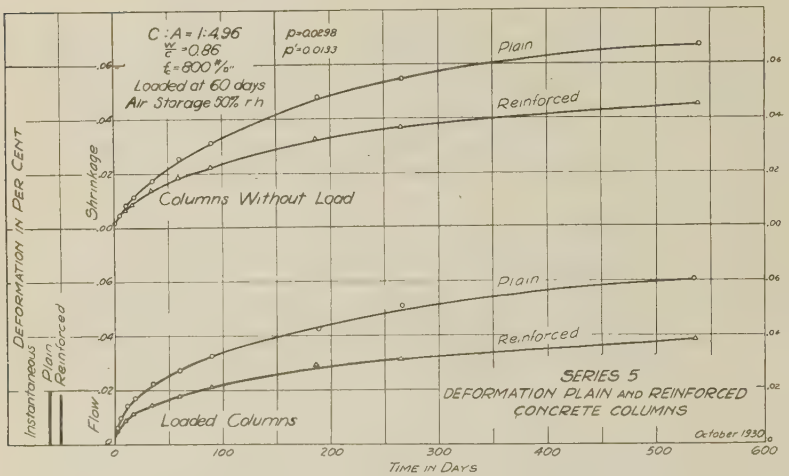

FIG. 15—DEFORMATION OF PLAIN AND REINFORCED CONCRETE COLUMNS—SERIES 5

Considering the curing conditions prior to loading it seems probable that a slight shrinkage had taken place during the 60-days curing period, in which case there was a small initial tension in the concrete and an initial compression in the steel. The longitudinal bars were ground flush with the plane ends of the columns immediately prior to applying the load, and the load was transmitted to the column through heavy steel plates bearing directly against reinforcing steel and concrete; hence stress was transmitted directly from load to reinforcement.

Considering the diagrams of Fig. 15, the following observations are made:

32. The effect of reinforcement is appreciably to reduce both shrinkage and flow.

33. There is a striking similarity between the shrinkage and flow diagrams, both for plain and reinforced specimens, though in general the shrinkage is somewhat greater than the flow.

34. The shrinkage after 18 months in air at 50 per cent relative humidity and the flow produced by a corresponding period of sustained compressive stress are each about ¾ in. per 100 ft. for plain columns and ½ in. per 100 ft. for reinforced columns.

35. For plain columns the combined flow and shrinkage over the loading period of 18 months is approximately six times greater than the instantaneous deformation which took place when the load was first applied.

36. Similarly, for reinforced specimens the combined flow and shrinkage is four times the instantaneous deformation.

37. By computations it can be shown that the compressive stress in the steel produced by load and shrinkage during the 18 months over which the observations extend is made up of the following:

Stress due to instantaneous deformation	5700 lb. per sq. in.
Stress due to flow	11400 lb. per sq. in.
Stress due to shrinkage	13200 lb. per sq. in.
Total change in steel stress	30300 lb. per sq. in.

Since the steel was structural grade, it appears that the stress was near the yield point. Obviously had the load been applied at an early age, as will often be the case in service structures, the yield point would certainly have been reached before 18 months.

38. Assuming the remainder of the load not carried by the longitudinal steel as being uniformly distributed over the full cross-section of the concrete, during the 18 months of sustained load, the sustained stress in the concrete was reduced from 775 lb. per sq. in. to 300 lb. per sq. in.

39. From observations of lateral deformation not here shown, there is computed as existing in the spiral hooping a compressive stress of 13800 lb. per sq. in. for both unloaded and loaded specimens, there being lateral shrinkage but no evidence of an appreciable lateral flow.

40. It seems evident that the yield point of the steel should be a factor in the design of columns carrying a large proportion of dead load when surrounding conditions are such as to produce shrinkage.

Effect of Alternating Periods of Sustained Stress—Figs. 16, 17 and 18 show graphically the results of the tests of Series 6, where specimens were subjected to alternating periods of high and low sustained compressive stress. For this series the specimens were loaded at the age of 28 days, first to a sustained stress of 800 lb. per sq. in. for a given period, then the stress was reduced to 40

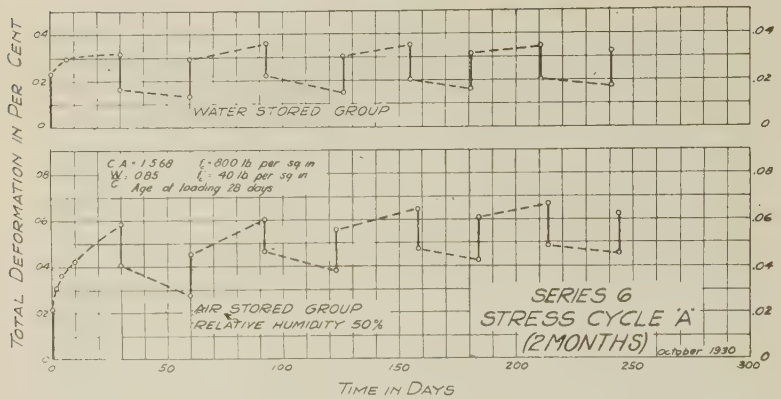

FIG. 16—EFFECT OF STRESS ALTERNATIONS—2 MONTHS CYCLE

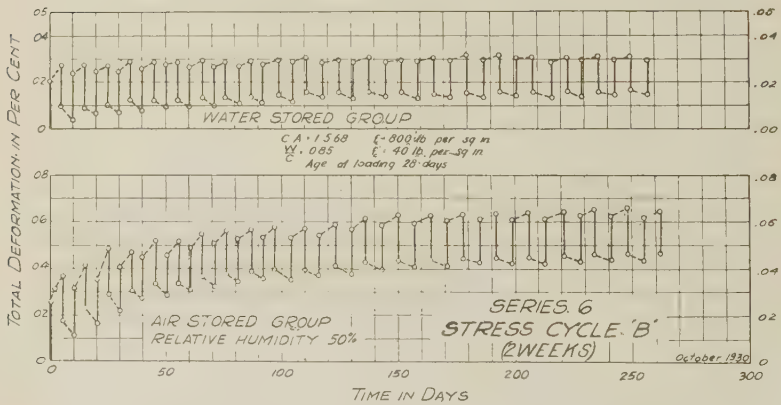

FIG. 17—EFFECT OF STRESS ALTERNATIONS—2 WEEKS CYCLE

lb. per sq. in. for the same length of time, and so the process of alternating high and low sustained stresses was repeated, the length of stress cycle varying between three groups of specimens but remaining substantially constant for the specimens of each group. The length of Stress Cycle A, for which the results are shown by the diagrams of Fig. 16, was two months, that is, each alternation consisted of one month at the stress of 800 lb. per sq. in., followed by one month at 40 lb. per sq. in.; the length of

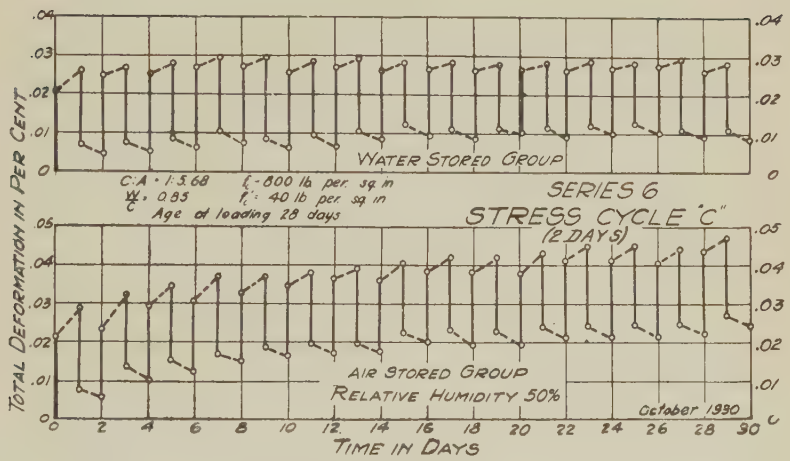

FIG. 18—EFFECT OF STRESS ALTERNATIONS—2 DAYS CYCLE

Stress Cycle B (Fig. 17) at first was 10 days, but later was two weeks; and the length of Stress Cycle C (Fig. 18) was 2 days.

Consulting the three figures, the following significant facts become evident:

41. The instantaneous deformation which took place at the time of first applying the load is greater than any succeeding value of the deformation, and greater than any value of the instantaneous recovery, demonstrating that a permanent set takes place upon the initial application of the load which is not later recovered. This is true regardless of the duration of the stress cycle.

42. Generally speaking, for specimens stored under water, the instantaneous deformations (after the first) and the instantaneous recoveries become somewhat less as the number of stress cycles is increased, but the decrease in these values is not large.

43. As a usual thing, for specimens stored in air there is little if any change in the magnitude of instantaneous deformations (after the first) with the number of alternations of stress, nor are there appreciable variations in the magnitude of the instantaneous recovery with number of alternations.

44. After the initial application of the load, there is general agreement between an instantaneous deformation and the

succeeding instantaneous recovery, regardless of the duration of stress cycle or condition of storage.

45. The rate of flow and of plastic recovery decreases as the number of stress cycles increases.

46. In general, the rate of flow for a given stress cycle is greater than the rate of plastic recovery for the same stress cycle. This characteristic becomes less pronounced as the number of cycles increases; it is more pronounced for specimens in air storage than for those in water storage.

47. Deformations and recoveries, whether instantaneous or plastic, for a given cycle are greater for specimens stored in air than for corresponding specimens stored in water.

Let the "stress deformation" be defined as the decrease from the original length (under minimum load) to that at the middle of any stress cycle at the instant preceding the release of maximum load. Also let "residual deformation" be defined as the decrease from the original length to that at the end of any stress cycle at the instant preceding the application of the maximum load.

48. Both stress deformations and residual deformations increase with the number of stress cycles. There are some indications that the magnitude of the residual deformation continues to increase after the stress deformation has become practically constant.

49. Both stress deformations and residual deformations increase at a more rapid rate with the number of cycles and become substantially larger for specimens in air storage than for those in water storage.

In Fig. 19 are plotted the residual deformations for water-stored and air-stored groups of specimens subjected to 2 months (Cycle A) and 2 weeks (Cycle B) alternations of stress. Consulting the figure it appears that:

50. Under similar stress conditions the residual deformation is approximately the same at the end of a given period of time regardless of the length of the stress cycle. This would also apply to the stress deformations. It is true for specimens in water storage as well as for those in air storage.

51. For Cycles A and B the residual deformations after 8 months of alternating load are approximately 3 times as great

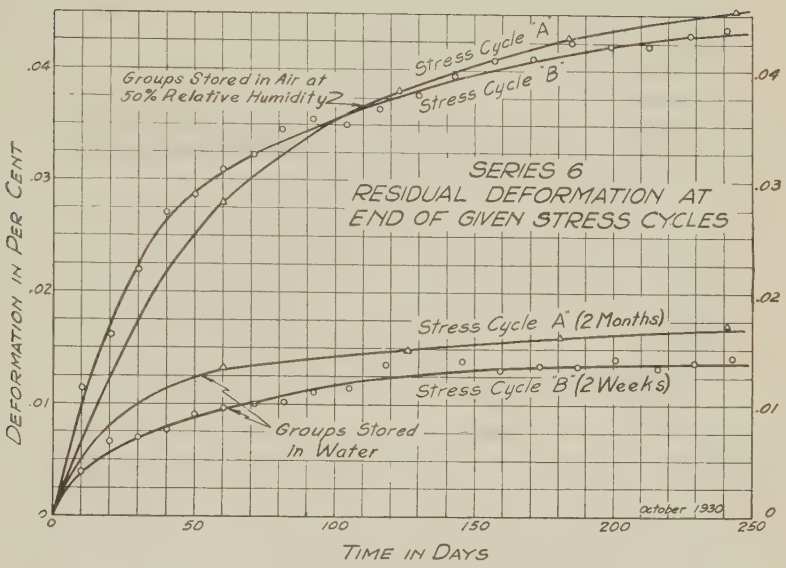

FIG. 19—EFFECT OF ALTERNATING STRESS UPON RESIDUAL DEFORMATIONS

with air-stored as with water-stored specimens; the corresponding stress deformations are twice as great for air-stored as for water-stored specimens.

Effect of Flow Upon Strength and Modulus of Elasticity—Table 10 and Figs. 20 and 21 give the results of tests upon specimens of Series 7 made to determine the effect of flow upon compressive strength and modulus of elasticity. For this series half of the specimens were placed under a sustained compressive stress of 800 lb. per sq. in. at the age of 28 days, while the other half without stress were maintained under corresponding conditions. At the ages of 5 and 12 months, specimens from each of these two groups were tested in compression under a gradually increasing load, the sustained load having been released prior to the application of the ultimate load.

Consulting Table 10 and the diagrams of Figs. 20 and 21, the following facts are in evidence:

52. The effect of flow under the action of a sustained load is to increase the compressive strength over that of identical con-

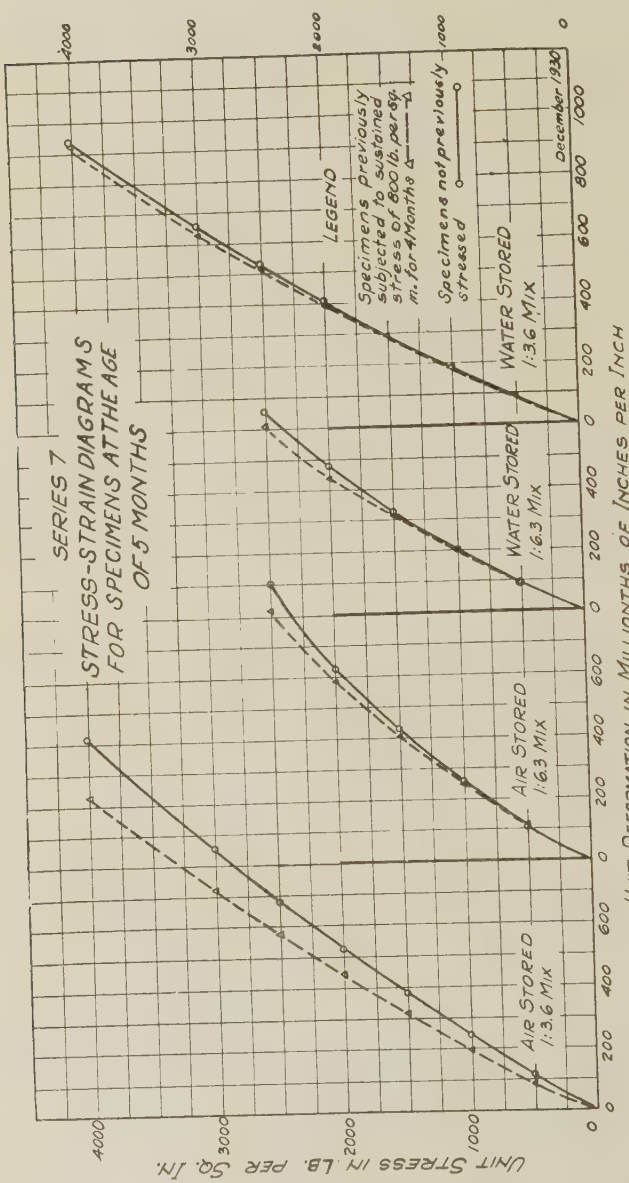

FIG. 20—SERIES 7

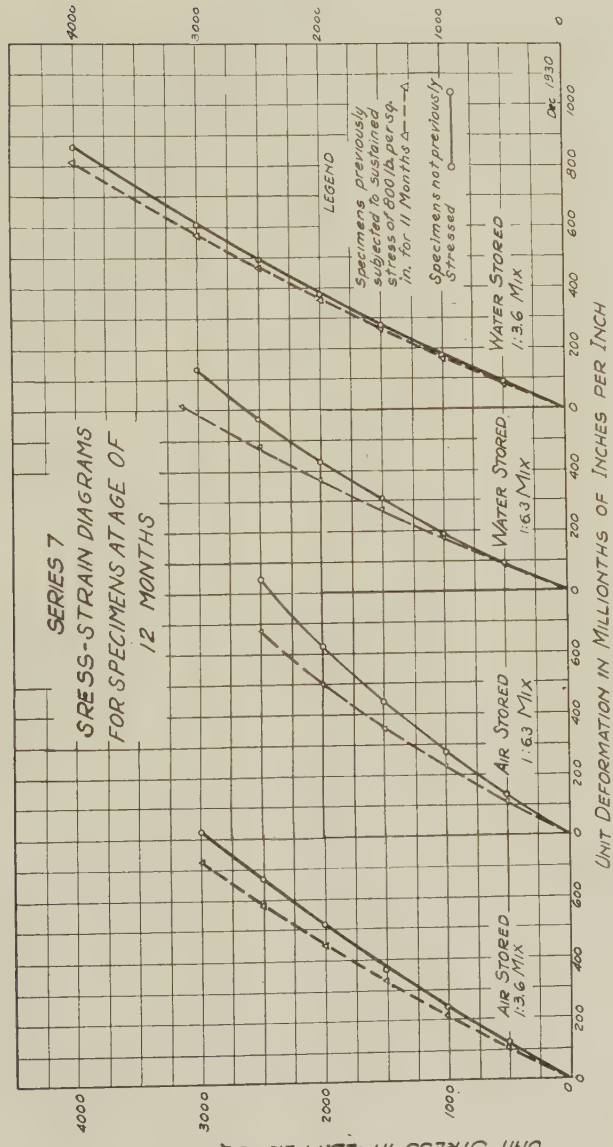

FIG. 21.—SERIES 7

TABLE 10—EFFECT OF FLOW UPON STRENGTH—SERIES 7

Age, Months	Storage	Compressive Strength, Lb. per Sq. In.			
		Rich Mix (1:3.6)		Lean Mix (1:6.3)	
		Stressed	Unstressed	Stressed	Unstressed
5	air	5340	5110	3260	3250
5	water	6220	6020	3460	3560
12	air	5200	4770	3660	3460
12	water	5940	5790	4220	4150

crete not previously stressed, but the amount of the increase in compressive strength due to flow is small. There are some indications that the longer the period of sustained stress, the greater this increase becomes.

53. The influence of moist storage conditions after the age of 28 days upon the compressive strengths at later ages is manifest, since at both 5 and 12 months the water-stored specimens exhibit substantially greater strengths than do corresponding air-stored specimens.

54. The effect of flow under the action of sustained stress is appreciably to increase the instantaneous stress-deformation ratio or the secant modulus of elasticity over that exhibited by identical concrete not previously stressed. This is demonstrated by the curves of Figs. 20 and 21, the dash lines for specimens in which flow had occurred having a substantially greater slope than the full lines for specimens not previously stressed. This is true for high stresses as well as for low ones.

54. The effect of flow is to render the instantaneous stress-deformation relation or modulus of elasticity more nearly constant for all stresses, as indicated by the relative straightness of the corresponding stress-strain diagrams of the figures.

55. The longer the period of sustained load, the greater the increase in the instantaneous modulus of elasticity over that for

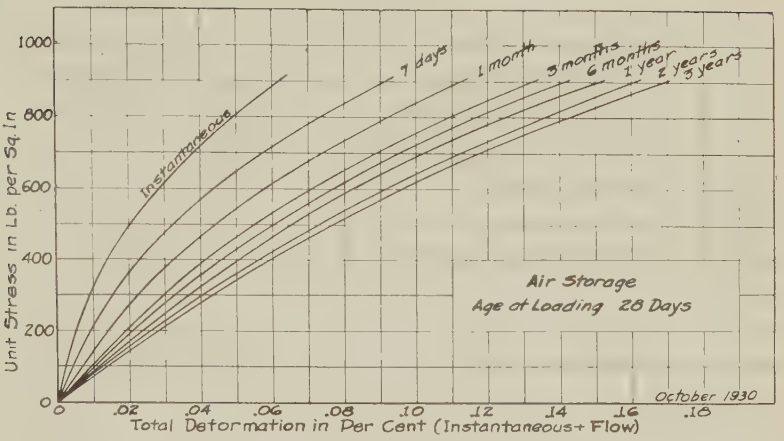

FIG. 22—STRESS-DEFORMATION DIAGRAMS—SERIES 2—AIR STORAGE, LOADED AT 28 DAYS

corresponding specimens not previously stressed. This time effect is more pronounced for the lean mix than for the rich one.

56. The greater the age, the more nearly constant for all stresses becomes the instantaneous modulus of elasticity. This is true for air storage as well as for water storage, and is true for specimens not previously stressed as well as for those previously subjected to sustained load.

57. The instantaneous modulus of elasticity is higher for specimens in wet storage than for corresponding specimens in dry storage. This is true regardless of age, mix, or previous stress condition.

Modulus of Resistance—Perhaps a clearer idea of the effect of sustained compressive stress may be gained by considering the relation between unit sustained stress and total unit deformation, including the instantaneous deformation and flow. With this thought in mind, the diagrams of Figs. 22, 23 and 24 have been prepared from the data of Series 2, the ordinates being unit sustained stresses and the abscissae being unit total deformations. Thus each diagram indicates the stress-strain relation for a group of specimens under the action of stress sustained for the period indicated on the diagram, and these time-stress-deformation curves have been collected into sets, each set for a given condition

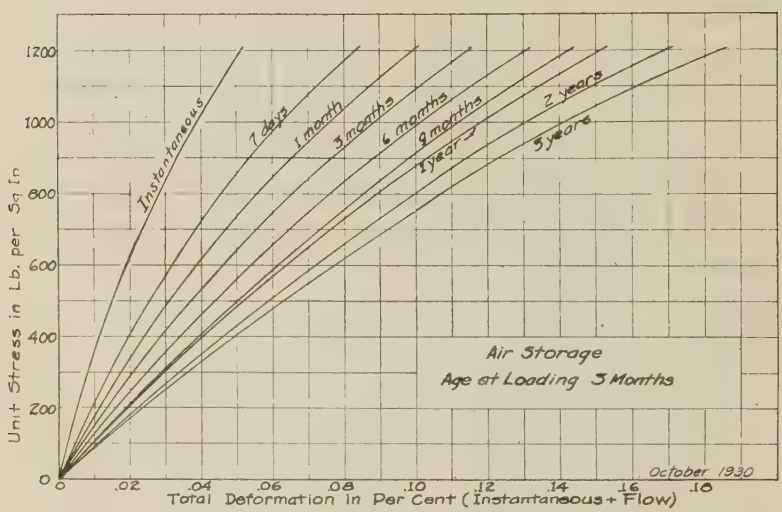

FIG. 23—STRESS-DEFORMATION DIAGRAMS—SERIES 2—AIR STORAGE, LOADED AT 3 MONTHS

of storage and age at application of sustained load. The points employed in plotting these diagrams have been taken from time-flow curves. Hence the curves of Figs. 22-24 pass through plotted points, and for this reason the points are not shown.

Modulus of resistance has been defined as the ratio of unit sustained stress to unit total deformation. Using the diagrams of Figs. 22-24 as a basis, values of the modulus of resistance for various intervals of sustained stress (800 lb. per sq. in.) up to 3 years. The results in millions of pounds per sq. in. are given in Table 11. The "instantaneous" modulus of resistance is merely the secant modulus of elasticity in the usual terminology.

Similarly computed values of the modulus of resistance for Series 3 and 4 are given in Table 12.

A study of the diagrams and tables indicates that the following relations obtain:

58. The modulus of resistance for concrete under constant sustained compressive stress decreases with time, at first rapidly and then more and more gradually for a long period. Under normal working stresses the sustained modulus of resistance

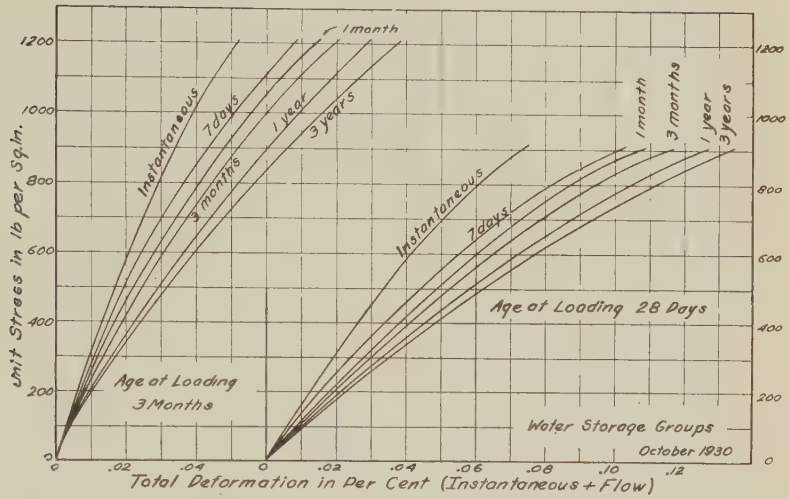

FIG. 24—STRESS-DEFORMATION DIAGRAMS—SERIES 2—WATER STORAGE, LOADED AT 28 DAYS AND 3 MONTHS

18 Months	0.70	0.88	1.42	1.47	0.55	0.67	0.83	0.87	1.11

*At a stress of 800 lb. per sq. in.

59. Under like conditions the modulus of resistance of concrete loaded at an early age always remains less than the corresponding modulus for the same quality of concrete loaded at a later age.

60. Other things remaining equal, the conditions of storage as regards moisture have an important bearing upon the magnitude of the modulus of resistance. Regardless of the period of sustained load, the sustained modulus of resistance is higher for a concrete in water storage than in air storage and is higher for a concrete surrounded by air of high humidity than for one surrounded by air of low humidity.

61. The mineral character of the aggregate influences to a marked degree not only the instantaneous modulus of elasticity, but even more so the sustained modulus of resistance. After 18 months of sustained load (Table 12) the modulus for limestone concrete is double that for sandstone concrete. The corresponding ratio for the instantaneous modulus is $\frac{4}{3}$.

Plastic Recovery—In considering the effect of alternating loads the question of plastic recovery received some attention. It was shown by diagrams that following each release of load there was an instantaneous recovery and that this was followed by a plastic recovery which increased with time.

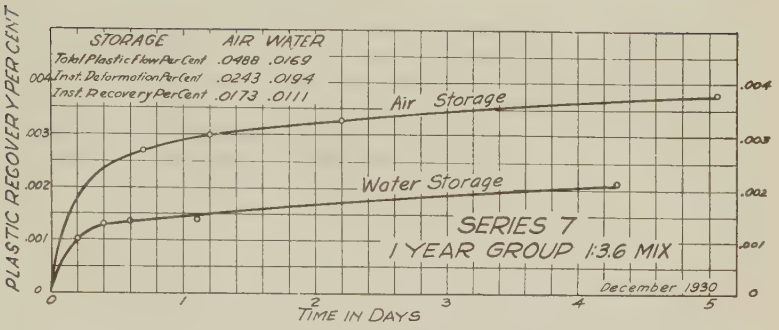

FIG. 25—PLASTIC RECOVERY—SERIES 7

The manner in which this plastic recovery takes place, and its magnitude when plastic equilibrium has been established, as compared with the preceding flow, are of interest.

Fig. 25 has been prepared by plotting observations of plastic recovery made on specimens of Series 7 which were tested in compression at the age of one year, after having been under load for 11 months. After the sustained load was released the specimens of this group were observed at intervals for several days in order to determine the general shape of the recovery curves for both air and water-storage.

Similarly, Fig. 26 shows residual deformation and plastic recovery curves for Group C of the alternating load tests of Series 6. The specimens of this group after fifteen 2-day alternations of stress were allowed to rest for a period of about 7 months, observations of changes of length being made periodically for both wet and dry groups. The full line curves of Fig. 26 are drawn through points which represent the residual deformations which were measured at the end of each successive 2-day cycle of stress, the measurement having been made just before another application of the load. The dash lines indicate the plastic recovery during the 7 months following the release of the last alternating load during which period the specimens were at rest.

An examination of Figs. 25 and 26 shows that:

62. The general shape of the time-recovery curves is much the same as for corresponding time-flow curves, but the rate of

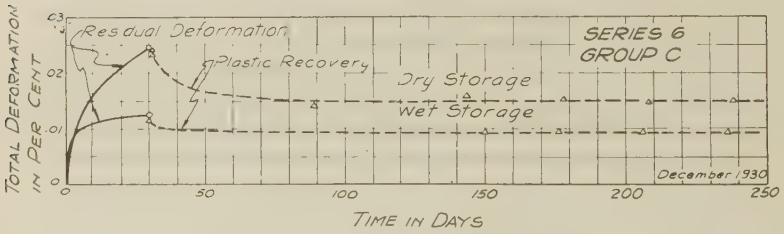

FIG. 26—PLASTIC RECOVERY—SERIES 6, GROUP C

recovery is comparatively small, and the state of plastic equilibrium is reached in a comparatively short time.

63. Plastic recovery for concrete in water storage is considerably less than the corresponding plastic recovery in air storage.

64. The plastic recovery as compared with the flow is a comparatively small quantity, much of it taking place within a few hours after the release of load. For example, Fig. 25 shows that the plastic recovery in 1 day is ¾ that in 5 days. Fig. 26 indicates that there is no further recovery after perhaps 2 months. Also, from Fig. 25 the plastic recoveries are respectively 0.004 and 0.002 for the dry and wet groups; while the corresponding flows for these groups, due to previously sustained load, were 0.048 and 0.016 per cent, values roughly ten times as great.

Summary of Flow Values—In order to render easy a comparison of the principal data concerning deformations produced by sustained stress which have been presented in the form of tables and graphs in the preceding pages, Table 13 has been prepared. In the Column headed "Instant Deformation," are given, in per cent, values of the deformations which took place immediately upon application of the sustained compressive stress stated under "Conditions." In the last column are recorded the plastic deformations or flows which were produced by the sustained stress subsequent to its application and during the time interval stated under "Conditions."

PART 2—SUMMARY OF VARIOUS PUBLISHED DATA CONCERNING FLOW OF CONCRETE

Following are brief abstracts of what are regarded as some of the more important published reports describing tests for which the phenomenon of gradually increasing deformations under the action of sustained loads has been observed and the results have been discussed. These include laboratory tests upon specimens, in the form of reinforced beams and slabs subjected to transverse loading and cylinders subjected to axial compressive stress, as well as field observations upon beams, slabs and columns in service structures in which deformations in both concrete and steel were measured over varying periods of time.

Among these published accounts there is no uniformity in the use of a term for the deformation due to sustained stress, it being variously designated as "plastic flow," "time yield," "time deformation," "flow," etc., and in the majority of tests reported the factor of shrinkage has been combined with that of flow without attempt at separation, their sum being considered as the "time yield." Obviously, "flow" is primarily a function of magnitude of stress, while "shrinkage" is primarily influenced by the surrounding moisture conditions, which determine the rate at which the concrete is relieved of its uncombined moisture.

At the end appears a summary of conclusions and a bibliography of articles, papers and discussions pertaining to flow and shrinkage.

Notes on the Effect of the Time Element in Loading Reinforced Concrete Beams, by W. K. Hatt, Proc. Am. Soc. T. M., vol. 7, 1907, p. 41. The tests were made during 1905 to 1907 at the Laboratory for Testing Materials, Purdue University, under the following loading conditions:

1. Continuously increased until failure.
2. Repeated loads.
3. Sustained loads.

The beams were of 1:2:4 broken stone concrete, 8 in. wide by 10 in. to the depth of the steel. They were loaded at the one-third points, the span length being 9 ft. except for the sustained load tests for which the span varied from 8 to 12 ft. in order to obtain various desired stresses in the steel. The percentage of steel was 1.00 except for the sustained load tests, where the percentage varies from 0.75 to 1.50 for the reason stated above. Age at test was about 60 days. It appears that the beams were stored in open air, without tempera-

ture control and without temperature or humidity records, and no account is taken of shrinkage due to moisture change. Following are tabulated the important results, average values being given.

DEFLECTION OF REINFORCED CONCRETE BEAMS (HATT)
Values in Inches

Approx. Stress in Steel Lb. per Sq. In.	Ordinary Load, Testing Machine	Repeated Load			Sustained Load, 2 Mo.
		Times Applied	Deflection	Set	
3000	0.050	1 710	0.025 0.035	0.005 0.005	0.100
8000	0.080	1 500	0.070 0.155	0.010 0.055	0.160
16000	0.140	1 515	0.195 0.250	0.060 0.090	0.290
29700	0.210	1 550	0.285 0.300	0.095	0.360

INCREASE IN DEFLECTION UNDER SUSTAINED LOAD (HATT)

Initial Stress, Lb. per Sq. In.	First Recorded Deflection, In.	Deflection after 1½ Months, In.
3000	0.04	0.10
8000	0.10	0.17
16000	0.15	0.29
29700	0.20	0.36

In his discussion Hatt says, "These results, taken together, show a sort of plasticity in concrete, by which it yields under the action of a load applied for a long time, or applied a number of times."

While the conditions surrounding the tests are not sufficiently well established to make the quantitative data of much value, these tests made nearly a quarter century ago clearly demonstrated that the time yield or plastic flow of concrete under the action of sustained flexural stresses was a quantity of considerable magnitude.

Shrinkage and Time Effects in Reinforced Concrete, by F. R. McMillan, Univ. of Minn., Studies in Eng. Bull. 3, 1915.

The tests here reported were made at the University of Minnesota in the years 1913-1914 under the direction of F. R. McMillan. They comprised observations on several beams and slabs (stored in air) which were subjected to sustained load. Deformations were measured between points set in the concrete in the top of the beams or slabs and in the steel in the bottom. Center deflections were also observed. The temperature ranged between 60 deg. and 80 deg. F. No record was kept of the humidity. The object of the tests was

to study shrinkage, plastic flow (called time effect in the paper) and Poisson's Ratio.

Test of a 30-in. by 5½-in. by 12-ft. beam.—The concrete was a 1:2:5 mix, the coarse aggregate being crushed limestone. 8 by 6-in. test cylinders made from the same concrete gave at 27 days an average compressive strength of 2500 lb. per sq. in. and a modulus of elasticity at f_c = 1000 of 3,500,000 lb. per sq. in.; 4 by 5-in. transverse specimens gave an average modulus of rupture of about 500 lb. per sq. in. The steel ratio for the longitudinal was 0.00796 at a depth of 4⅝ in. from the top of the beam. The transverse steel was ⅜-in. plain round rods spaced 12 in. on centers at a depth of 5 in. No curing data are given except the statement that the beam was left exposed to the laboratory air. At the age of 41 days the beam was placed on supports thus applying a dead load calculated to produce a maximum steel stress of 8000 lbs. per sq. in., and a concrete stress of 335 lb. per sq. in. was applied. At 80 days a live load (sand-bags) of 500 lb. was applied, effective at the third points. After sundry applications and removals of load, at the age of 107 days the full live load of 1500 lb. calculated to give the same maximum stress as the dead load, was applied and sustained except for periodic instantaneous removal and reapplication.

The effect of shrinkage was determined by transverse measurements and these corrections have been applied to the longitudinal deformation given.

The actual stresses for a live load change calculated from the observed deformations, assuming a modulus of elasticity of 30,000,000 for the steel and 3,500,000 for the concrete, are about 300 lb. per sq. in. for the concrete and about 2600 lb. per sq. in. for the steel. The deformation due to stress in the concrete at the center of span after almost 60 days of dead load, was about twice the instantaneous deformation due to dead load. After 600 days, the total deformation due to stress was about three times the sum of the instantaneous dead and live load deformations. At the end of this period, the total deformation at the center of the span, due to stress, was about 0.11 per cent of the gage length. Including the shrinkage, the total deformation after 600 days was about four times the instantaneous deformation. The observed deformation in the steel at the end of a 530-day period which began with the application of the live load, which deformation corresponds to a steel stress of 12,000 lb. per sq. in., was about five times the instantaneous live load deformation. The effect of shrinkage before cracking or bond failure occurs is to decrease the observed steel deformation.

Tests of four 4 by 5 by 42-in. beams.—This group of tests was undertaken to study further the time effect and shrinkage in concrete. Four similar beams were made and stored under the same conditions for the entire period of test. On one which was without load, the shrinkage alone was measured, while on the others, the flow due to sustained load over a period of time was observed.

The concrete was 1:2:4 mix, the coarse aggregate being crushed limestone of pea size. The specimens, which were 4 by 5 by 48-in. beams, were covered with wet sacks at the time of casting, but were left open to the air after the

first day. The depth to steel was 4½-in. The steel ratio was 0.0078 for the first beam and 0.0085 for the others.

Each beam was tested on a 42-in. span with a center load of 860 lb., calculated to give approximately 650 lb. per sq. in. stress in the concrete and 15,000 lb. per sq. in. stress in the steel. Measurements of longitudinal deformation were made both on the top of the beam and in the steel, and center deflections were observed.

It appears that there was considerable variation in humidity conditions with a considerable resulting effect on the regularity of shrinkage and with some effect on flow. The total deformations due to load alone after a year were from 0.08 to 0.12 per cent, which values were from 3 to 4 times the instantaneous deformation.

Slab tests.—A 6 by 8-ft. by 3-in. thick two-way slab, supported at four edges, and a 10 by 10-ft. by 4¾-in. thick one-way slab, supported at two edges, were also tested under the action of sustained load.

For the greater part of the time, the live load on the 6 by 8-ft. slab was 100 lb. per sq. ft. Only the dead load of its own weight was applied to the 10 by 10-ft. slab.

Deformation and deflection measurements were made as in the beam tests, except that the shrinkage observations were made on the edges of the slabs over the supports.

Much the same results as were obtained in the beam tests as regards time deformation, time-deflection trends, and ratio of total load deformation to instantaneous load deformation, were obtained. Two noteworthy results manifested themselves. Due to shrinkage alone, the steel of both one-way and two-way slabs was under considerable compression, this shrinkage producing a deflection which continued to increase as the shrinkage increased; and in the two-way slab, the yielding of the concrete due to sustained stress was a higher multiple of the instantaneous load-deformation in the transverse direction than in the longitudinal direction, showing that the rate of yielding increased with stress.

Significance.—These tests served not only to demonstrate that concrete does yield considerably with time, but also point to the probable effects of flow, especially when combined with shrinkage, on compound structural members, such as reinforced concrete beams and slabs.

In tests of beams and slabs, with the zero of live load measurements established under dead load conditions of no cracks and the steel under compression due to shrinkage, if cracks are produced by the application of live load, there would be thrown on to the steel the dead load tension previously carried by the concrete and thus the apparent deformation due to live load would be greater than its true value. Also the gradual increase of steel stress with time may be due either to further yielding of the concrete in tension, thus opening up new cracks, or to a complete breaking down of the bond through the region of maximum moment.

In members subjected to flexure, the continued deflection is augmented by shrinkage, since the compression fibers, in addition to yielding plastically,

must shrink a greater amount than those on the tension side because of the restraining effect of the steel. Furthermore, the continued shrinkage on the tension side operates to increase the number of cracks and thus increase the average deformation, and hence the deflection.

In regard to the slab tests, it was found that under the condition of full dead and live load stress, the tensile steel at center of span showed compression after a year of test. It is possible that in a service structure, where a slab is not free to shrink in all directions, this condition would not occur.

The test of the 10 by 10-ft. slab showed that the time yield had a much greater effect on the continued deflection than did the shrinkage.

Thus it appears that in determining the probable total actual stress in any flexural member after any period of time, flow, coupled with shrinkage is a factor for consideration.

Time Tests of Concrete, by A. H. Fuller and C. C. More, Proc. Am. Conc. Inst., vol. 12, 1916, p. 302.

This paper reports tests made in 1915 at the University of Washington in connection with measurements of deformation in a reinforced concrete building, as result of observations that deformations in the building increased with time as the load remained constant. The test consisted of first applying load to 3 compression specimens (cast from the same concrete as, or cut from, the building), according to a schedule which was approximately the same as the loading schedule for the building, after which treatment the load was allowed to remain constant. The time from the beginning of the first part of the test to the beginning of the sustained load test, is different for each specimen. No information is given regarding the character of the concrete and the curing and environmental conditions of the building and specimens, nor is it stated whether the observations in the building were on compression or flexural members. Shrinkage was included in the values of deformation.

The thesis of the authors is stated as follows: "The modulus of elasticity is a measure of the relation of stress to deformation as determined from time tests in which the rate of application is the same (as in a structure on which time-load observations were being made) would furnish means for making a fairly satisfactory determination of the existing stresses." This would appear to be a satisfactory method of approximately determining the stresses in a structural member under observation provided only that all the influencing conditions are the same for the specimen as for the structure.

For the sustained load tests, the data which are given by the investigators represent values of deformation measured from the start of the previous loading operations and which values therefore include what flow occurred during the previous test. A comparison of the rates of flow, however, is instructive and in the following table are shown the flow between the 25th and the 60th day after the beginning of the test.

From this tabulation it will be noted that the rate of flow is greater for higher stresses than for lower stresses.

A discussion of this paper by F. R. McMillan presents data in diagramatic form illustrating the use of the above mentioned method in determining the

INCREASE IN DEFORMATION IN PER CENT
25 to 60 Days After Zero of Test

Specimen	Stress, Lb. per Sq. In.	Increment of Deformation, %
A	650	0.064
B	650	0.060
C	1150	0.090

probable actual stresses in a structure. Cases of columns in a service structure are also cited, in which it is shown that some 200 days after measurements were begun an increase in steel stress due to combined flow and shrinkage amounted in one case to as much as 22,000 lb. per sq. in.

The Flow of Concrete under Sustained Load, by E. B. Smith, Proc. Am. Conc. Inst., vol. 12, 1916, p. 317.

In 1914-1915, E. B. Smith, then with U. S. Bureau of Public Roads, Washington, D. C., conducted flow tests on a reinforced concrete beam and on concrete compression cylinders.

For the flexural tests there was employed a gravel concrete beam of 1:2:4 mix; reinforcement, approximately 0.75 per cent; dimensions 5 in. wide, 8 in. full depth, 7 in. effective depth, clear span 10 ft.; loaded at center with concentrated load of 1225 lb., calculated to produce a maximum stress of 1000 lb. per sq. in.; loaded at the age of two weeks, strain measurements along top fibers of beam. Load was sustained for 19 days, when it was released and readings were continued for 9 days more. Storage conditions are not stated.

Test results show:

1. Deformation increased with length of period of sustained load (including both shrinkage and flow).
2. A maximum deformation at end of 19 days for the top fibers of the beam at the center of span was 0.035 per cent.
3. Maximum deformation was 2½ to 3 times the instantaneous deformation.
4. Instantaneous deformation was greater than instantaneous recovery after 19 days of load.
5. Plastic recovery very small.

The compression tests were made on two 6 by 24-in. cylinders of a 1:2:4 gravel concrete loaded to a stress of 700 lb. per sq. in. One was stored in air and one was kept saturated with water. Measurements of longitudinal deformations were made on a 20-in. gage length. Corresponding unstressed cylinders were maintained under parallel storage conditions, in order that dimensional changes due to causes other than stress might be determined. All cylinders were cured for 29 days in wet sand and the dry storage specimens were thereafter kept 7 days more in air before loading.

The wet specimen was unloaded after 17 days under load, at which time the flow (making corrections for shrinkage) was 0.036 per cent. The dry specimen

was unloaded after 28 days of sustained load, the flow being 0.046 per cent. After 17 days under load, the flow in the wet specimen was about 82 per cent of that of the dry specimen.

Tests of Large Reinforced Concrete Slabs, by A. T. Goldbeck and E. B. Smith, Proc. Am. Conc. Inst., vol. 12, 1916, p. 324.

During the period 1914-16, the authors of the above named paper conducted at the U. S. Bureau of Public Roads, Washington, D. C., tests on reinforced concrete slabs, during which tests a time-yield was noticed. In part of their discussion they offer the following evidence which is not supported by any attendant data:

"During the tests of one of these slabs . . . this phenomenon was first discovered and a series of experiments was begun to obtain data regarding the flow of concrete. Since it is not the object of this paper to discuss the facts or theory . . . the following statement . . . (is given).

"When concrete is subjected to a compressive fiber stress of 700 lb., the immediate fiber deformation is only about 50 per cent of what it will be if the stress is maintained for three weeks. Within 24 hours after the application of the load, the deformation has increased an additional 20 per cent; during the first hour the deformation may show a change of 5 per cent or more. Furthermore, the recovery of the deformations, after the removal of the load is slow and not complete.

"This fact is mentioned here to show the importance of taking all the deformation readings at approximately the same time after the load is applied, and in each case a new set of deformation readings under zero load must be taken just before each load application."

The Flow of Concrete under Sustained Loads, by E. B. Smith, Proc. Am. Conc. Inst., vol. 13, 1917.

In this paper, E. B. Smith of the U. S. Bureau of Public Roads, Washington, D. C., described time tests of compression cylinders and beams, using gravel and limestone as the large aggregates. The proportions in each case were 1:2:4, and in each group there were unstressed specimens which served as controls.

In the compression tests, the cylinders were 3 in. in diameter by 24 in. long and were loaded to a stress of 840 lb. per sq. in. Cylinders were cured in the open air and sprinkled once daily for the first week. Load was applied at the age of 28 days. Deformations were measured over a 20-in. gage length. The load was released after having been sustained for 50 days. In the following table are given values of the total deformations (elastic deformation plus flow):

It is significant that the deformation of the gravel concrete was 20 to 30 per cent greater than that of the limestone concrete.

The beams were 5 in. wide by 8 in. deep, effective depth 7 in., clear span 10 ft., steel ratio approximately 0.75 per cent, central load 830 lb., Load was sustained on the gravel beam for 34 days and on the limestone beam for 48 days, after which the load was completely removed. The concrete deformation in the gravel concrete beam was about 20 per cent greater than that for the

Days of Sustained Load	Total Deformation Due to Load, % of Length	
	Gravel Concrete	Limestone Concrete
0	0.042	0.032
3	0.087	0.060
14	0.126	0.095
50	0.157	0.124
50 Load released	0.119	0.090

limestone concrete beam, although the limestone concrete beam showed a slightly greater deflection. The concrete deformations had increased about 100 per cent within the given loading periods. Steel stress due to load increased from about 11,000 lb. per sq. in. to about 18,000 lb. per sq. in. in 34 days for the gravel concrete.

Following are some of the conclusions drawn by E. B. Smith:

The law of concrete flow is asymptotic. The flow continues at a gradually decreasing rate and yet is an appreciable amount during three to four weeks. It then continues more slowly for an indefinite period, but this change is small.

The total combined effects of shrinkage and flow in compression may amount to as much as 0.2 per cent.

The effect of flow within the material itself is either to relieve the stress condition, if the construction and loading make this possible, or to gradually change the length or position of the member.

The magnitude of flow deformations vary quite largely with the kind of aggregate and the mixture.[1] The modulus of elasticity[2] of concrete is different for each mixture and aggregate. It changes and decreases in value with time and as the flow deformations increase.

In the case of a reinforced concrete beam, the effect of flow in the concrete is to lower the position of the neutral axis, thus enlarging the compressive cross-section area and relieving the unit stress value. More stress is thrown on the steel.

In the discussion that followed F. R. McMillan brought forward data to show that in columns he had investigated in building in service, steel stresses as high as from 20,000 to 36,000 lb. per sq. in. were developed, which latter stress corresponds to a deformation of about 1½ in. per 100 ft.

Design of Reinforced Concrete Slabs, Trans. Am. Soc. C. E. Discussion by F. R. McMillan, vol. 80, 1916, p. 1743.

Two groups of test results not previously discussed in this paper are briefly reported. Tests of the first group were made on four 4 by 5-in. beams with a

[1]The great effect of moisture conditions was evidently not appreciated at that time.
[2]Here is meant the ratio of unit stress to total deformation, after any given period of time.

42-in. span. All concrete was of a 1:2:4 mix. Measurements were made on an 8-in. gage length spanning the center section of the beams. Pertinent data follow; shrinkage has been eliminated from the results by means of observations on similar unstressed beams.

TIME YIELD OF REINFORCED CONCRETE BEAMS, GROUP 1 (MCMILLAN)

Beam No.	Coarse Aggregate	Reinforcement	Calculated Stress, ($n = 15$) Lb. per Sq. In.	Age When Load Applied
11	pea size limestone	1⅜″ sq. twist	670	33 days
13	pea size limestone	2 5/16 pl. round	650	33 days
118	¼″ to ¾″ limestone	1⅜ pl. round	730	103 days
121	sandstone	1⅜ pl. round	730	103 days

Beam	Initial Unit Deformation, Inches	Relation of Total Deformation to Initial Deformation			
		30 Days	90 Days	200 Days	530 Days
11	0.000335	2.49	2.66	3.50	4.09
13	0.000302	2.48	2.78	3.28	3.74
118	0.000246	2.40	2.84	3.29	....
121	0.000180	1.57	2.08	2.68	....

In the second group were beams and slabs with dimensions and loading schedules shown below.

Specimen	Mix and Coarse Aggregate	Time Kept Wet, Days	Depth, In.	Width, In.	Effect. Depth, In.	Span In.	Steel Ratio	Age at Dead Load Application Days
A Beam	1:2:4 limestone pea size	1	5.00	4	4.50	42	0.0085	33
B Beam	1:2:4 limestone ¼″ to ¾″	not wet	5.50	30	4.62	144	0.0080	41
C Slab	1:2:4 limestone ¼″ to ¾″	31	4.87	120	4.35	120	0.0046	135
D Slab	1:2.50:4 limestone pea size	57	3.00	96	2.62	72	0.0049	59

Important live load variations:
Beam A. Dead load and 860 lb. at center applied at age of 33 days.
Beam B. Loaded at ⅓ points, 500 lb. at 80 days, 1500 lb. at 88 days.
Slab C. 50 lb. per sq. ft. at 174 days after dead load application.
100 lb. per sq. ft. at 275 days after dead load application.
Slab D. 50 lb. per sq. ft. at 68 days.
100 lb. per sq. ft. at 71 days.
Live load removed at 82 days.
Live load reapplied at 94 days.

The results of tests on beams and slabs of the second group are shown in the following table.

TIME YIELD OF BEAMS AND SLABS, GROUP 2 (MCMILLAN)

Type Loading	Unit Instantaneous Deformation			
	Specimen A	Specimen B	Specimen C	Specimen D
Dead load	....	0.000200	0.000076	....
Live load				
0 days	0.000280	....	....	0.000042
3 days	....	....	....	0.000065

54 days	....	0.000075	....	....
174 days	....	....	0.000058	.....
275 days	....	....	0.000043	....

Type Loading	Ratio, Total to Sum, Instantaneous Deformations			
	Specimen A	Specimen B	Specimen C	Specimen D
Dead load				
50 days	2.57	....	2.90	2.24
100 days	2.68	2.32	....	2.66
200 days	3.39	3.11	3.20	3.08
650 days	4.25	3.63	4.00	4.11
950 days	4.60	3.71	....	4.39

Consulting the results of the two groups of tests it is seen that the total deformation after a six months of sustained load is roughly three times the initial deformation, and after two years is roughly four times the initial deformation. From another point of view, the ratio of moduli for steel and concrete, n, which ranged from 9 to 15 at the time of initial loading, may increase to 20 or 30 in a few months, and from 35 to 60 in 2 years.

It is noteworthy that here for the first time were reported tests extending over a period of two years or more, and the discovery was made that flow was still taking place at the end of these extended periods of observation.

Extensometer Measurements in a Reinforced Concrete Building Over a Period of One Year, by A. R. Lord, Proc. Am. Conc. Inst., vol. 13, 1917, p. 45.

In this paper A. R. Lord reports the results of tests made in 1914 and 1915 on a 25 by 26-ft. flat slab in a reinforced concrete warehouse located in Chicago. The load, which was twice the design load, was left in place for about a year, and strain-gage measurements were taken periodically during this time. The slab was 10 in. thick and the concrete was a 1:2:4 mix. What were believed to be corrections were made in the results for temperature changes (based probably on air temperature and the coefficient for steel) but the deformation reported include shrinkage. The test load was a uniformly distributed layer of sand.

The results are best stated in the form of general conclusions, as follows: The ratio of deformations at 1 and 55 days is about 1:2.5 and the ratio of de-

formations at 1 and 230 days is about 1:5 (results not dissimilar to those of previous tests).

The continued deformation of the concrete was noted, but the rate of deformation of the steel was not so great as that of the concrete, showing that although flow took place continuously, shrinkage operated to reduce the tensile stress observed in the steel (see McMillan's paper on Time Tests of Concrete).

Due to flow, and therefore increased deflection in regions of negative moment, a shifting of the moment took place, resulting in a still greater increase in deflection at regions of positive moment.

The increase in total moment figured from steel stress was relatively small.

The "straight line theory" of reinforced concrete is inapplicable to the conditions surrounding this test even with the low stresses present in the concrete and steel.

Plasticity and Temperature Deformations. by S. C. Hollister, Proc. Am. Conc. Inst., vol. 15, 1919, p. 127.

Load deformation data are presented for tests made at Purdue University on a narrow reinforced concrete slab. Under the conditions of the test, which are not reported, the elastic deformation is about the same as the "plastic" deformation for all magnitudes of load, for both steel and concrete. Plastic deformations evidently include shrinkage. Plasticity is defined as that deformation which does not disappear upon the removal of load, i. e., permanent set.

A Study of Column Test Data, by F. R. McMillan, Proc. Am. Conc. Inst., vol. 17, 1921, p. 150, and Discussion by M. B. Lagaard, loc. cit. p. 172.

Incidental to a general discussion of reinforced concrete spiral-wound columns, McMillan reviews briefly his own and other flow data.

In his discussion of McMillan's paper, Lagaard presents more recent data regarding the column flow tests on a building at the University of Minnesota (which tests have been previously mentioned in this paper in connection with McMillan's discussion of other papers). Also there are given the results of tests on three columns in reinforced concrete warehouses.

The columns in the building at the University of Minnesota were still decreasing in length (due to flow and shrinkage) after a period of six years. The tests on these columns were begun after they had been in existence for about two months, so that observed deformations do not include those due to shrinkage and to flow for that preliminary period. Assuming a constant modulus in the steel of 30,000,000 lb. per sq. in., the increase in stress for the six years varied among the several columns from 36,000 to 45,000 lb. per sq. in. The percentage of vertical steel in these columns varied from 0.7 to 2.1.

In one warehouse, in which the columns had 3.7 per cent of vertical steel and 1.6 per cent spiral hooping and the tests were begun at an age of three weeks, the increase in vertical steel stresses for an observed period of 4½ years was 14,000 to 15,000 lb. per sq. in. It is also interesting to note that the lateral shrinkage during this period corresponded to steel stresses of from 11,000 to 15,000 lb. per sq. in. Another noteworthy feature of these tests is that in one column the vertical gage lines in the concrete showed about 20 per cent more

deformation than did those in the steel. This may have been due to the fact that the concrete and steel gage lines were not in the same vertical element and some bending was taking place.

Tests on another warehouse column containing 4.5 per cent vertical steel and 1.0 per cent spiral, showed, after nearly 5 years, a concrete deformation of 0.046 per cent and a steel deformation of 0.029 per cent, the latter corresponding to a stress of about 9,000 lb. per sq. in. In this column the vertical elements in which the concrete gage lines were located made angles of about 60 deg. and 120 deg. with the element containing the steel gage lines.

Conclusions stated by Lagaard are: High compressive stresses are likely to exist in the vertical steel reinforcement of concrete columns due to the combined effects of load, shrinkage, and time-yield.

The transverse steel will also have high compressive stress due to the action of shrinkage.

The compressive stresses in the vertical steel will be lessened when the percentage is increased.

Fatigue of Concrete, Discussion by H. F. Clemmer, Proc. A. S. T. M., vol. 23, 1923, p. 339.

In connection with what he calls "static load fatigue," Clemmer reports the following of cantilever beams subjected to static loads which produced stresses of various percentages of their moduli of rupture. "The critical percentage of stress which caused failure was found to be 71 per cent. A number of beams failed at the end of approximately 105 hours under a load causing a stress of 71 per cent of the breaking stress. With a stress of 84 per cent, the beams failed at the end of 14 hours." Clemmer also states that most of the set due to a static load is temporary and is recovered after a time.

Plastic Yield, Shrinkage and Other Problems of Concrete and Their Effect on Design, by O. Faber, Min. of Proc. Inst. C. E. (Great Britain), vol. 225, 1927-28, Part I.

Faber reports the results of laboratory tests made in 1926-27 on six simply supported beams, each 2 in. wide, 5 in. deep, effective depth 4½ in., of span 15 ft. The concrete was approximately a 1:1¾:3½ mix with a water cement ratio of 0.69. The tension steel consisted of two $\frac{3}{16}$-in. round rods in all of the beams, with the addition of a like amount of compression steel in beams 5 and 6. As tested the dead load of each between supports was 150 lb. At 28 days test cubes of the concrete of beams 1 to 4 exhibited a compressive strength of 3400 lb. per sq. in., test cubes for beams 5 and 6 gave 3300 lb. per sq. in. and test cylinders for beams 5 and 6 gave 2600 lb. per sq. in. The steel for beams 1 to 4 had a yield point of 50,300 lb. per sq. in. and that of beams 5 and 6, 28,600 lb. per sq. in. Storage conditions as regards temperature and humidity are not stated.

All beams were stored in air continuously, except No. 4 which was kept wet after the age of 30 weeks. Beams 1 to 4 were placed upon their end supports and loaded at age of 4 weeks; beams 5 and 6, at the age of 5 weeks. Beam 3 was unloaded at the age of 30 weeks. Deflection measurements were made periodically beginning with the time of loading. Deformations in steel and

concrete were observed on beams 3 and 4 between the ages of 10 and 18 weeks and on beam 6 between the ages of 6 and 15 weeks.

The following table gives the centrally applied live loads for the several beams, and also gives calculated values of concrete and steel stress, as well as calculated and observed deflections. The calculated stresses and deflections are based upon an assumed straight line variation of compressive stress in concrete with no tension in concrete, and upon modulus of elasticity of 4,000,000 lb. per sq. in., $n = 7.5$. The observed deflections are those that took place at the instant the loading tests were begun. It will be noted that the observed instantaneous deflections are roughly 0.6 of the corresponding calculated values.

BEAM LOADINGS, STRESSES AND DEFLECTIONS (FABER)

	Beam No.					
	1	2	3	4	5	6
Live load, lb.	0	30	60	90	0	30
Calculated Stresses, lb. per sq. in.						
Concrete	676	946	1216	1487	608	851
Tension steel	13750	19250	24750	30250	13640	19100
Comp. steel	....	....	....	....	2540	3550
Calculated Instant. Deflection, in.	0.474	0.622	0.770	0.918	0.47	0.61
Observed Instant. Deflection, in.	0.30	0.35	0.40	0.50	0.29	0.37

The behavior of the beams under sustained load is indicated by the two following tables, taken from graphs prepared by Faber, the first giving observed deflections and the second giving deformations of top and bottom fibers at various ages. The values show the combined effect of plastic yield and shrinkage. Ages are counted from the day the specimens were cast. Consulting the tables, it is seen that both deflections and compressive deformations (top) increase substantially as time goes on. Further, for the tensile fibers (bottom) of some of the beams, the effect of shrinkage nearly offsets that of plastic yield.

BEAMS UNDER SUSTAINED LOADS (FABER)

Observed Deflections, Inches

Age, Weeks	Beam Number					
	1	2	3	4	5	6
4	0.30	0.35	0.40	0.50	....	....
5	0.34	0.41	0.54	0.65	0.29	0.37
10	0.57	0.67	0.89	1.01	0.55	0.67
20	0.78	0.89	1.16	1.25	0.69	0.80
25	0.80	0.93	1.19	1.26	0.71	0.82
30	0.81	0.98	1.22	1.31	....	....
40	0.85	1.01	....	1.40	....	....

BEAMS UNDER SUSTAINED LOADS (FABER)

Observed Deformations, Top and Bottom Fibers
(Positive Signs Indicate Elongations)

Age, Weeks	Observed Deformations, Per Cent of Gage Length					
	Beam 2		Beam 3		Beam 6	
	Top	Bottom	Top	Bottom	Top	Bottom
6	....	....	....	....	0	0
8	....	....	....	....	—0.0081	+0.0050
10	0	0	0	0	—0.0133	+0.0062
12	—0.0125	+0.0005	—0.0130	+0.0026	—0.0187	+0.0075
14	—0.0145	+0.0035	—0.0168	+0.0053	—0.0240	+0.0100
15	—0.0150	+0.0052	—0.0171	+0.0070	—0.0250	+0.0105
18	—0.0220	+0.0040	—0.0240	+0.0074	....	....

Assuming the deflections to vary directly with the deformations, Faber has calculated the probable deformations of the top fibers of four of the beams up to the age of 32 weeks, due to combined shrinkage and plastic yield as well as the corresponding strains which took place when load was applied at the age of four weeks. These values are compared in the following table. It is instructive to observe that the calculated deformation at the end of 32 weeks due to plastic yield plus shrinkage is on the average nearly three times the calculated deformation taking place at the time the load was applied.

COMPUTED TOP FIBER DEFORMATIONS IN BEAMS

Between Ages 4 and 32 Weeks (Faber)

Beam No.	Calculated Elastic Strain, In. Per In.	Top Deformation Due to Shrinkage and Plastic Yield, In. Per In.
1	0.00017	0.00052
2	0.00024	0.00066
3	0.00030	0.00084
4	0.00037	0.00087

From a study of these tests and other data Faber separates the element of shrinkage from plaster yield and draws the following conclusions:

1. At a stress of 1000 lb. per sq. in., the plastic yield in 36 weeks is approximately equal to the total shrinkage and each is approximately twice the elastic strain.

2. The plastic yield varies with the elastic strain, being roughly double its value, while the shrinkage remains constant.

3. The total deformation in 36 weeks is roughly 6 times the elastic strain at 600 lb. per sq. in., about 5 times that at 1000 lb. per sq. in., and about 3½ times that at 1400 lb. per sq. in.

4. In beam No. 6, with compressive reinforcement, for the period 5 to 22 weeks, the calculated increase in stress due to shrinkage and plastic flow was 11,700 lb. per sq. in. for the compression steel, and 3,800 lb. per sq. in. for the tension steel. For beams 2 and 3, the calculated additional stresses in the steel from 4 to 36 weeks were 1,400 and 4,300 lb. per sq. in. respectively.

Conclusions

A review of the abstracts of the preceding pages giving the results of tests by various investigators justifies the following general conclusions:

1. All concrete under the action of sustained stress flows or plastically deforms for a long period of time, certainly for several years. This is true regardless of whether the concrete be plain or reinforced and is true for beams and slabs subjected to bending moment as well as to columns subjected to direct compression.

2. Regardless of the character of the concrete or of the conditions surrounding it, flow increases with the magnitude of the sustained stress, as well as with time. Other things being equal the flow is proportional to the instantaneous deformation or that which takes place as the load is applied.

3. When concrete is in air, shrinkage continues for a long period of time, the amount of shrinkage depending upon the dryness of the atmosphere, but being independent of stress conditions. This is true for reinforced as well as for plain concrete.

4. In a reinforced concrete column the combined effect of shrinkage and flow under sustained load is gradually to relieve the compressive stress in the concrete until the yield point of the steel is reached. There is evidence that under normal load conditions the spiral hooping of a column surrounded by dry air, due to lateral shrinkage, is always in compression.

5. In beams and slabs reinforced in the normal manner the combined effect of shrinkage and flow is gradually to lower the neutral axis at sections of positive moment and to raise the neutral axis at sections of negative moment. This results in an increase in deflection, in a reduction of compressive stress upon the extreme fiber of the concrete, and in an increase in the tensile stress in the steel. In continuous and restrained beams and slabs there is also brought about, due to flow, a gradual redistribution of moments tending to equalize those of opposite sign.

Basis of Design For Hurricane Exposure

Report of Committee 308

BY ALBERT SMITH, AUTHOR CHAIRMAN*

This brief report prepared by Mr. Smith has been submitted to the critic members of his committee: D. C. Coyle, Hardy Cross, W. J. Knight, G. A. Maney, L. E. Ritter and W. J. Spiker and since redrafted. The report is here supplemented by the Author-chairman's discussion and discussion invited for subsequent publication, from the critic members of the committee and others.—Editor.

The structural frame shall be designed to resist all the force of the wind on the total exposed surface.

In computing wind loads, the following unit pressures, varying with the height above sidewalk shall be used:

0 ft. to 200 ft.—20 lb.
200 ft. to 300 ft.—25 lb.
300 ft. to 400 ft.—30 lb.
400 ft. to 500 ft.—35 lb.
500 ft. —40 lb.

except that structures located completely within a solidly built up section may be designed for 10 lb. of pressure below the highest complete shelter found within 400 ft. of its walls.

Spread footings, pile footings and caps and caissons shall be so designed that the loads and stresses from the combination of dead, live, and wind loads shall not exceed by more than 50 per cent the design units for dead and live alone.

All columns whose vertical wind load does not exceed 20 per cent of the dead and live load may deliver what wind moment they carry in their lowest section into square spread footings,

*Smith and Brown, Engineers, Inc., Chicago.

square pile clusters and to caissons without increasing such footings for wind. Where the footings are rectangular they shall be examined for soil pressure, pile load and steel and concrete stresses and if the increase from wind vertical and moment exceeds 50 per cent of the dead and live units they shall be redesigned.

All members of the structural frame whose connections cause them to bend when the building deflects under wind may be regarded as sharing in the resistance to the wind.

The structural frame shall be regarded as a unit in resisting the wind pressure by the bending of its members and the moments in all joints of the structure shall be assigned in proportion to the stiffness of the joint which depends on the stiffness of the members connected at such joints. Where two members share the moment at a given joint, the moment shall be divided between them in proportion to their respective stiffness.

The moments so found in the members may be reduced to the face of the column, for beams, and to the top and bottom of the beams, for columns. The connections of all members shall be designed for these reduced moments by the stress units hereinafter specified.

The stiffness of the joints of braced bents at floors where the bracing begins or is stopped, is less than that of joints at the same floor of continuously braced bents whose members have the same properties. At offsets and at all places where shallow or no beams are placed between columns which have stiff girders in floors above, and where downward going bracing bays start, an uncertainty exists as to the amount and location of the horizontal wind shear which will be transmitted.

This horizontal wind shear shall be assumed to be transmitted at three floors and in assigning stresses to girders, columns, and horizontal floor bracing, an excess of at least 75 per cent of the detoured wind shear must be divided among these three floors to cover this uncertainty.

Where the bracing for a tower apparently could be stopped at the main roof line and transferred to other lines the tower bracing shall be carried at least two stories below the top of the bracing of the enlarged section below.

Where a column of a braced bent is carried on a girder, allowance shall be made in distributing the stresses, for the deflection of the girder, as affecting both the moment and the vertical load of the riding column and the columns adjacent in the bent.

If columns designed for dead and live loads are found to be inadequate for combined stresses of dead, live and wind loads, they shall be redesigned to make them adequate by increasing the size, or adding to the vertical steel or by increasing the spiral or by adding vertical steel wired to the spiral at the corners of the column or by a combination of these devices.

Where the spandrel beams are relatively shallow, the wind stresses in interior flush beams and joists will be relatively large. Such flush beams and joists shall be redesigned for the combined stresses from dead, live and wind loads.

DESIGN UNITS

Beams—Where no wind rods are used, the capacity of beams to resist wind moment shall be computed for a fibre stress of 500 lb. per sq. in. in the bottom fibres of the beam, neglecting the steel provided for static loads. Where the moments exceed the capacity of the concrete, steel wind rods shall be added of such cross sectional area that, taking the distance between the centers of the top and bottom rods as the effective depth the fibre stress shall not exceed 27,000 lb. per sq. in. for medium grade steel, neglecting the resistance of the concrete.

The bond of these wind rods shall not exceed 150 per cent of the bond unit for static loads, except that where a length curved on a radius of not less than 10 in. is inserted in the column the bond of such curved length may be 225 per cent of the bond unit for static loads. Where straight wind rods project through the column into the beams, the bond in the column must be equal to the sum of the compression in the steel on one side and the tension on the other. Wind rods shall project into the beam to the point at which the combined positive static and positive wind moment

will not stress the positive static steel more than 150 per cent of the static steel unit stress.

For the combined static and wind shear the unit of diagonal tension and stirrup stress shall be taken as 150 per cent of the units for static load alone. Girders, whose ends are connected to columns by wind rods, shall be counted as fulfilling the condition of "Special Anchorage" for static load.

Columns—The combined stress, consisting of dead and live load, vertical wind load, and the wind moment transformed into equivalent centric load, shall not exceed 150 per cent of the capacity by code for dead and live loads only. The wind moment in the column at the top or bottom of the beam may be transformed by the formula Equiv. Cent. Load $P_{WM} = \frac{AMv'}{I}$, where A is the area inside the spiral, v' the distance of the spiral from the center of gravity and I the moment of inertia of the total section of the column.

DISCUSSION BY ALBERT SMITH, AUTHOR-CHAIRMAN

WIND PRESSURE UNITS

To ESTIMATE the expectable velocity of wind which may produce the maximum pressure on a building, two rather indefinite factors must be applied to the records of maximum velocity by three-cup anemometers or four-cup anemometers corrected to three-cup equivalents—one for height of instrument, and one for gust intensity. See Table 1.

The reported velocities are average velocities for five minutes. In that time the record of pressures shows that the velocities have varied from 25 per cent of the average to 175 per cent of the average. On the face of it, we should add 50 per cent to the corrected reports of average readings to determine the proper design pressure. These gusts, however, may be of small cross section.

It is probably sufficiently proved that near the ground the width of gusts is small. It is not proved that at a height of say 150 ft. in a clear air way the width of gusts is small. Fleming[1] quotes Stanton's conclusions from observations taken on the high level footway over the draw-span of the Tower Bridge at

London. Stanton declared that he found that gusts might occur whose intensity would be practically uniform over the whole structure. Where a comparatively steady high velocity wind is

blowing between 1000 ft. and 2000 ft. above the earth, the gusts of which we have record originate by the deflection of masses of air from the swiftly moving stream toward the earth. It is not reasonable to suppose that these deflected masses are splinters of air current less than 100 ft. wide. On the contrary, it is logical to assume that these are very much larger masses, which as they approach the earth are split up successively by the roughness of the surface of approach and the infiltration of the slower currents below. The maximum velocity at the center of the gust is probably indicative of the velocity of the main air current above. Thus a one minute velocity in New York of 91 mi. per hr. at 454 ft. elevation shows a 30 second velocity much greater, and is ample justification for assuming that the main current of air is traveling much faster than 100 mi. per hr.

Pressure is determined by applying a coefficient to the square of the velocity. Dryden and Hill found at the Bureau of Standards[2] that a tower model whose proportions were 1:1:3 received a total pressure which can be expressed as $P = .00384\ V^2$, and they predict that higher towers will show a larger coefficient. Other observers have found that long plates receive a higher unit force than square plates.

It is my contention that we should start with 40 lb. (100^2 x .004) for say 1500 ft., and not diminish it until we reach the elevation at which we are sure that the width of the gust having an average pressure of 40 lb. is less than the width of the structures to which we propose to apply the unit. I believe that this point cannot safely be taken as higher than the 500 ft. point above sidewalk, or 300 ft. above the base of the clear air-way

I propose that the pressure units should be 40 lb. above 500 ft. from sidewalk, 35 lb. between 400 ft. and 500 ft., 30 lb. between 300 ft. and 400 ft., 25 lb. between 200 ft. and 300 ft., 20 lb. between 100 ft. and 200 ft., and 15 lb. below 100 ft.

I have no confidence that there is any place in the country where these pressure units will not be exceeded during the next 20 years, but I am confident that in buildings carefully designed for the stress units set forth by the committee and for these pressures, there will be no overstrain that will damage the structural frame.

[2]Scientific Paper No. 523, p. 731.

COMPUTATION OF WIND STRESSES IN BUILDINGS

In a building of 22 stories, having 45 columns, the wind causes stresses whose total number for two directions of wind is nearly 10,000. A large part of these stresses are not important to the designer. A few upper stories may be dismissed from consideration for all stresses. Most intermediate columns have minor axial stresses from wind which need be computed only for one or two stories. With all these deductions the number of stresses to be computed and marked on a set of framing diagrams is very large. Any method which will give us, reliably, the wind stresses in a building which will not be exceeded by 5 per cent nor be in excess more than 10 per cent should be quite satisfactory to the designer.

Several short methods of calculation for single bents have been proposed. Some appear likely to have a maximum error of only 5 per cent. If however, the amount of wind which will come in this bent is not determined within 25 or 30 per cent the accuracy of distribution within the bent is of little use.[3]

Any structure must be regarded as a whole in computing its wind stresses, and when the building is unsymmetrical in any respect, and is of great height, the labor of making the closest practicable approximation to the true stresses is not only justified, it is essential.

For a symmetrical building with all bays in the same direction equal, and having intermediate columns so turned that their stiffnesses are proportionate in the bents in which they are intermediate, a fair approximation of the wind moments at the joints may be made by the following assumptions.

a. All points of contraflexure at the middle of the lengths of all columns and beams.

b. Equal vertical wind shears in all beams.

Each floor of a building deflects horizontally as a unit under wind pressure. If the building is symmetrical, both for layout

[3]Mr. Fleming in his very interesting book, "Wind Stresses in Buildings," (John Wiley, 1930) quotes Prof. Burr's statement that "So long as the stresses found by one legitimate method of analysis are provided for, the stability of the structure is assured." We should not allow this truth, so excellently stated, to make us satisfied with crude methods of finding wind stresses in buildings. After all, are they "legitimate?" I take it Prof. Burr did not mean that if the stresses as arbitrarily divided between 40 or more paths are provided for, the structure is safe. Nor if a weight be hung on a thread and a rubber band of the same length, that the factor of safety is the weight divided by the sum of the two ultimate strengths. The designer is charged with the duty not only of supplying enough strength, but also of putting it in the right place.

and framing, all points along the wind exposure of the floor deflect equally.

Even in the most symmetrical building, however, computations made with the assumptions given above must have some approximate corrections. All buildings have, in one or the other direction of the wind, much shallow framing whose resistance to the wind, if it is symmetrical, may be subtracted directly from the total moment at the given floor.

Even in the most symmetrical buildings the I of the end columns of the principal bents may be so much less or so much more than one half that of the intermediate columns of these bents, that the calculations by the method outlined above will be seriously in error.

Either the columns should be adjusted for stiffness or an allowance should be so made in the stresses that the designer can be confident that his assumed stresses will not be exceeded.

Where a building is unsymmetrical but has equal column spacing, the eccentricity of the wind load with respect to the stiffness of the building can be computed and adequate allowance made in the stresses without too greatly loading the design.

When, however, for a given direction of wind, the beam spans vary widely or the wind resistance is very unsymmetrical or the beam and column stiffnesses are made disproportionate to their wind function by other load requirements, or as often happens, all of these unfavorable conditions exist, we must use some more powerful method of computing the distribution of the wind stress among all the resisting members with a reasonable degree of accuracy.

The method shown herewith has been developed in tabular form so that engineering draftsmen might fill in the tables and compute the stresses and learn to understand the method while they computed. For a building with 45 columns we estimate that the tabulation of $\frac{1}{R}$, the true K, and the distributed moments for one floor can be made by one man in two and one half days. The total work for three floors, in two directions and the placing of computed and interpolated stresses on the general stress diagram is of the order of two men for two weeks.

There will still remain the examination of columns for wind stress, and in some cases the correction of many of them, and the design of the brackets for a steel frame, or the wind rods for a concrete building. A very competent designer, with a draftsman helper, would probably find plenty to do for a week after all stresses are known.

The wind stresses in Eddystone Belmont were first laid out by the approximate method, roughly corrected for eccentricity of column spacing and column and beam stiffness. These figures were used in the design for estimate, and contract. As always, after the estimate plans go out there was plenty of time for computing more exactly. We found, by calculation, that in the major stresses our allowances were ample, but that we had in some bents used an excess of steel, and carried the wind reinforcing too high, and in some bents we found our wind reinforcing deficient. A careful approximation of the stresses was more rapid than the calculation, but even though our allowance for error was large, we needed the reassurance of the calculation. For this building the calculations here shown might have been greatly shortened. The calculations for joists and for flush beams might have been lumped together in an approximate total without danger of a large error in the final moments in the important beams. These calculations after having been originally made with some abbreviations were expanded to a complete table to enable readers to study the relation between moments of joints with varying conditions.

AN EXAMPLE OF WIND STRESS COMPUTATION

To apply, with reasonable amounts of labor, the equation shown in Fig. 1, it has been found necessary to develop charts from which the factors $\frac{1}{I_c}$ and $\frac{I_B}{L_B}$ can readily be obtained.

I have made, but not given in this paper, the tabulation of the calculation of the I's of square columns varying from 11 in. to 33 in. in gross dimension and with spirals varying from 8 in. to 30 in. For these calculations the E for 3000-lb. concrete was taken as 3,600,000 and the n as 8 and for 2000-lb. concrete, as 3,000,000 and 9.6. The values of I are computed as:

$$I_{2000} = .0833D^4 + .008p\ (D - 3)^4$$
$$I_{3000} = .10D^4 + .008p\ (D - 3)^4$$

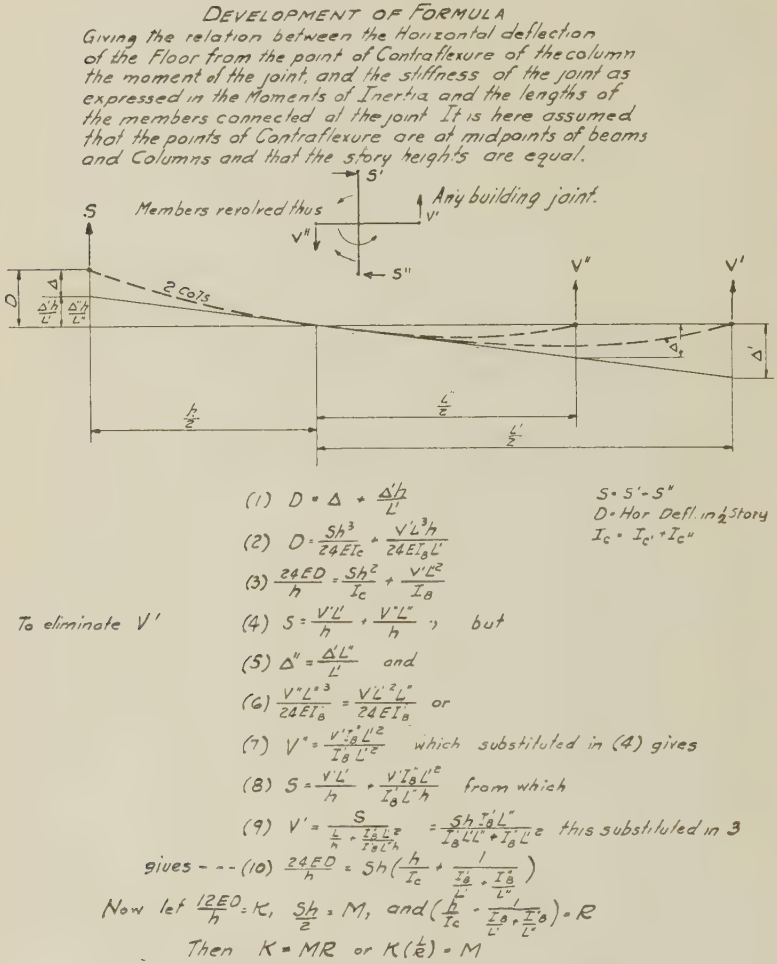

FIG. 1—DEVELOPMENT OF FORMULA

It is obvious that for the smaller values of p, the diameter of the steel ring is larger and the I of the steel proportionately greater than for the larger values of p, also that for large spirals the I of steel is greater than for the same percentages in smaller columns. The $.008p$ used here is a reasonable mean of these variations for the larger percentages. For the smaller percentages, the steel contribution to the I is small. In each square on this table, in addition

to the I in thousands, there are shown the maximum column load in thousands and 1000 times the reciprocal of $2I$. In Fig. 2 are shown the curves plotting 1,000,000 times these reciprocals against the maximum safe column load. Numbers obtained from these curves are to be multiplied by the story height in feet.

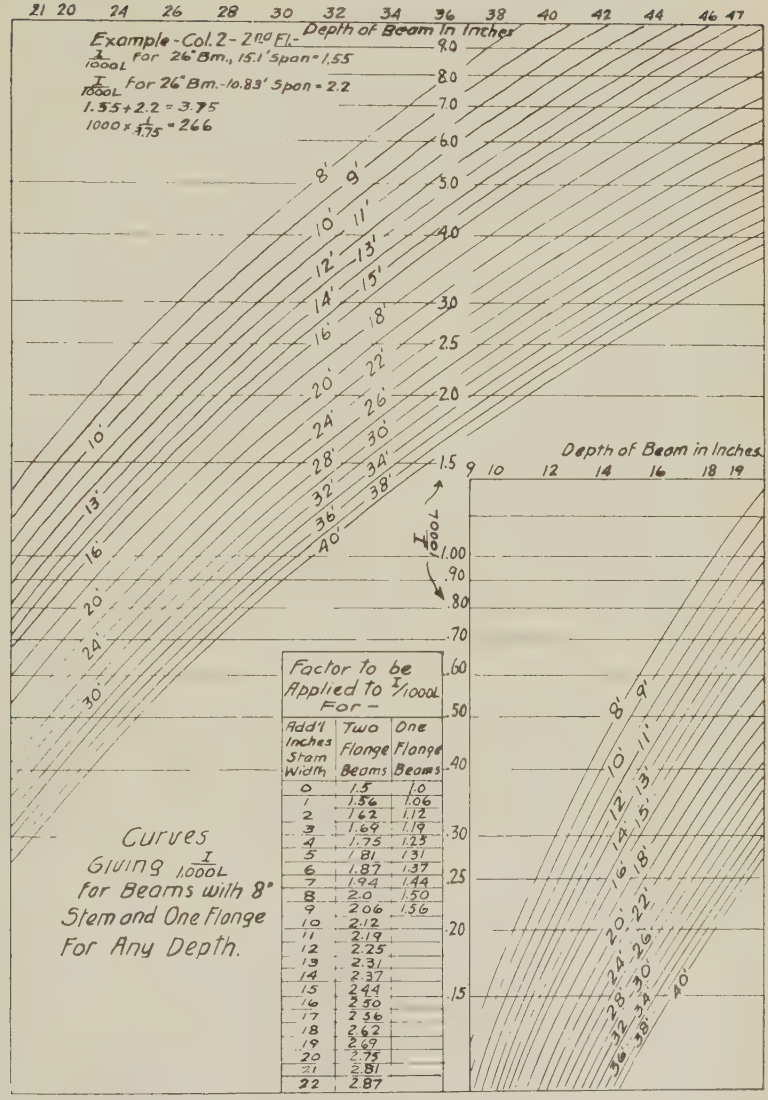
The use of the load to determine the reciprocal of the stiffness factor of columns leads to error because the curves are laid out for the minimum section which can be used to carry that load. If an excess of steel is used in any column, the $\frac{1{,}000{,}000}{2I}$ as determined by the actual load and the excessive percentage will be too large, and the stiffness factor will be too small. The effect of this error on the final moments is small but some effort has been made in using these curves to make the figures for $\frac{1{,}000{,}000}{2I}$ relative by roughly adjusting them to each other after the columns on Tables 2 and 3 have been filled in. The joints, whose final stiffness factors are most affected by these errors, are those whose moment is small and the most important stresses are very slightly affected.

Fig. 3 gives the beam curves from which $\frac{I}{1000L}$ can be obtained for spans ranging from 8 ft. to 40 ft., and for depths varying 9 in. to 48 in. The scale on the left edge permits the direct determination of the reciprocal for joints having only one beam. The curves are made for beams 8 in. wide and having only one flange. The I of the stem—without steel—is counted as $\frac{8d^3}{12}$, and the I of the one flange, with the steel, is counted as also equal to $\frac{8d^3}{12}$. For wider beams I have added $\frac{d^3}{12}$ to the I for each inch of increased width of stem, and for beams with two flanges I have added $\frac{8d^3}{12}$.

A table of coefficients is given for increase of stem widths for one and two flange beams.

It is, of course, quite impossible to make a rational determination of the I of concrete beams for stiffness. It is quite clear that the method here used is only approximate. Short spandrel beams, for instance, are likely to have very light reinforcement for dead and live loads. The final error from this cause is much reduced by the fact that the short beams have more wind moment than the long beams, and will certainly have as much wind reinforcing. Being short, their wind reinforcement will cover so large a portion of their length that the final error in the I is not so large as at first appears.

These assumed values for the I of beams tend to give us excessive stiffness for short beams. The practice here followed of using c. to c. of columns minus one quarter of the width of each column as the span of the beam tends to error in the other direction for short beams. The resultant of these errors is



Example - Col. 2 - 2nd Fl. -

FIG. 3

probably quite small. The most serious question is whether the difference between $\frac{16d^3}{12}$ and $\frac{24d^3}{12}$ truly represents the difference between the stiffness of spandrel and interior beams. After much computation the I's here used seem to the writer to give the best relative results for varying depths, widths, and flanges.

Tables 2 and 3 show the calculation work tabulated for Eddystone Homes, a 22-story reinforced concrete building in Chicago. See Fig. 4. The wind action on this building is so intricate that we regard it as a fair sample of the worst case. It has been worked out here for the second, the tenth and the seventeenth floors. The columns change size at the ninth and at the sixteenth floors, and since most of the columns are rectangular and the beam span change is unusually large, the stiffness factors and the moments are not proportionate to those at the second floor. Probably in most buildings with square columns and uniform depth of spandrels, two, instead of three calculations would be sufficient, and the second one might be made only partially. The complete tabulation and calculation of these three floors give us a very interesting study of the distribution at any one floor, and the change of distribution caused by the framing changes in higher stories.

In Tables 2 and 3 and the headings explain themselves as terms in the formula of Fig. 1. The multipliers 1000 and 1,000,000 are used for convenience in tabulating.

When the column $\frac{1}{R}$ is filled out we can solve the equation $K = M/\frac{1}{R}$ to get the average value of K. In a symmetrical building the average K would be the true K; that is the deflection of the floor would be the same at all points along the line of exposure. If, however, the building is stiffer at one end than at the other, there would be less deflection at that end, and K, which is D times a constant, will vary from end to end. We may regard the stiffness units as similar to fibres in a beam and compute the center of gravity of the stiffness, (See Fig. 5). From the eccentricity thus determined we compute the moment of eccentricity, computing now the moment of inertia of the stiffness units. We can compute the moment stress on the fibres at any point, or on the stiffness units at any point, located and identified as in Fig. 5. If we are regarding the stiffness units as fibres, the average K is to be regarded as the direct fibre stress, and the moment fibre stresses are to be added to or subtracted from the average K to give the true K at braced points along the exposure.

It seems reasonable to regard the axis of the beams as the location of the moment resistance, assembling the groups of joints acting along one line, where a number of beams are nearly in line, an approximation by inspection to the average line of action is probably quite close enough. Where a number of beams of small stiffness are over several feet apart, there is no useful purpose served in listing each as a separate force. The error in an approximate location of their center of gravity causes very small error in the important moments, and the moments in the shallow beams themselves are not important.

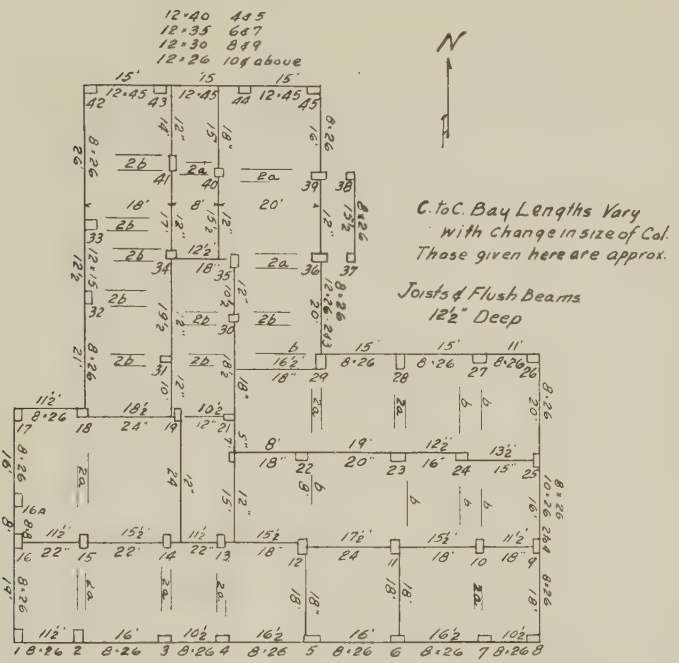

FIG. 4—EDDYSTONE BELMONT BLDG., SHERIDAN RD. AND BELMONT AVE. MCNALLY AND QUINN, ARCHITECTS. SMITH AND BROWN, ENGINEERS, INC. DIAGRAM OF FRAMING FOR DETERMINING STIFFNESS FACTORS FOR WIND STRESSES

The true K's for each group of joints having been determined we return to Tables 2 and 3 and multiply these values into the quantities $\frac{1}{R}$ to get the total moments at each of the joints.

These total moments are divided between the column sections above and below the floor, in proportion to the shears, except where there is great difference in the stiffness of the column above and below the floor. Where this disparity exists, the point of contra-flexure above is below the middle and the point of contraflexure below is below the middle; and the column below should be assigned moment in proportion to its stiffness. The column below should be assigned a moment somewhat greater than the total moment multiplied by the ratio of the shears. The ratio of the shears is found from the general stress diagram. For the second floor East and West, the shears above and below are 470,000 and 492,000. The proportion of moment above would be $\frac{470}{962} = .49$.

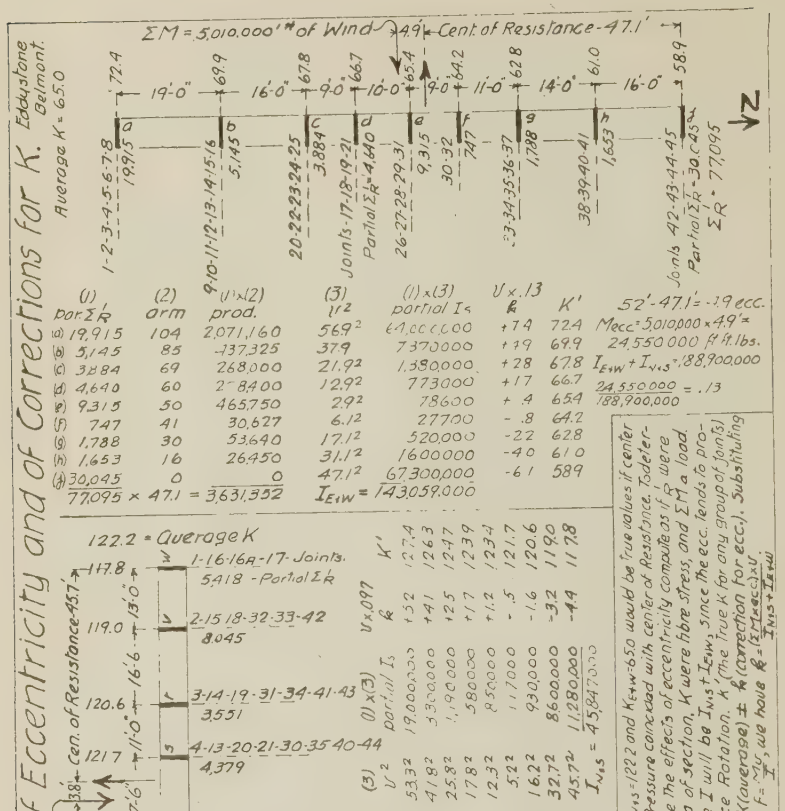

FIG. 5—CALCULATION OF ECCENTRICITY AND OF CORRECTIONS FOR K

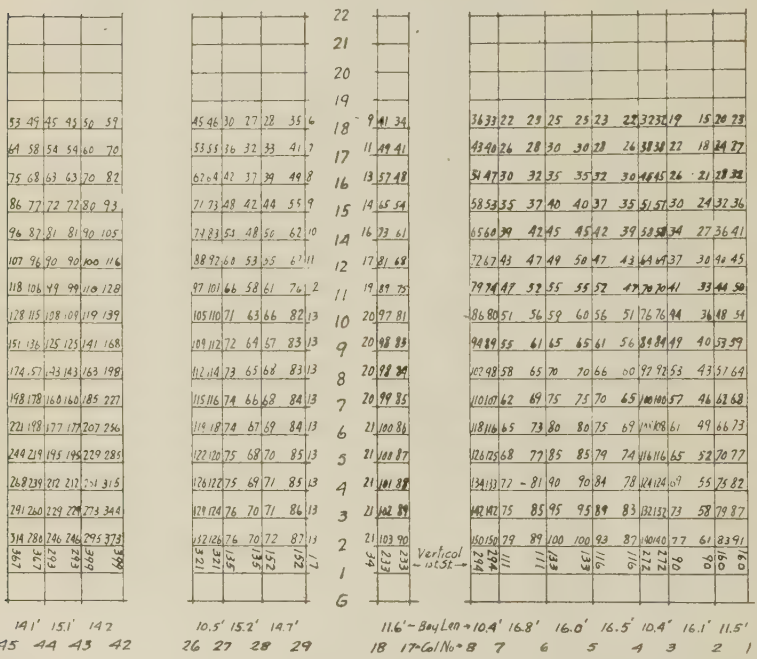
Revised m & m' obtained as for E & W stresses - See Table 2

The total joint moment is divided between the beams on either side of the column in the proportion of their values of $\frac{I}{1000L}$. In the column marked "%" is given the percentage found by dividing the larger $\frac{I}{1000L}$ by the sum. The correction of these moments is described later.

The moments here computed are those existing at the intersection of the center line of column with the center line of beam. These moments must be reduced to the face of the column and the face of the beam. Beam moments must be multiplied by the ratio one-half the span divided into one-half the span less one-half the column width. Similarly, the column moments must be multiplied by the ratio one-half the story height divided into one-half the story height less one-half the beam depth.

ACCURACY OF THIS METHOD

The results show that the assumption that points of contraflexure are at the middle of beams and columns is rarely exactly correct, and is often largely in error. After much recomputation of the joints adjacent to a beam whose end moments are unequal, we have found that if each moment is multiplied by a factor found by dividing the difference by twice the sum of the moments, the positive and negative correction found will make the corrected moments nearly correct.



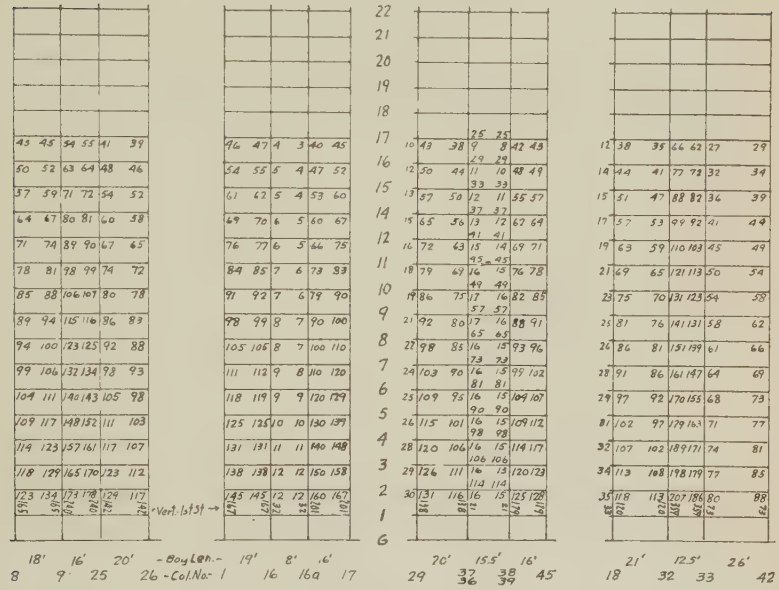
Where the column size changes, points of contraflexure above and below are not at mid-height, and in the rare case where the column wind stress at such a floor is critical, allowance must be made for additional moment at the upper end of the column below and at the upper end of the column above.

The wind moments for the various floors are computed for the full story height. In distribution of the moments the stiffness factors are based on beam lengths equal to the center to center of columns less one quarter the width of the two columns, and the column height is taken as floor to floor less one quarter the depth of two beams. In very short spans, whatever error this practice involves is magnified in effect. It is our practice, however, to make very short beams shallow.

FINAL SOLUTION FOR VERY UNSYMMETRICAL BUILDINGS

The stresses for Eddystone Belmont, shown on Tables 4 and 5, give a fairly accurate distribution of the moments and vertical

TABLE 4—EDDYSTONE BELMONT BLDG.—WIND EAST AND WEST



stresses in respect to bending of the beams and columns. Another element of deflection, that due to shortening of columns, must be taken into account.

It is clear that unless the exterior and first intermediate columns have a fibre stress from wind of the same sign and proportionate to their distance from the neutral axis of the bent, so that the floors remain in the same plane, secondary stresses are set up in the joints. These secondary stresses will remove vertical load from the exterior columns, and put loads of the same sign and of larger amount, in the intermediate columns. The major part of this transfer takes place in the upper third of the building, and in some cases the beams in the second bay of the bent require reinforcement for a few stories from the top.

In Eddystone Belmont, bay 17-18 is shown having moments of 103,000 ft. lb. and 90,000 ft. lb., and vertical loads in the columns of 199,000 lb. and 233,000 lb. It is quite certain that

TABLE 5—EDDYSTONE BELMONT BLDG.—WIND NORTH AND SOUTH

this bent cannot have the deflection which would result from the column deformation for these stresses. The stresses there shown are much too large. It is possible to make free hand adjustments of these stresses. To describe the adjustments which could properly be made in the stresses of this building is beyond the scope of this paper. I hope to compute a number of crooked buildings, and describe such stress adjustments, so that the designer will have available an example which will show the order of the stress aberrations, and can make an estimate instead of a guess, in the crooked problem before him.

ACCURACY OF THE CONVENTIONAL METHODS

This calculation has been prepared to show that the conventional methods not only leave a chance for error in determining what load comes to each bent, but involve in odd framing, errors in a single bent that are much too large. The labor of these calculations is considerable, but the engineer can readily deter-

mine what a conventional method would give him for moments in any one of these bents, and then determine for himself whether the error is tolerable.

Readers are referred to the JOURNAL *for June, 1931 for discussion which may develop. Such discussion should reach the Secretary by May 1, 1931.*

Economics of Light Weight Concrete in Buildings

*Report of Committee 406, Use of Light Weight Concrete in Buildings**

BY FRANK A. RANDALL, AUTHOR-CHAIRMAN†

In the last few years several aggregates have been developed to produce lighter weight concretes, in addition to cinders which have been used extensively in some localities for many years.

The desirability of an aggregate to produce a lighter weight concrete is usually prompted by relative costs. With unit costs and strengths of the concretes equal, in general of course, the lighter concrete will produce the cheaper frame.

The present study is an attempt to show the comparative costs of the structural frames for concretes of various weights and costs. To cover all buildings in this comparison would be a large undertaking and it was necessary to introduce limitations which are stated in the following paragraphs. The author is of the opinion, however, that the data developed will apply without serious modification to the general problem.

The graphs and tables show how much more can be expended profitably to reduce the weight of concrete.

In using the data submitted herewith it should be borne in mind that an interior panel only is considered. For exterior panels, the effect of reduction in weight of the concrete floor construction is less than for interior panels, for two reasons. First, the spandrel girders and exterior columns carry the wall construction in addition to, usually, only one-half panel of floor construction and, hence, the dead weight of the floor is a smaller portion of the total load carried than for an interior panel.

*Prepared by Mr. Randall, this report was reviewed and in general approved before publication by the critic members of the committee to whom Mr. Randall makes acknowledgment: Frank Brown, of Smith & Brown, Chicago; Emil Praeger, New York City; W. S. Wolfe, of Smith, Hinchman & Grylls, Detroit.

†Structural Engineer, 205 West Wacker Drive, Chicago.

Second, particularly in high buildings, the sizes of the spandrel girders, and, sometimes, of the columns must be increased due to the wind load stresses; and this increase will be greatest for the lightest weight concrete, other conditions being the same.

A similar effect to that last mentioned would take place were the building subjected either to a live load or a wind load in excess of that for which it is designed, that is, the percentage of overstress would be greatest for the lightest weight concrete. The obvious answer is to design for the proper loadings, if possible. This is not a difficult matter as to live loads for the type of buildings considered, namely, residential or office. In the matter of wind loads, the judgment of the designer is required. Building ordinance requirements are minimum requirements, and it might be quite proper to use somewhat higher wind loads for the lighter weights of concrete than for the heavier weights of concrete in order to secure equivalent stiffness of the building.

One reason for the choice of panel size is that this size is used in Part Two, Cost Data in the *Handbook of Reinforced Concrete Building Design* of the American Concrete Institute.[1]

The lower limit of weights of concrete considered in this report is perhaps theoretical. Concrete weighing 60 lb. per cu. ft. has been used in 4-in. slabs spanning 5 ft. with a design live load of 100 lb. per sq. ft. and concrete weighing between 75 and 100 lb. per cu. ft. has been used in long span joist construction.

GENERAL ASSUMPTIONS

Type of Building. The buildings considered are of the residential or office type.

Loading. The loadings in pounds per sq. ft. of floor, used in the calculations, are as follows:

Live load	40
Partitions	20 (with no reduction of the live load on the beams and girders which is equivalent to an increase of the partition load on the beams and girders.)
Floor finish	5
Plaster, direct	5
Plaster on metal lath	10
Composition roofing	5

Panel Size. An interior panel 18 ft. square is considered.

[1] A. C. I., *Proceedings*, Vol. 24, p. 537. 1928.

Story Height. The story height is taken as 11 ft. floor to floor, for all stories including the basement.

Building Code. The unit stresses and regulations of the new proposed Chicago Building Code for fireproof construction are followed. This code embodies, substantially, the 1928 Joint Code and the American Institute of Steel Construction Code. Steel floor beams are designed as composite beams in accordance with the provisions of the new Chicago Code.

Concrete Stresses. The following unit compressive stresses in concrete are used as a maximum:

Floors	2000 lb. per sq. in.
Columns	3000 lb. per sq. in.

Unit Costs. The following unit costs of materials in place are assumed:

Reinforcement bars	$0.035	per lb.
Reinforcement mesh	0.045	per lb.
Spirals	0.05	per lb.
Structural steel	0.04	per lb.
Formwork	0.25	per sq. ft.
Concrete (substructure)	0.40	per cu. ft.
Excavation and backfill	2.70	per cu. yd.
Wood piles	25.00	each
Caissons (complete)	1.25	per cu. ft.
Plaster on joist construction, excess cost over plaster on solid slabs	0.01	per cu. ft. of building

VARIABLES

Weights of Concrete. Five weights of superstructure concrete are considered ranging from 50 lb. per cu. ft. to 150 lb. per cu. ft. as follows:

Type	Weight
A.	50 lb. per cu. ft.
B.	75 lb. per cu. ft.
C.	100 lb. per cu. ft.
D.	125 lb. per cu. ft.
E.	150 lb. per cu. ft.

Types of Floor Construction. Two types of floor construction are considered, viz.:

F.	Solid slabs 4 in. thick
G.	Steel form 20-in. joists

Types of Frame. Two types of frame are used, viz.:

H.	Concrete
J.	Steel

Building Heights. Six heights of building are considered ranging from five to thirty stories, and basement, viz.:

K.	5 stories and basement
L.	10 stories and basement
M.	15 stories and basement
N.	20 stories and basement
O.	25 stories and basement
P.	30 stories and basement

Foundations. Spread footings at 3000 lb. per sq. ft. are used under the 5 and 10-story buildings; wood piles at 25 tons each, under the 15 and 20-story buildings; and caissons on hard pan (50 ft. high) at 6 tons per sq. ft., under the 25- and 30-story buildings.

Cost of Superstructure Concrete. Three unit costs of superstructure concrete are considered, viz., thirty, forty and fifty cents per cu. ft. in place.

DETAIL ASSUMPTIONS

Stresses. The value of j was taken as equal to 0.875 for slabs, beams and girders. For slabs, the positive and negative moment coefficient was taken as 1/12; for beams, the positive coefficient was taken as 1/16 and the negative coefficient as 1/12. Unit shear was taken at 60 lbs. per sq. in. with the longitudinal reinforcement anchored. The allowable unit pressure under steel column bases was taken as 600 lbs. per sq. in.

Column Loads. The full panel area of 324 sq. ft. was used in computing the column loads, the load on the area occupied by the column being compensated by a reduction of one foot in the length of the column when computing the weight of the column, i. e., by using 10 ft. instead of 11 ft. for the length of the column.

Slabs. For the 4-in. solid slabs, the 18-ft. panel was divided into three equal spans. The slabs were designed for full continuity, using L as the distance center to center of the intermediate beams.

Beams and Girders. All beams and girders were made as shallow as possible, economically. Steel beams were designed for an L center to center of connections. The following allowances in center to center dimensions of steel framing were made: for beams, 6 in.; girders, 15 in. Concrete beams and girders were designed for the clear distance between supports.

Concrete Columns. Spirals were used in all cases. The sizes were kept constant in each group of five stories. For the type A and B concretes throughout all stories and for the type C, D and E concretes in the upper five stories, the column design was based on 2,000-lb. concrete; for the balance of the columns, 3,000-lb. concrete was used. Three spacers weighing ¾ lb. per ft. were used for core diameters from 10 in. to 19 in., inclusive, and four spacers for larger columns.

Steel Covering. The top flanges of steel beams were placed 3 in. below the top of the concrete slab, with 2-in. covering on the sides and bottoms. For the concrete slabs a minimum covering of ¾ in. was used on the bottom, and 1 in. on the top of the reinforcement steel. For the concrete joist construction a minimum covering of 1½ in. was used on the bottom and 1 in. on the top. For the upper five stories of the steel columns the minimum covering was taken at 2 in., and for the remainder a minimum covering of 3 in., in which latter case, only, the increased unit stresses for combination columns were used.

Weights of Structural Steel. To make allowance for details and rivets, steel beams were figured center to center in addition to the weight of the connection angles; and one foot was added to the column story height to include column splices, rivets and other details.

Excavation. For spread footings and concrete pile caps, 3 in. was included in the excavation outside of the finished concrete.

DESIGNS

The designs involved 20 roof panels, 20 floor panels, 620 columns and 120 foundations, all different. Consistency of design was kept in mind at all times in order to produce as truly comparable results as possible.

ESTIMATES

After the designs were completed, a careful estimate of all quantities was made to which were applied the unit costs. In the appendices are tabulated the quantities of material for each of the 120 conditions. Appendix 1 is a tabulation of the total quantities of materials in the floors, columns and foundations with the 4-in. solid slab and concrete frame. Appendix 2 is for

joist construction with concrete frame; appendix 3, 4-in. solid slab with steel frame; and appendix 4, joist construction with steel frame. These tables are included in order that they may be used with unit costs different from those assumed in this paper.

Superstructure concrete of the various weights was kept separate from foundation concrete and the three different unit prices were used for the superstructure concrete, producing three total costs for each of the 120 buildings. These costs were then reduced to costs per cu. ft. of building, tabulated in Tables 1 to 3, inclusive, and which have been plotted in the following graphs:

Fig. 1 shows the cu. ft. (of building) cost for the 4-in. solid slabs for concrete (H) and steel (J) frame construction based on a unit cost of 30 cents per cu. ft. of the five weights of superstructure concrete.

Fig. 2 is the same as Fig. 1 excepting that the superstructure concrete is priced at 40 cents per cu. ft.

Fig. 3 is a similar set of curves with the concrete priced at 50 cents per cu. ft.

Fig. 4 is for the joist floor construction with the concrete and steel frames and the five weights of concrete costing 30 cents per cu. ft.

Fig. 5 is the same as Fig. 4 excepting the concrete is priced at 40 cents per cu. ft. and

Fig. 6 is the same for 50-cent concrete.

For those who prefer the tabular to the graphic, Tables 1, 2 and 3 show the same data as used in the preceding figures.

Table 1 shows the total cost per cu. ft. of building of the floors, columns and foundations, with superstructure concrete at 30 cents per cu. ft., for the five weights of concrete, the six story heights and for the two types of floor construction with both the concrete and steel frame.

Tables 2 and 3 contain the same data for superstructure concrete at 40 cents and 50 cents per cu. ft., respectively.

DEDUCTIONS

A study of these curves is of interest as disclosing:

1. The effect of increase in building height upon the cost of the structural frame, roughly 1/10 of a cent per cu. ft. of building per story for the range considered.

2. The greater effect of weight of the concrete in the higher buildings, roughly twice as much difference in the 30-story as in the 5-story building.

3. The comparative cost of concrete frame and steel frame, the difference in cost varying from about one cent to 1½ cents per cu. ft. of building.

4. The additional price that profitably may be spent for a lighter weight concrete in order to reduce the cost of the structural

frame. For example, it would be worth while to pay 10 cents more per cu. ft. to secure a reduction from 150-lb. concrete to 130-lb. concrete in a concrete frame building thirty stories high and a reduction to 115-lb. or 100-lb. concrete in a five story building, depending on whether the floor was of solid slab or joist construction. The savings are more favorable in the steel frame building.

We are hopeful that the data developed will prove of value.

(Tabulations constituting appendices 1 to 4 on following pages.)

Readers are referred to the JOURNAL *for June, 1931, for discussion which may develop. Such discussion should reach the Secretary by May 1, 1931.*

Discussion of the Paper by Helmer Swenholt:

"Design and Construction of Bonnet Carre Spillway"*

BY C. E. GRUNSKY†

There are some features of the Bonnet Carre Spillway described by Captain Swenholt, which might well be further elucidated for the benefit of the engineering profession. Among these are the following:

Why, for example, in view of the infrequent occurrence of the large discharge, which is anticipated about once in five years, was the spillway not made longer? A maximum overflow depth of 4 or 5 ft. would have been more desirable than 8 ft. Moreover it might even have been possible to secure the desired maximum flow at elevation 24 ft. over a weir crest without controlling the flow with gates or needles and yet without excessive premature functioning of the spillway. Operation costs could have been thereby materially reduced. The results of any studies made of such an arrangement, if topographic features do not preclude it, would be a welcome addition to the paper.

Undoubtedly there must be good reason for supporting the concrete weir structure on piles. Under ordinary conditions this would seem to the writer an undersirable arrangement because the separation of the ground from the base of the pile supported structure by settlement may take place and thereby the piping out of the soil from under the structure is facilitated and maximum uplift is invited. Generally speaking and entirely without personal knowledge of, and, perhaps, without application to conditions at the spillway site, it may be stated that such structures should preferably rest directly with their full weight upon the underlying ground. It is good practice moreover to add weight

by providing an overhead sand box if there is considerable difference in elevation between the high water on one side of the spillway and the low water stage on its other side, so that by heavy loading the underlying material will be compacted and the danger of piping out the support will be reduced. Furthermore, it may frequently be advisable to place such a structure on a layer of pervious material, such as sand, so that percolating waters which get past the upper lines of sheeting and of cutoff walls may find easy passage to a down-stream outlet.

The line of steel sheet piling close to the upstream edge of the weir affords it a maximum amount of support along or near its upstream edge. Longitudinal cracking of the floor along the trench feature, shown at the face of the weir, and into the piers may result if there should be more settlement of the piles than of the sheeting. Some explanation would be desirable as to this location of the sheeting in preference to a location under the crest line of the weir where it would have been equally effective in checking the underflow. Again referring to ordinary conditions and to a structure without pile support, the sheeting would then, it seems to the writer, more logically be placed just above the weir structure with concrete resting against it and not upon it.

The reason for the second line of steel piling at the stilling basin is not clear. Something at that point in the nature of protection against under-cutting in case of a failure of the flexible concrete mat and rock fill may be desirable, but the sheeting, as described, functioning to retard underflow, will build up pressure under the fore-apron and this pressure, unless measures for adequate relief have been provided, might float the fore-apron. Under an extreme, and probably unwarranted assumption, that water might find more obstruction to flow at the down-stream line of sheeting than at the upstream line, the uplift due to a difference in head of some 12 feet just before a release of the needles could easily be sufficient to lift and crack the apron.

The engineering profession is under particular obligations to Captain Swenholt for his clear and concise description of this spillway which, because of the great volume of water to be handled, marks a forward step in flood control practice. Later accounts of its effect on flood stages will be eagerly looked for by all hydraulic engineers.

Discussion of Paper by L. J. Mensch:

"Composite Columns"*

BY DAVID MOLITOR†

Some years ago the writer reviewed an article published in 1911, by Dr. F. Emperger on "A new use of cast iron in columns and arch bridges" describing a rather exhaustive series of tests from which he deduces the following conclusions:

1. That the strength of reinforced concrete columns was increased only slightly by vertical bars, while the hooping was mainly responsible for the enhanced carrying capacity.
2. Composite columns, consisting of a steel or cast iron core and encased in a concrete envelope with vertical reinforcement and hooping, could be designed to give exceptional results but depend mostly on the hooping for their greater strength.
3. Filling the interior of the cast iron cylinder with concrete materially diminished the ultimate strength of the encased column. A marked reduction in strength also, followed when octagonal or square spirals were substituted for the round form.

The form of column giving the highest strength according to Emperger, consisted of a hollow cast iron cylinder surrounded by a concrete encasement containing very little vertical reinforcement, but considerable spiral steel, as shown in Fig. 1.

Without attempting any further description of these experiments, it is at once apparent that the author's test columns differ from those of Emperger in that the hollow core feature was disregarded and only solid sections were tested, giving some rather erratic results depending on whether the hooping was capable or incapable of acting.

From all the test data on composite columns examined by the writer, it would appear that the element of weakness in such columns, as in ordinary hooped concrete columns, is due to insufficient hooping material to resist lateral bursting. No

†Structural Engineer, Detroit.

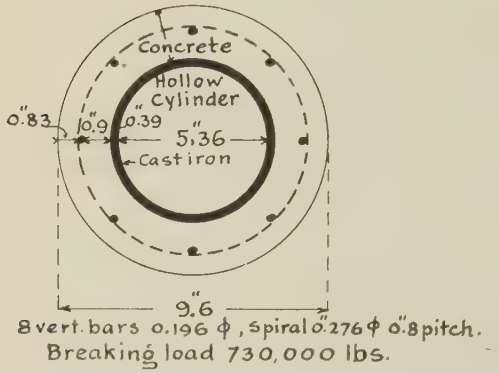

FIG. 1

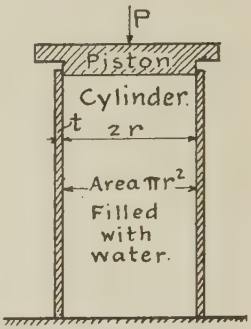

FIG. 2

matter how much core material is supplied, if the hoop strength is not properly provided, the column fails under a low test load.

To illustrate this point, let the cylinder Fig. 2, represent a hollow column as of spirally welded pipe, filled with a liquid, as water, and supported on a base with water-tight connection. On top of the cylinder is a piston acting as a column cap and fitting into the cylinder with water-tight joints but not otherwise transferring any vertical load to the tube. Disregarding details and assuming absolutely tight joints, this is at once a column capable of sustaining any load P by stressing the cylinder only in hoop tension. Let F represent the allowable working tensile stress in pounds per sq. inch, and referring to Fig. 2.

Then the unit pressure on the cylinder wall would be $p = \frac{P}{A} = \frac{P}{\pi r^2}$ and the hoop tension pr would require a thickness of metal $t = \frac{pr}{f} = \frac{P}{f\pi r}$.

The required steel area $= \frac{2\pi r\, P}{f\pi r} = \frac{2P}{f}$ = constant for any given load P.

Hence for $P = 1{,}000{,}000$ lbs. and $f = 18{,}000$ lbs., the steel area would be 112 sq. ins., requiring a cylinder of any diameter with a corresponding thickness t to give this area. Thus for $t = 1$ inch, the diameter would be 35 inches, and the pressure on the water would be 1000 pounds per sq. inch.

In this example we are dependent on a frictionless liquid which transmits the full pressure to the cylinder wall. Now substitute concrete for the liquid and note that most of the lateral pressure is absorbed by internal friction or stress, and only a small fraction of the unit pressure will remain to exert hoop tension, although in the absence of the tension element the concrete core would burst when the load P attains a certain magnitude.

Therefore, there is no reason why such a column could not be designed for any unit load up to or even exceeding the crushing strength of the concrete and require only a relatively thin enclosing steel cylinder, or spiral, subjected only to tensile stress.

According to this reasoning, which accords with the results obtained from tests, it would appear that the capacity of a composite column does not depend on the amount of vertical steel contained therein, but on how well the concrete is confined within the hooping or tensile shell surrounding the concrete core.

The Emperger cast iron columns substantiate this conclusion to a marked degree, for when the hollow c.i. cylinder is filled with concrete, the strength is materially reduced, because the cast iron shell is not suitable to resist hoop tension.

The best solution of this problem (still to be verified by tests) might be found by providing sufficient steel in the form of heavy spiral steel without appreciable vertical steel, designed entirely to resist tension. For this purpose flat bars would be preferable to round hooping bars and the maximum pitch of the spiral should be such as to prevent the flow of concrete through the open space and yet not so small as to prevent good bond between the core and the insulation.

The several test columns described by Mr. Mensch do not reveal any definite consistency in behavior and we must conclude that the underlying law for the strength of composite columns is still somewhat doubtful.

For columns consisting essentially of a steel core with concrete encasement, the increased strength which may exist is undoubted-

ly due to increased stiffness of the steel rather than to direct carrying capacity of the concrete.

For columns consisting of a concrete core surrounded by steel hooping, the increased strength is a direct function of the amount of hooping provided, because it is the hooping which directly opposes the lateral bursting pressure and prevents failure by diagonal tension.

Readers are referred to the JOURNAL *for June, 1931, for further discussion, including author's closure.*

The American Concrete Institute and Concrete Research*

BY DUFF A. ABRAMS

The American concrete institute is a working organization which depends for results solely on the voluntary effort of the members who give so freely of their time and experience in the work of its committees and in the preparation of papers and reports for the benefit of all.

Probably the most outstanding accomplishment of the year 1930 was the organization of many new technical committees and the increasing activity of the committees already organized. The Institute now has 71 technical committees made up of 218 individuals. Each committee has been assigned a well-defined field for study and report.

The committees are grouped under the following headings:

Research
Materials
Engineering Design
Architectural Design
Specifications
Construction

Joint Efforts

It is the purpose to cover the entire field of concrete materials and usage and to bring to the members the most reliable data, experience or opinion bearing on all phases of concrete work.

The method of appointing an author-chairman who is responsible for the initial form of the report, has been most successful. Before a report is submitted to the Institute it is reviewed by two or more critic members who are selected on account of special qualifications for the work at hand.

*Address of the President, 27th Annual Convention of the American Concrete Institute, Milwaukee, February 26, 1931.

Another outstanding event of 1930 was the completion of the first full year of publication of the new JOURNAL. Publication of the JOURNAL was begun in November 1929; the first 8 issues comprise Vol. 26 of the *Proceedings*. These 8 issues contained 1238 pages, by far the largest number of pages published in any year. Seven issues of the current JOURNAL, September 1930 to March 1931, contain 1294 pages.

The JOURNAL has been highly successful in meeting the needs of the Institute members. The Institute is no longer dependent upon one annual forum for discussion of its problems; it now has ten forums in addition to the annual convention. The papers published in the JOURNAL are of a high order of merit and will, no doubt, place this publication in the first rank of journals devoted to concrete.

An examination of the published *Proceedings* of the Institute from 1905 to 1931 shows some interesting and significant changes in the center of interest of the members.

A classification of the material in the proceedings for two-year periods at about five year intervals gives the following results:

	Per Cent of Total Pages of Papers and Reports					
Years Averaged	Re-search	Design	Con-struction	Speci-fication	Products Plant	Misc.
1905 and 1906	4	3	31	13	39	9
1910 and 1911	14	11	52	17	6	0
1916 and 1917	34	9	36	13	4	4
1920 and 1921	34	19	44	5	4	1
1925 and 1926	40	12	29	12	5	2
1930* and 1931*	50	18	17	13	2	0

*JOURNAL, Nov. 1929 to Feb. 1931

At the beginning most attention was given to products plants, construction and specifications, with little space devoted to design and research. This condition has undergone a gradual change during the quarter-century of the Institute's active life, until the present publications exhibit a predominant interest in research with the remainder nearly equally divided between design, construction and specifications. Since the beginning of publication of the JOURNAL 50 per cent of papers and reports have been devoted to research. In arriving at this figure *Abstracts* and *News Letters* were not considered.

Probably the most interesting phase of this change is that it has apparently come about without aim or guidance on the part of those responsible for the direction of the Institute, but rather as an unconscious adaptation of the work of the Institute to the greatest needs of its members.

It is my belief that the best interests of the Institute demand a still greater recognition of the function of research in our field to the end that the Institute may become the recognized clearing house for concrete research.

What is the field for research in the concrete industries? It is obviously impracticable here to attempt to present a detailed outline of future research, however, some of the broader problems can be touched upon. It can safely be stated that we shall never have an adequate basis for specifications, design and construction in concrete and reinforced concrete until we develop a sound theory. If we had a complete theory of concrete we should be able to calculate in advance all the properties and behavior of any concrete or reinforced concrete member or structure. At present practically every different mixture of concrete materials presents a new and unsolved problem.

Workability is the starting point of every phase of concrete work—yet the most fundamental phases of this subject are still undiscovered. What are the characteristics of the individual constituents of a concrete mix which dictate the amount of water which must be used in order to produce a mix of a given degree of workability? There must be well-defined characteristics of the materials which can readily be measured which will give us the answer to this problem. What influence has the specific gravity of the cement, and its fineness and composition? What are the characteristics of the aggregate, size and shape of particles, specific gravity, surface condition? What properties of the water (surface tension, viscosity, fluidity, specific gravity)? In our previous studies of workability we may have kept too close to the problem. Suppose we broaden the problem and make it a study of the factors governing the plastic state of any granular material mixed with any liquid. In this case concrete becomes only a special case of a much broader problem. I believe it is only along such lines that we will learn the true principles underlying workability of concrete.

There are many differences of opinion regarding the relative merits of different types of aggregates which would no doubt be reconciled by adequate research.

A similar analysis should be made of the elements of concrete mixing. What are we endeavoring to accomplish when we put a batch of concrete in a mixer and turn it over for one minute? No adequate theory of concrete mixing has been presented.

There is need of a better correlation between cement tests and the properties and behavior of the same cements in concrete.

There is much work to be done in the development of proper methods and mixtures for concrete floors.

The committee on Properties of Mass Concrete has pointed out many new problems, most of which have not yet been touched upon in previous investigations.

The studies made by our committee on Durability of Concrete have been made by the members of the committee and presented to the Institute as a voluntary contribution. It is doubtful if the entire annual budget of the Institute would have been sufficient if we had been called upon to pay the cost of this work.

The reports presented at this convention by the committee on Reinforced Concrete Column Investigation is an excellent example of the manner in which the Institute can sponsor research projects. This program of tests carried out at the University of Illinois and at Lehigh University will involve an expenditure of about $40,000.00, all of which has been contributed from sources outside the Institute. If the Institute were required to pay all the costs of such a program the cost would have been double the figure given. It was only due to the interest of the Universities and the loyalty of the men in charge to the Institute and its aims that this work could be carried at an expenditure which represents only the cost of labor and materials.

The Institute has no research laboratory, it has no research staff, it has no funds which are adequate to finance an extensive research program, yet it has at its disposal many research laboratories and in its membership most of the leading experts on concrete. Experience in the column tests has shown that adequate funds can be secured for a well-considered program of tests. If all these factors can be brought together, it will furnish

a method of adding immensely to our knowledge of concrete and concrete materials.

We hear a great deal about over-production; however, this condition is not yet apparent in the field of research.

Mr. Walter Lippmann, Editor of the New York *World*, a keen observer of modern life, has pointed out that the most remarkable development of the past 25 years is not the machine age or mass production, but rather that men have discovered how to make discoveries. In other words, research has been reduced to a formula. Any engineering problem can be solved if we have the will to solve it.

This view should encourage us in the belief that our problems can be solved if they are attacked with skill and courage.

While it is natural that I should emphasize the importance of research, I do not mean to minimize other phases of our work, such as specifications, design, construction and shop manufacture. However, research covers all of these departments and is, in fact, of no value until it is translated into office and field usage. Research is the handmaiden of design and construction. The writing of adequate specifications will become child's play when we have at hand adequate information upon which to base the various requirements; this information can be furnished only by research.

Studies of Concrete Mixtures*

BY S. C. HOLLISTER†

In the course of concrete mixing and placing it has been the experience of many that there are occurrences in the behavior of the mixture that are not readily explained by the customary concepts of mixtures. For example the following queries arise from experience in concrete mixing:

1. What causes the "fatness" that is acquired by concrete mixtures on prolonged mixing or working?
2. Why is there sometimes a crazing and checking of trowelled surfaces?
3. What causes shrinkage?
4. Why is there a change in consistency of mix on prolonged mixing?
5. Why is there frequently a lack of bond between coarse aggregate and matrix?
6. Is there any relation between heating during prolonged mixing and the physical state of the mix?
7. Why does prolonged rodding improve the strength of concrete?
8. Is uniformity of consistency a measure of the desirable objective of the mixing process?
9. What are the characteristics of cements that often affect the mixing, placing and handling of the concrete mixture?
10. Can water be withdrawn from mix after placing—how much can be withdrawn safely and what is the result?

These and other problems arising in the concrete craft are not in the writer's opinion explained by the customary concepts of the composition of a concrete mixture during its workable state.

It is the purpose of this paper to relate many of the phenomena mentioned above, through the medium of a more detailed concept of the concrete mixture prior to hardening.

Concrete in a structure consists of an arrangement of variously sized inert particles called aggregates bound together by hardened cement. At the time of casting, concrete consists of the aggregates, cement and water. The change from wet concrete to

*Presented at the 27th Annual Convention, A. C. I., Milwaukee, Feb. 24-26, 1931.

†Professor Structural Engineering and Assistant Director Materials Testing Laboratory Purdue University.

hardened concrete involves the chemical activity of the cement made possible by the water present in the mix. The quality of the finished concrete is dependent upon the amount of cement, the amount of water and the nature, size, amount and gradation of the various aggregates.

There are two major characteristics by which the concrete mixture is usually judged; (1) its placeability and (2) its strength. A concrete for a given purpose must first of all be of such a plasticity that it may be properly placed. After it is once placed it is then judged by its strength and other correlated qualities. In both these characteristics the amount of mixing water is of prime importance. Anyone with practical experience knows the relation of water in producing a workable mix. Abrams[1] has established the dependence of the resulting strength primarily upon the relationship of the amounts of water to cement. Talbot and Richart[2] developed in the mortar-voids method of proportioning the same relation in another form.[3]

In the practical use of concrete the workability of the mixture is of especial importance. It is not only dependent upon the amounts and forms of the dry ingredients, but also upon the amount of water used in mixing, and especially upon the consequences of wetting these ingredients when considered together with the circumstances of mixing and placing. Thus the study of the train of events attendant upon the addition of the water assumes increasing importance. Stress is laid upon the importance of considering the ingredients *as they occur in the mix*, and the effect upon such occurrences of the various circumstances common to the mixing operation.

WATER AND SAND

When a grain of sand is slightly moistened two things transpire: (1) a small portion of this water is absorbed into the body of the grain of sand; and (2) the unabsorbed water surrounds the grain of sand in a film, which film is held in position by the force of surface tension.

When two grains of sand are moistened and brought together they are prevented from making direct contact by the film of water. If the amount of water surrounding the two particles is

[1]References are listed at the end of this paper.—EDITOR.

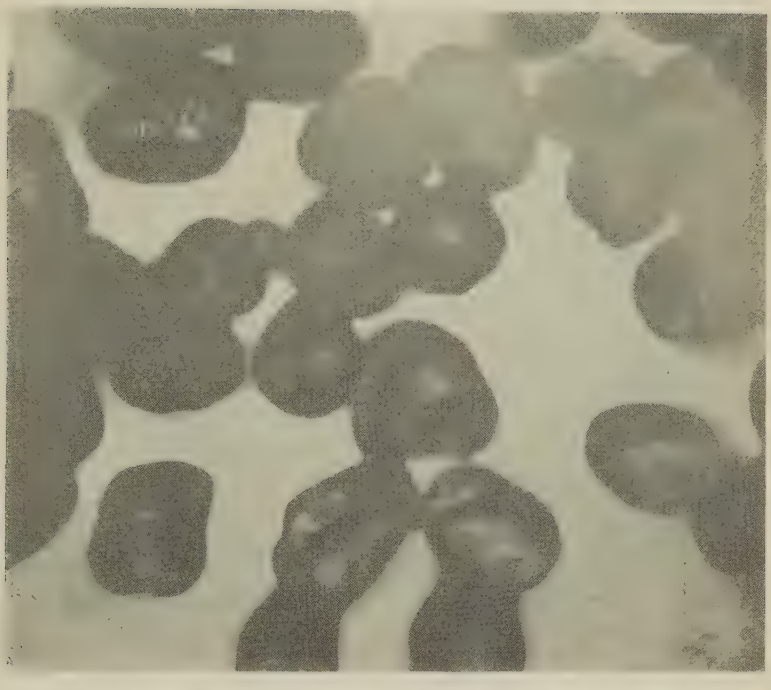

FIG. 1—LIQUID FILM ON GRAINS OF STANDARD OTTAWA SAND

small there is an insufficient amount of water to form an envelope to encompass both particles at once. Instead each grain is covered with an independent surface film which undertakes to maintain its separate form. The consequence is that the film of water holds the two particles from coming in close contact, because each grain behaves as though it were now larger than originally by the increase in diameter of the thickness of the water film. (See Fig. 1).

If the water surrounding these two particles is now gradually increased this excess water collects in the neck between the two grains and the water surface now tends to form a "peanut shape" surrounding both particles. It is now seen that a considerable amount of surface tension is acting to pull one particle toward the other. Under such conditions the two particles are no longer held apart.

The above discussion explains why dry sands are increased in bulk upon gradual moistening and why upon further increase of moistening a point of maximum bulking is reached beyond which further increase of moisture gradually diminishes the bulking until it almost entirely disappears.[4]

It can be demonstrated that for a given liquid the amount of moisture required to produce maximum bulking in a sand also the amount of the bulking are functions of the surface area of the sand.[5] A fine sand bulks more than a coarse sand and requires more liquid to produce this bulking because the surface area is greater for the fine sand.

A given sand will, of course, readily support the moisture required to produce maximum bulking without tendency of this moisture to drain off. This amount is not sufficient to produce a consistency in the wet sand comparable to that of the average concrete mixture.

WATER AND COARSE AGGREGATE

Assuming an impervious material, when gravel is moistened a film of water is formed on the surface of each particle in much the same manner as the film of water is formed around the grain of sand. For a given amount of gravel the surface area of the particles is less than for the surface area of a similar volume of sand. The amount of water necessary, therefore, to moisten the given volume of gravel (that is, to produce the film on the surface of the particles) is very much less than for the same volume of sand.

Whatever water is necessary to wet the surface of the gravel particles will not be sufficient to produce an appreciable mobility of the gravel. If, however, this wetted gravel be combined with a little more than enough of the wetted sand than would be required to fill the gravel interstices greater mobility will result. Even this amount of water, however, will not produce a workability such as is desired for concrete.

If the stone possesses much absorptive power at the time of wetting, a considerable amount of water will be taken up in saturating the stone. If the absorption is rapid, additional water must be supplied in order to give lubrication to the stone in the

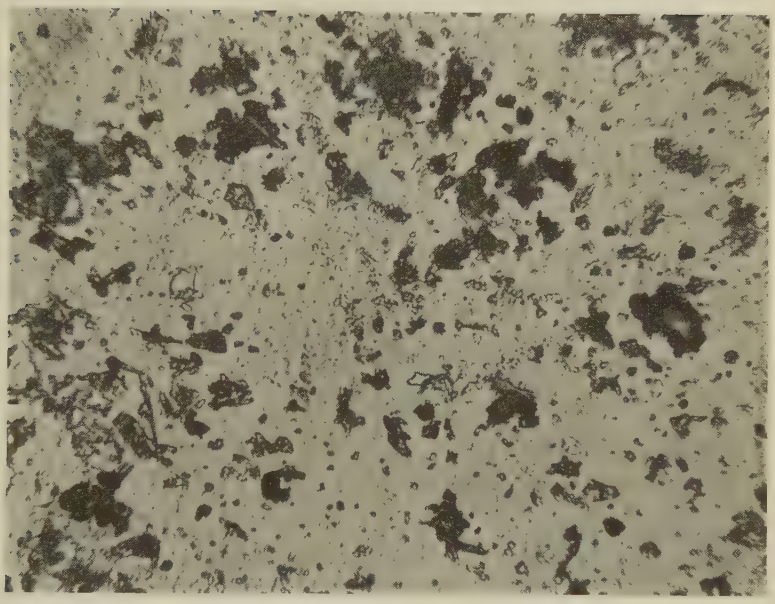

FIG. 2—DISPERSION OF CEMENT IN WATER (x275)

mix. On the other hand if the absorption is slow, less water will be needed by the stone to render it workable in the mix.

The shape of the stone particles not only affects the ease with which these particles move over one another in the mix but it also affects the amount of water required to wet the surface.

WATER AND THE CEMENT

The wetting of cement is a considerably different phenomenon from the wetting of sand. One need only think of the relative diameter of a grain of cement to the thickness of the water film to realize that a cement grain would be entirely inundated by such a film.

As shown in Fig. 2 the cement particles are of varying size and the fine particles tend to cling to the surface of the larger ones. When water is brought into contact with such a cluster of particles it engages the entire cluster, because the thickness of the surface film of water is relatively so large there is no tendency to separate

or disperse the particles and wrap each one individually with a film.

While in this instance an excess of water was present in order to obtain proper illumination, the tendency of cement to occur in clusters has been observed in a mass of more compacted structure. In either case as the water was quickly evaporated the voids between grains of cement are readily discernible.

THE MECHANICAL MIXTURE

Let us now bring together the three ingredients: the wetted gravel, the wetted sand and the wetted cement. Our first consideration is the mechanical arrangement of these wetted particles to produce a uniform dispersion. The sand grains fill the interstices between the particles of gravel, and in addition force the particles of gravel somewhat apart. The cement particles are to be found in clusters adhering to the particles of sand and gravel. The water exists in a film around the sand grains, the particles of gravel and the clusters of cement.

It will be found that where the water is just enough in amount to produce these films the mixture will be too stiff a consistency for proper working. Any additional water stirred into the mixture must occur in the small interstices remaining between the wetted particles of ingredients. This water may be termed "free water" in the mixture. Its only function is to aid in producing workability.

It should be noted that the water producing the film on the several ingredients is there for the sole purpose of producing workability for the mixture with the single exception of the water assigned to the cement. It is now important to consider the reaction between the cement and the water assigned to it and the effect upon the cement of all other water occurring in the mixture.

THE HYDRATING PROCESS

When water comes in contact with cement there is begun a long train of events, the conduct of which is the deciding factor in the extent to which this cement may impart strength to any given mixture. These events may be divided into two groups: those occurring prior to solidification and those occurring after solidification. It is not the purpose of this paper to go into

detail concerning the events in the second group. A large amount of research has already been done to determine the nature of such activity and the results of these researches have been published elsewhere.[6, 7, 8, 9] It is, however, desirable to develop here the processes occurring prior to hardening of the cement because it is while those processes are going on that the manipulation of the given mixture is possible. Whatever is accomplished prior to hardening will, of course, affect the processes subsequent to hardening, and conversely, what is left undone during the period in which manipulation is possible is not recoverable subsequent to hardening.

The question has often been raised whether a film of air is entrapped when the water first encompasses a cluster of cement grains or a single grain. The writer has been unable to observe under the microscope the presence of any such film. It is quite certain that the process of colloidal formation begins very soon after the water is added. If there is a film of air, therefore, separating the water and the cement it is very likely that this air is absorbed by the water. If this were not so and the air was present it would indeed be very difficult to initiate the colloidal formation.

If water is added to cement and is at once rapidly evaporated there is evidence of a cementious action having taken place. It would not appear that this could be so if there was an insulating film of air about the cement, unless this film of air were rapidly broken down. It is the writer's opinion that in either case the film of air, if at all present, is not of great consequence in our present consideration.

The water begins to dissolve the surface of the cement particles in contact with it. The substance thus produced in solution forms a jelly or colloid.[10] The strength of this solution depends upon the amount of water immediately at hand, which water causes in proportion to its amount a dilution of colloidal substance.

Observation of successive stages of colloidal formation and behavior develops many important facts which explain other phenomena noted in the process of mixing and handling the concrete mass. The amount of water usually present under ordinary conditions of mixing is greatly in excess of the amount of water

necessary to hydrate the cement. In addition to this water immediately in contact with the cement particles there is the large amount of water on the surface of the sand and coarse aggregate particles.

For some minutes after the water has come in contact with the cement no change is visible in this water. Gradually the water develops a variation in density so that it appears to wrinkle, giving much the appearance of wavy window glass. Then quite suddenly the waviness becomes very pronounced so that it looks like a shrunken film of varnish. At this point the formation of the colloid is quite well advanced. It is important to note that throughout this process of colloid formation the cement particle does not dissolve but remains as a nucleus in the colloidal mass.[13]

The action of the water in diluting the colloidal substance requires special attention. The more water present for a given amount of colloid the weaker that colloid. Furthermore the weaker the colloid the greater the amount of volumetric shrinkage upon the evaporation of the included water. Since the entire setting processes take place only in the colloidal substance present the weaker that colloid the less its physical strength. Fig. 3 shows clearly this phenomenon. The clusters of dark spots forming the boundary of the pattern in the figure are cement particles around which has been formed a rich colloid while these particles were submitted to hydration. Water extended over the entire area of this group and by this water colloidal substance distended, becoming the more dilute the farther it spread from the cement particles around the margin. Now, as the water gradually evaporated, all of the colloidal material shrank, the greatest shrinkage taking place in the central area of the pattern where the colloid was weakest. In this area the colloidal film thus formed was too weak to withstand the shrinkage stresses, hence producing cracks. It will be seen that these cracks are widest in the area of weakest solution and that they taper gradually and finally disappear as they approach the marginal area in which occurred the rich colloid.

It is thus seen that the water occurring in excess of that necessary to form a rich colloid becomes a rapidly weakening influence. This would appear to support the soundness of the physical law enunciated by Abrams that the strength of a port-

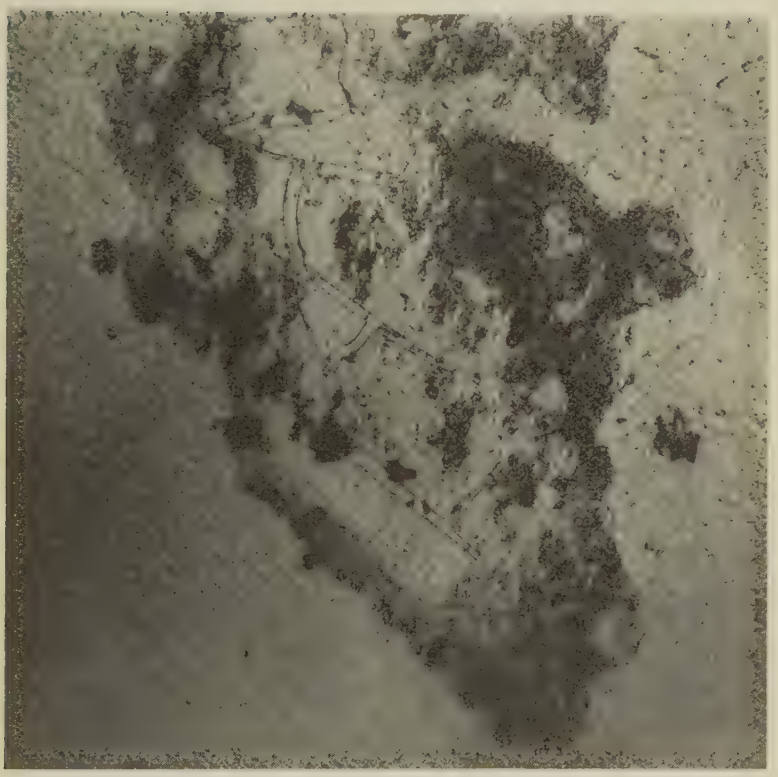

FIG. 3—CRACKING OF SHRUNKEN COLLOIDAL FILM DUE TO GROSS EXCESS OF WATER (x450)

land cement concrete mixture is a function of the ratio of the amount of water to the amount of cement in the mixture.[1]

While the above described phenomenon is taking place about the particles of the cement, other physical changes are taking place in a concrete mixture. From the time the colloidal "syrup" begins to form there is a gradual rise in the temperature of the mixture. This rise appears to continue until the stage of gel-formation, at which point the rate of temperature rise increases for some minutes. Thereafter the former rate of temperature rise continues up to the beginning of hardening. The consistency of the mixture during the period of colloid formation remains nearly

the same with a slight reduction in slump. At the time of gel-formation the consistency is noted markedly to stiffen. Thus a mixture with a 4-in. slump may stiffen to a 1-in. slump or less on formation of the gel.

With the use of a blend of two standard portland cements at a room temperature of 70 deg. F., evidence of "syrup" was noted from 10 to 15 minutes after the water was brought upon the cement. The gel state occurred at from 40 to 45 minutes after wetting the cement. These values are different for different brands of cement.

Whether the "syrup" or gel mentioned above represents the hydration of aluminates only, prior to hydration of the silicate group, or whether both are proceeding simultaneously or whether the state noted originates from another source than those just mentioned the writer cannot say. For the purpose of this paper the significant thing is that there is this jelly-like substance surrounding the cement particles and that its presence has a bearing upon the workability of the mix.

Another test was made to determine the volumetric effect on a block of neat cement of the shrinkage of colloidal substance noted in Fig. 3. A given amount was mixed with a gross excess of water and agitated from time to time for a period of six hours, after which it was allowed to settle and harden. It was noted that the upper portion of the mass of cement was "fat" and slimy, whereas the lower portion was very much less fat. Upon hardening in a smooth glass container it was found that a glaze formed next to the glass, and that this glaze, at three days, had developed a considerable adhesion to the glass. Upon air curing there appeared checks in the top face and these checks developed into cracks extending down halfway from the top face. (See Fig. 4.) The cracked portion was that portion formed of excessively wetted colloidal substance noted before setting took place.

It should be noted that the amount of water was far in excess of that in a concrete mix and that the amount of shrinkage is not at all comparable to that to be found in concrete unless placed under water. The significant relation is that between shrinkage and excessively wetted colloid, and that such colloid is readily floated to the top surface of a mix, when the mix is wet, or when

it is considerably agitated. Over-working of the top surface by troweling or otherwise will promote this accumulation of "fatty" mortar and if dried too rapidly will produce cracking. Many floors and sidewalks have exhibited this tendency.

Microscopic examination of the glazed surface above mentioned disclosed cracks in the glaze itself soon after exposure to the air.

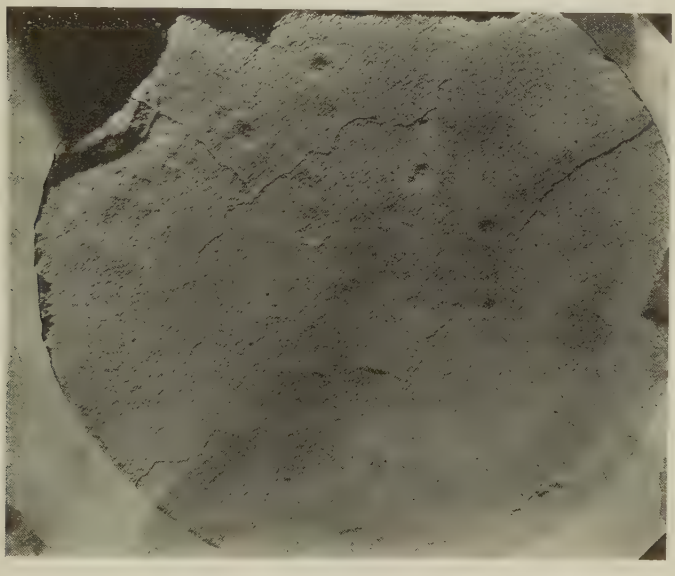

FIG. 4—CRACKS IN BLOCK OF NEAT CEMENT CAUSED BY GROSS EXCESS OF WATER

It would appear that there is a relation between crazing or surface checking and the shrinkage on loss of water in excessively extended colloidal substance collected at the surface. Technique which would tend to work the colloidal material *away from* the surface to be exposed would seem to reduce the occurrence of crazing.

Shrinkage on drying of a concrete mass, aside from temperature effects, would seem to be related to the richness and wetness of the mix, since these factors are the elements involved in extent of colloidal formation.

The foregoing test indicates one other important action.

Excess water does not produce more colloid of the desired richness, but instead dilutes (and hence weakens) such colloid.

The question now naturally arises, What is the relation between water and colloid? If the colloid goes into solution the escape of such solution would also mean the escape of what was originally colloidal substance, and there would consequently be a loss of strength proportionate to such escape.

W. I. Freel, of the Materials Testing Laboratory at Purdue University, made some tests to determine the solubility of cement in water. He found that the agitation of cement in an excess of water for various periods of time followed by settling of cement particles until the top liquor was clear, produced a top liquor which when decanted had a specific gravity of unity. This would indicate that the colloidal substance does not go into solution, but instead, is diluted but not dissolved by the water.

Tests were made to determine whether the liquor formed by the method used by Mr. Freel would show any sign of cementious characteristics when mixed with a known sand to form a mortar. No cementing ability was found by such tests.

FACTORS ARISING FROM CHARACTER OF AGGREGATE

There appear to be various views among investigators as to the proportion of strength of concrete contributed by the mortar and by the coarse aggregate. The coarse particles cannot contribute to the strength of concrete unless a bond between them and the mortar can be established.

As previously described a film of water is present on the surface of the coarse aggregate at the beginning of the mixing operation. Particles of cement lodged against this film cannot readily penetrate it. And for the number of such particles there is too much water in the film to admit of a satisfactory degree of colloidal strength being formed in the film that will reach through the film to the surface of the aggregate.

If this film of water cannot escape until after final setting a poor attachment to the stone is effected by the mortar. That such poor attachment is often obtained in concrete is shown by the fact that on fracture numerous examples occur in which the coarse aggregate itself is not fractured but instead pulls away from the matrix.

FIG. 5—WATER VOIDS AGAINST BOTTOM OF COARSE AGGREGATE IN OVER-WET MIXTURE

A microscopic examination was made of numerous specimens of which on the one hand the aggregate had pulled away and on the other the aggregate had fractured. In general it was found that where the aggregate pulled away a slight glaze was noticeable on microscopic examination, this glaze being similar to that formed by cement colloid alone upon evaporation of the moisture. Examination of the socket in the matrix out of which the aggregate was removed showed a surface consisting of very fine particles of sand together with the cement, the whole surface displaying a pitted sugary structure.

It is exceedingly difficult to obtain a satisfactory photograph conveying a correct impression of the observation made on the plane of contact between mortar and certain types of stone.

Fig. 5, however, is a piece of over wetted concrete on which some of the faults of excessive water just described are plainly visible. The concrete specimen was photographed in its upright position as cast. At the top are plainly seen portions of two sockets from which the stone fell away from the matrix. Arrows point to voids existing along the underface of a fractured stone. Voids such as these are often found in mixtures less wet than the one shown in the figure, especially if the aggregate has low absorption at the time of mixing.

A comparison of the properties of aggregates before and after use in concrete indicates clearly that for the particular types of stone observed, the bond to that stone was effected by sufficient available absorption on the part of the stone to pull in the water forming the film. Fracture of such absorbent stone was effected if the matrix was as strong as, or stronger than, the stone itself.

The effect of the absorption of water by the aggregates in affecting the strength of the concrete was found to result in an increase in the strength of such concrete commensurate with the change in the water cement ratio.

Increase in strength made possible by lowering the water cement ratio through the use of absorbent aggregate gives rise to speculation as to possible improvement in the quality of concrete produced by removal of excess water by this or other means. The investigations of Pearson[11] at the Bureau of Standards upon portland cement stuccos indicates the importance of the removal of water from the fresh coat by the proper amount of absorption by the undercoat. The same principle is involved in the use of sand molds in cast stone work. The undesirable results of excessive absorption by untreated gypsum molds indicates the necessity of control of such absorptive processes. The technique developed in the studio of John J. Earley[12] involves, in part, removal of excess mixing water through controlled capillary absorption.

CONVENTION DISCUSSION

W. A. Slater—Mr. Hollister has spoken of the development of something like a jell around the cement, as one of the agents in producing workability and that the effect is greater after continued mixing. I raise no question as to that. I do not know anything about it, I have to admit, but I want to call attention to a development within the last few weeks at Lehigh University. We were testing a conveyor designed to transport concrete from the central mixing plant to the place where it is to be used. It is a closed drum conveyor. A mix was designed using seven gallons of water per bag of cement. We charged the conveyor and at various intervals from the time of leaving the laboratory, for two and a half hours, samples were taken from the drum and analyses made of them, separating the ingredients into their various constituents and measuring them. We found that the amount of cement apparently increased until, after two hours and a half, from our measurement we would say that we had about thirty to forty per cent more cement than when we started out. We were not being fooled entirely, because the amount of water remained constant, the amount of sand decreased and the amount of decrease in the sand was just about the same as the amount of increase in the cement. We concluded that we were grinding up the sand as we went along, but the point I wanted to call attention to particularly was that the slump regularly decreased from the beginning until the end, although the amount of water remained constant. We concluded that the amount of material ground up in the operation had an important bearing on the amount of slump. It is entirely possible there were other factors at work too, but I think that must have had something to do

with it. Having nothing to do with this particular part of it, but as a matter of interest, the strength also increased as the time from the beginning of the transportation increased. I do not remember how much but it was a very substantial increase for the specimens taken after two and a half hours over those taken at the beginning.

P. H. BATES—I am particularly pleased to see that Professor Hollister is injecting a little physics into his engineering course because I think if his students once sense that this whole matter of making concrete is chemistry, and chemistry a branch of physics, we will have gotten around to the fundamental basis on which to study concrete.

Professor Slater cites the interesting discovery that in mixing concrete he made cement. Nearly 20 years ago a well-known contractor in Pittsburgh had a contract for grouting some veins in a mine shaft in order to prevent leakage of the water into the shaft. After some time he noticed that the bottom of the shaft in which he was not supposed to do any grouting was filling up, and he had to stop his grouting He measured the amount of grout he had in the bottom of his shaft and found that it was many times the amount of cement he had purchased, and he was very much alarmed about the whole matter.

I think we have got to realize that this matter of the setting of cement is a colloidal phenomenon, nothing more nor less, and will have all the characteristics of a colloidal material. You can assume it is an inorganic glue (probably you are sitting on a chair fastened with an organic glue) and you know exactly what happens when you do not treat an organic glue properly; if you use too much water or not enough, it does not glue. It is the same way with cement, and runs through many, many similar phenomena. A great many of you have noticed the work done by Miller at Minneapolis, the effect of alkali on concrete. If he cures concrete at a high temperature and puts it in alkali, it is almost immune to attack. You can dilute the white of an egg with water indefinitely, but if you once subject it to a high temperature, it is no longer soluble. Professor Miller probably has done that in treating his concrete at a high temperature.

For further discussion which may develop, see JOURNAL *for Oct., 1931 (Vol. 28.) Such discussion should reach the Secretary by Sept. 1, 1931.*

The Use of Color in Concrete*

Progress Report of Committee 408—Recommended Practice in the use of Color in Concrete

W. D. M. ALLAN, CHAIRMAN

INTRODUCTION

The American Concrete Institute appointed Committee 408 in July, 1930, to draft a Recommended Practice for the Use of Color in Concrete because of the growing demand for information on this subject.

The principal classes of color materials are: 1. Pigment admixtures; 2. Selected aggregates; 3. Chemical stains; and 4. Water and oil vehicle paints.

The Committee planned to make each of these sections the basis of a separate report or to suggest to the Institute that committees be appointed to cover each one.

Of the four classes of color work, there is most urgent demand for information on the use of pigment admixtures in troweled concrete surfaces which is the basis of the Committee's first report. Based on a study of the whole problem of the use of color in concrete, the Committee suggests the following subjects which might be developed as additional separate reports:

Pigment admixtures

1. In monolithic concrete walls
2. In cast stone and precast units.
3. In stucco and mortar

Selected aggregates

1. Color possibilities of natural aggregates.
2. Color possibilities of manufactured aggregates.
3. Combination of colored aggregates and colored mortars.
4. Surface treatments of concrete to develop color value of aggregates and mortar.

*Presented at the 27th Annual Convention, Milwaukee, Feb. 24-26, 1931.

Chemical stains

1. Chemical composition of stains and reaction with concrete to produce color.
2. Application of chemical stains to concrete surfaces.

Paints

1. Composition of water and oil vehicle paints.
2. Application of paints to concrete surfaces.
3. Protective value of paints on concrete srufaces.

Much has been written in technical papers on these subjects and a great deal that is of value has been presented to the American Concrete Institute which could be assembled under proper headings, supplemented by more recent information and put into usable form.

In presenting this recommended practice for the use of pigment admixtures in troweled concrete surfaces, the Committee has followed each section where it seemed desirable to do so with a sub-section of discussion. This method makes possible the inclusion of explanatory material for those who desire it, without making unnecessary reading for those who are interested only in the specific recommendations.

The Committee hopes that a large number of members, users and manufacturers interested in color, will comment freely on all parts of the following proposed recommended practice to the end that all who desire to get thoroughly permanent colors in their troweled concrete work may do so.

There are several points in this report upon which there is important division of opinion, e. g., several members feel that the use of the dust coat is sufficient to produce satisfactory work; while others feel equally certain that the dust coat is to be avoided on all but unimportant work. It must be admitted that many satisfactory dust coat jobs have been produced and in the hands of skilled workmen with close supervision, this method has possibilities. On the other hand, it must be admitted that excess of fines on the surface of concrete wear or weather surfaces leads to dusting and crazing. No satisfactory basis has yet been developed for evaluating these two ideas or arriving at the proper method of handling. From the anticipated discussion in the JOURNAL and from suggestions and criticisms received direct by committee members, it is hoped to be able to present for

adoption, a Recommended Practice for tentative adoption at the 1932 convention.

Progress Report on a Proposed Recommended Practice for the Use of Pigment Admixtures in Troweled Concrete Surfaces

PURPOSE

This recommended practice is designed to furnish the best information available on the selection and handling of pigment admixtures, laboratory tests for their quality and methods of using pigments in troweled concrete surfaces.

PART 1

General Requirements for Pigments

Only inorganic pigments, as limited in this section, should be used in troweled concrete surfaces. Synthetic and natural mineral pigments are satisfactory if they meet the following requirements:

1. Insoluble in water.
2. Free from soluble salts.
3. Free from acids.
4. Fast to intense sunlight.
5. Fast to heat up to 300 deg. F.
6. Not to exceed 2 per cent by weight of free moisture.
7. Fast to alkali and weak acids.
8. Free from calcium sulphate in excess of 15 per cent by weight.
9. At least 90 per cent of synthetic pigments pass a 325-mesh sieve and at least 90 per cent of natural pigments pass a 200-mesh sieve.

Discussion—The manufacturers of concrete pigment admixtures should be in a position to guarantee that materials meet these requirements. The test procedure which appears as appendix to this report will assist the purchaser in getting a prompt report from a recognized testing laboratory covering the suitability of a pigment based on the requirements above.

Synthetic pigments usually have a high degree of purity and uniformity. They are more brilliant and the cost per pound is usually higher than for natural pigments. For particularly important jobs and where brilliant colors are desired, synthetic pigments are recommended. For dull colors, natural pigments meeting the requirements above will be satisfactory, provided the amount of pigment added does not reduce the quality of the concrete so that it will not resist wear and weather. Frequently the smaller amount of syn-

thetic pigment at a higher price per pound will produce the results desired at a lower cost than the natural pigments.

In general, the finer the pigment the greater its coloring value.

Calcium sulphate sometimes occurs as a filler in pigments and it is necessary to limit the amount because of the detrimental effect of the sulphate on the concrete.

Some pigments have the property of absorbing moisture from the air and care should be taken to keep them dry; otherwise, they will be lumpy. When they are mixed with cement and stand for some time before being used, the moisture may react with the cement to cause caking. The limit of 2 per cent of moisture is intended to apply to the free moisture in the pigment and not to chemically combined water.

Selection of Pigments

Red—Use either synthetic or natural oxides of iron.

Yellow—Use synthetic yellow oxide of iron.

Buff—Use either natural or synthetic yellow oxides of iron.

Brown—Use synthetic or natural brown oxides of iron.

Black, Gray—Use synthetic black iron oxide.

Green—Use only synthetic chromium oxide; Cr_2O_3, at least 98 per cent pure.

Blue—Use synthetic cobalt blue at least 98 per cent pure and free from sulphates.

Methods of Test

Wherever iron oxide pigments are required, the purity shall be at least 98 per cent iron in the form of Fe_2O_3 after ignition at from 900 to 1000 deg. Centigrade for synthetic pigments and for natural pigments, the purity shall be at least 55 per cent, determined in the same manner.

Pigments shall be tested for purity in accordance with the test procedure in the appendix to this report.

The amount of pigment shall not exceed the proportions of 12 pounds of pigment to one sack of cement, (94 pounds net).

Discussion—In general, the least pigment used to obtain the desired color value, the better. This is especially true of surfaces that are to be subjected to heavy wear or to water or frost action. When necessary to use the maximum amounts of pigment shown above, special care must be taken to place the colored concrete with a minimum of water, to increase the time of mixing and to get more than average curing.

The recommendation for the use of synthetic black oxide of iron is based on the difficulty of getting definite non-fading black color with other blacks frequently used. While some organic blacks have and maintain a deep black

color they are light and fluffy and difficult to mix. If sufficient time and care are taken to obtain a thorough mix they are satisfactory. Not more than 3 per cent by weight of cement of organic pigment should be used. Cobalt blue is recommended in preference to ultramarine blue because of the large amount of fading which in cases has resulted in a total disappearance of the color when the ultramarine blue has been used. For specific jobs where some fading is not objectionable and where the manufacturer will guarantee the durability of the ultramarine blue, within reasonable limits of fading, it may be used under the manufacturer's direction.

Pigments used as admixtures in concrete must be considered as fine aggregate. Experience shows that because of the fine grading of the pigment, which is desirable for color value, it dries up the mix rapidly, leading to the tendency to use more mixing water. This, in turn, reduces the cementing value of the cement paste and results in inferior concrete. As the amount of pigment is increased, it is desirable to decrease the amount of fines below the No. 50 mesh screen in the aggregate used. Care must be taken not to increase the amount of mixing water used per sack of cement, above that required to produce concrete of the quality needed for the job if it were not be colored.

Color Value of Pigments

No table of definite color values can be given for pigments in concrete. It is necessary for the user to prepare sample panels of convenient size and combine the pigment in various accurately weighed amounts with a definitely known amount of cement, aggregates and water, such as he will use on the job. All proportions must be accurately made and the whole mass thoroughly mixed, placed and finished exactly in the way it will be done on the job. The panels should then be cured in the same manner that the job will be cured and then allowed to dry. The surface of the panel should then be wiped off with a mixture of one part paraffin oil and one part of benzine or similar vehicle and allowed to dry. From these sample panels, the color values possible with different materials and combinations can be determined and then, by reference to the data covering the method of producing the original panels, the color can be duplicated within very narrow limits.

Discussion—Color values cannot be established except by trial because the fineness of the pigment, color of the cement and aggregate, quality and quantity of the mixing water, time of mix, amount of troweling and method of curing all affect the values obtained.

A record should be kept of the exact proportions used in each panel so that the results can be duplicated. If the source of any of the materials is changed, a new series of panels should be prepared. A slight variation in either pigment,

cement, aggregate, water or method of mixing, placing or curing will produce variations in the finished job.

Some members of the committee have strongly urged that some standard of color values should be developed. A standard color chart has been suggested and all colors could be graded as 100 plus or minus depending on their tinting value.

Another suggestion strongly advocated is that the color values be taken from color charts prepared by the manufacturers and the concrete prepared and placed according to the directions of the manufacturers. The committee does not wish to rule against either of these plans but it recognizes that neither of them is feasible at present and the problem raised is important and needs solution.

Blending Pigments

Considerable skill and adequate equipment are required to blend successfully two or more pigments. Contractors and other users of pigments with a good "eye for color" can enlarge the range of colors available by blending or mixing the primary colors. This is frequently necessary on polychrome jobs and where slight variations in colors are desired. It is recommended that blended colors be purchased from reputable color manufacturers unless the user is sufficiently experienced and equipped to blend his own pigments. An accurate record of the exact amounts of colors used, weighed to the nearest ounce, for one-sack batches is absolutely necessary to get satisfactory results with blended colors.

Proportioning Pigments

All the materials entering into the batch must be carefully weighed. The quantities of pigment and other ingredients to be used are determined from the sample panels. Uniform results require that every batch be proportioned, mixed, placed, finished and cured exactly like every other. Even though the aggregate, cement and water may be measured by volume, the pigment must be measured by weight.

Discussion—Measuring pigments with a dipper or by any other volume method may be satisfactory for rough work where uniformity and high grade wearing surfaces are not required but this method is unreliable even with skilled workmen for important jobs. If the pigment has to be mixed on the job the color at least should be weighed out accurately at the plant or shop and delivered to the job in containers, each one containing just enough pigment for each batch.

Mixing Pigments

Pigments must be thoroughly mixed with the cement and with the cement and aggregate to get uniform work. There are several ways in which the pigment and cement can be mixed and the methods are described in the order of their value:

The color mixer, which is a tight, revolving metal drum with stationary paddles or blades, or a stationary drum with revolving paddles or blades of sufficient capacity to hold one-half, one or more sacks of cement with the pigment, is the best method for mixing pigments. The cement and pigment are accurately weighed and placed in the mixer and mixed for not less than ten minutes. When the batch is mixed it is sacked and kept dry until it is used.

In the absence of a color mixer on important work, it is recommended that factory-prepared colored cement be purchased from a reputable manufacturer.

Another method that will prove satisfactory if care is used, is to mix the accurately weighed proportions of cement and pigment by passing the two materials through a $\frac{1}{8}$-inch screen several times until all particles of pigment are thoroughly incorporated with the cement. This should be done at the plant where the materials can be kept dry and where weighing equipment is available.

Another method of mixing pigments on less important work is to use a concrete mixer. The aggregate and cement are put into the mixer and turned over a few times, then the measured amount of pigment is added in small portions, care being taken to get the pigment well distributed throughout the batch. This should be added in small quantities to avoid the danger of lumps forming which are very difficult to get thoroughly mixed. The mixing should continue until the pigment is uniformly distributed throughout the mass and then the water is added. The wet mixing should continue until the mass is of uniform consistency and the pigment is thoroughly distributed.

Discussion—Attempting to mix by hoeing together pigment and cement in a mortar box can produce satisfactory results only in the rarest cases and this practice should not be considered if uniform, reliable results are desired.

Regardless of the mechanical means employed, both the dry and wet mixing must be continued until the pigment and cement, or the pigment, cement

and aggregate are mixed to a uniform color. The best method of determining if the mixing has progressed long enough is to take a small amount of the material, possibly a shovelful and place it in a pan, wheelbarrow, or on a smooth concrete surface. Then spread it out in a thin layer with a trowel and trowel this thin layer hard. If streaks of pigment or cement can be seen, the mixing must continue until later trials show no streaking.

PART 2

Types of Troweled Colored Concrete Surfaces

In general, the use of color in troweled concrete surfaces can be divided into three approved types of construction:

Two-course monolithic construction, in which the colored top course is placed before the base course has hardened, so that the two courses harden as one-course construction.

Regular two-course construction, in which the colored top course is placed on a hardened base course.

One-course construction, wherein the pigment is used throughout the thickness of the section.

Discussion—Two-course monolithic construction is best practice wherever possible, because danger of a separation of the two courses is eliminated.

Regular two-course construction is used where it is not desirable to place the finish until some time after the base course has been placed.

One-course work is not common except in very thin slabs and in other work where only light tints are wanted.

The terminology developed for the three types of color jobs has been criticized as not definite enough. However, the changes suggested have been no improvement. Further study is needed.

Thickness of Colored Topping

For severe wear and exposure, the colored topping should be not less than 1 in. thick. For moderate wear and exposure the colored topping should be not less than ¾-in. thick. These apply to two-course monolithic work. For regular two-course work, all colored toppings shall be at least 1 in. thick.

Selection of Aggregates

Aggregates should be selected for grading, cleanness, durability and color.

For all severe wear and/or exposure, the aggregates should be composed of fine and coarse particles graded as follows:

Fine aggregate—All passing a ¼-in. screen, not more than 10 per cent passing a 50-mesh screen and not more than 3 per cent passing a 100-mesh screen.

Coarse aggregate—All passing a $\frac{3}{8}$-in. screen and all retained on a $\frac{1}{8}$-in. screen.

Aggregates should be hard, durable sand, pebbles or crushed materials free from dust, loam, clay or vegetable matter and contain no flat, elongated or flaky particles.

For moderate wear and/or exposure coarse aggregate may be omitted.

Aggregates should be selected from a source where the grading and moisture content remain uniform throughout the job.

Discussion—The grading of the fine and coarse aggregates should be such that there is a predominance of the larger sizes.

Where possible, the aggregates should be selected to match or strikingly contrast with the color of the mortar. When the mortar wears from the surface, the color of the exposed aggregate will have a marked effect on the color and appearance of the surface. Translucent aggregates, such as light colored, crushed marble, help maintain the desired color if the mortar surface wears away.

If the supply of aggregate is not uniform as to grading and moisture content, the user should screen his own materials and store them so that they are uniform.

Proportions of Cement and Aggregate

For severe wear and/or exposure, the proportions should be approximately one sack of cement, one cu. ft. of fine aggregate and two cu. ft. of coarse aggregate.

For light wear and/or exposure, the proportions should be approximately one sack of cement and two cu. ft. of fine aggregate.

The proportions of aggregate may be varied to correct for workability and consistency.

Discussion—The above proportions may have to be varied depending on the type of work, the grading of the aggregate and the amount of pigment used. In varying the proportions, as much of the coarse aggregate as possible should be worked into the mix. These proportions are on a damp and loose volume basis.

Mixing Water

Mixing water should be free from injurious amounts of acids, alkali, oil or vegetable matter and should be fit to drink.

The total amount of mixing water to be added with each sack of cement should not exceed 5 gal., including the free moisture in the aggregate. In adjusting the proportions of aggregate, correction for free moisture should be made.

Discussion—Impure mixing water, especially if it contains acids or alkali, may lead to efflorescence.

For particularly severe wear and/or exposure the total amount of water should be reduced to 4½ gal. per sack of cement. Accurate moisture determination for the aggregate must be made. When changing proportions of fine to coarse aggregate or of aggregate to cement, correction must be made in the amount of mixing water so that at no time the total amount of water added per one-sack of cement exceeds 4½ or 5 gal.

Consistency

Colored concrete for troweled surfaces should be placed as stiff as possible. The slump in no case should exceed 4 to 5 ins. Very little, if any water should appear on the surface when it is screeded or straight-edged.

Discussion—Stiff consistency is necessary to prevent the fine material coming to the surface during placing and troweling. The concrete should be stiff enough so that it has to be rolled or lightly tamped into place.

Mixing

Colored concrete, especially for two-course monolithic and regular two-course work, should be mixed not less than two minutes after all the materials, including the water, are placed in the mixer if the cement and pigment have been thoroughly mixed before being placed in the mixer. At least five minutes longer will be required for mixing if the pigment has not previously been mixed with the cement.

Discussion—The grading and proportions of aggregate recommended above, will tend to be more harsh than the average cement finisher is in the habit of working. Increasing the mixing time up to five minutes will improve the workability and at the same time increase the intensity of the color and improve the strength and wearing properties of the hardened concrete. The time of mixing for all batches should be the same.

Placing

Two-course monolithic and regular two-course work should be placed on bases that are clean and free from water. In *two-course monolithic* work, the base should stand until all the surface water has either evaporated or has been broomed or screeded off or removed in some other manner. All laitance or scum shall be removed before the colored concrete is placed.

In *regular two-course* work, the base should be broomed or cleaned and roughened just before it hardens. Before the colored concrete is placed, the surface should be scrubbed with water to remove all dirt. If there is oil or other foreign material on the

base, it should be removed with soap and hot water or with sharp edged tools. When the washed surface has begun to dry slightly, a mixture of cement and water or one part of cement and one part of sand mixed to a thick creamy consistency should be broomed onto the surface in a uniform layer about $\frac{1}{8}$-in. thick. Before this grout coat begins to dry the topping should be placed.

The colored concrete should be deposited in small batches close together and screeded or straight-edged to grade. Special care shall be taken when straight-edging to fill up and prevent low places in the topping. The surface should then be wood floated and allowed to stiffen before the steel trowel is used. Areas of colored topping should be placed, small enough so that by the time of finishing all of the topping will have stiffened to the same degree.

Discussion—Any water on the base, whether it be from the fresh concrete or applied for washing, should be removed or allowed to evaporate before the colored concrete is placed. Otherwise this water will rise through the colored concrete, tending to cause efflorescence and dusting. In two-course monolithic construction the danger of water from the base rising through the colored topping will be reduced to a minimum by placing the base as stiff as possible.

Troweling

Steel troweling should be delayed as long as possible and still be able to finish to a smooth compact surface. Troweling should be reduced to a minimum and the final strokes be made all in one direction. Sprinkling the surface with water to aid in troweling should not be permitted.

Discussion—Any working of the surface even with a straight edge or screed tends to bring fines to the surface. Steel troweling is particularly bad. The surface should be worked as little as possible. Fines lead to dusting, checking and blotchy color. If the troweling is delayed until all the water sheen has disappeared and the concrete has stiffened slightly, the danger of drawing fine material to the surface is reduced to a minimum. Attempting to fill up low places by troweling surrounding material into them will result in discoloration and the tendency toward dusting. Low places should be leveled with the straight-edge and wood float.

Filling Low or Wet Areas

Filling in low or wet places with dry mixtures of pigment and cement or pigment, cement and aggregate should not be attempted. Steel troweling wet places should be delayed until the excess water has disappeared. Low places should be filled with a concrete mixture exactly the same as is being placed and care

must be taken not to work the concrete in the low places any more than any of the other surface. When filling a low place, the concrete for several inches around should be roughened and then brought back to grade along with the added concrete by using the straight-edge and float.

Curing

All colored concrete surfaces should be damp cured for not less than seven days. Where subjected to severe wear or exposure the damp curing should continue for not less than 10 days. The surface at no time during these periods should show any tendency toward drying. Ponding, completely covering with damp sand or with approved grades of heavy waterproofed paper or fabric should be required.

Discussion—Nowhere in concrete work is proper curing of more importance than in troweled colored concrete surfaces. Strength, resistance to wear, freedom from dusting and checking are as much dependent on proper curing as upon any one factor. In hot, dry or windy weather, the surface should be protected from the sun and wind immediately after steel troweling. The curing should be started as soon as the surface has hardened enough to prevent damage.

Surface Treatment

After the concrete has been cured as required above, it should be washed off with clean water and allowed to become thoroughly dry. If after washing a light colored deposit or film, called efflorescence or bloom appears on the surface or if the color seems to have faded, the surface may be dampened with water and washed with a solution of one part of muriatic acid to 10 parts of water. The acid is put on uniformly over the surface with a long handled brush or broom and allowed to remain for not more than five minutes, when it is entirely removed with an abundance of clean water. It may be necessary to repeat the acid treatment. The acid should not be allowed to remain long enough to start etching the surface and should not be used at all on heavy wear surfaces.

Efflorescence may be removed by steel brushing or rubbing with steel wool. The material loosened in this way should be broomed from the surface before it is washed or given any other surface treatment.

Rubbing the surface with a mixture of equal parts of paraffin oil and benzine or naphtha will remove the efflorescence if it is not too thick. This treatment is sometimes used to brighten the colored surface.

Washing the surface with liquid soap which has been allowed to stand overnight and then scrubbed off with warm water improves the colors and wearing surface. This treatment should be repeated two or three times over a period of four months.

Ordinary floor wax aids in brightening the colors and filling the surface so that it is more easily kept clean.

There are numerous other commercial waxes and resins which applied to the surface will aid in brightening colors.

This progress report has been submitted to the following committee, which voted as follows:

W. D. M. Allan, Chairman
C. A. Cooke
J. G. Ahlers
M. R. Rust
J. W. Ayers
E. M. Waldo
John Mott
Rexford Newcomb

Of whom 7 have voted affirmatively, one negatively and none has refrained from voting.

Respectfully submitted,
W. D. M. Allan
Chairman, Committee 408.

Appendix—Report Committee 408

Laboratory test procedure for determining the quality of pigment admixtures

Acidity of Pure Oxides

Boil five grams of pigment with 200 cc. of distilled water in a 300 cc. Erlenmeyer flask for 20 minutes. Cool under the tap and filter through a 15 cm. filter paper into another similar flask. Wash with about 40 cc. water. Add three or four drops 1 per cent phenolphthalein indicator, and titrate with $\frac{N}{100}$ sodium hydroxide.

Standardization of Sodium Hydroxide

Weigh accurately a convenient quantity (suggest .06 grams) of acid potassium phthalate $C_8H_5O_4K$ (obtained from the Bureau of Standards). Dissolve in cold water and titrate with the $\frac{N}{100}$ sodium hydroxide, using phenolphthalein as before.

The normality of solution equals $\frac{\text{weight } C_8H_5O_4K}{\text{burette reading x } 0.204}$

Percent H_2SO_4 in sample equals $\frac{\text{burette reading x } .049 \text{ x normality x } 100}{5}$

Blank tests should be run on the water used both in standardizing and the actual determination.

Routine Test for Presence of Acid

A ten gram sample of pigment is allowed to digest in 150 cc. of distilled water one minute. Filter off the pigment and analyze the filtrate with methyl orange or phenolphthalein.

Test for Moisture

Weigh out accurately a one to three gram sample of pigment into a fused quartz crucible, which has previously been thoroughly cleaned, heated to a temperature of 125 deg. C. cooled in a desiccator, and weighed.

Place the crucible, with the material, in the electric furnace, and heat to 110 deg. C. for one and one-half hours. Remove from the furnace, place in desiccator until cool and weigh.

Computation: Loss of weight divided by the original weight times one hundred equals percentage of moisture.

Determination of Percentage of Ferric Oxide

Solution: Dissolve ½ gram oxide in about 20 cc. 1-1 hydrochloric acid in 100 cc. beaker. Add enough stannous chloride to keep the solution very nearly in the reduced state. (If solution is over-reduced, add enough permanganate solution to restore yellow ferric color.)

Reduction: When the solution is complete, reduce the ferric oxide by adding stannous chloride drop by drop until the solution is entirely colorless. Then add one drop in excess. Wash solution into a 400 cc. beaker containing 250 cc. of water, add 20 cc. titrating mixture and 10 cc. of mercuric chloride. Titrate with potassium permanganate to a permanent pink color.

Computation: Percentage of Fe_2O_3 = burette reading x normality factor x 200.

Potassium Permanganate Solution: About 4 grams per liter or of such strength as to give 1 cc. equal to 1/100th gram ferric oxide.

Stannous Chloride: 100 grams stannous chloride, 100 cc. concentrated hydrochloric acid, 100 cc. water. Make up to liter and add a few pieces of metallic tin.

Titrating Solution: 160 grams manganese sulphate, 1320 cc. sulphuric acid, 1.84 Sp. Gr., 330 cc. of syrupy phosphoric acid, 1750 cc. water.

Mercuric Chloride: Saturated.

Determination of Sulphur (gravimetric method)

Mix thoroughly 1 gram of the finely ground pigment with 8 grams of sodium carbonate and from 0.5 to 0.7 gram of sodium nitrate, in a large platinum

crucible. Heat carefully over a Bunsen burner or blast-lamp until the mass appears perfectly liquid and in a state of quiet fusion. Run the fused mass well up on the sides of the crucible and plunge the crucible half way into cold water. When cold, treat in a tall narrow beaker with boiling water until all soluble salts are dissolved, and no hard lumps remain. If the solution is colored blue or green by $Na_2Mn_2O_8$, add a few drops of alcohol. The solution will now be colorless, or yellow if chromium is present. Allow the undissolved matter to settle and decant the solution through a filter into a small beaker. Wash the residue with hot water once by decantation and then pour it upon the filter and wash four or five times. Add hydrochloric acid to the filtrate until just acid, evaporate to dryness and heat one hour longer at 110 deg. C. Moisten the residue with hydrochloric acid and set on the hot plate for a few minutes, add 50 cc. water, heat till all soluble salts are dissolved, filter and wash until the filtrate measures 85 or 90 cc. (If the silica in the ore is low, evaporation to dryness is unnecessary. Simply acidify and filter.) Heat this latter to boiling and add 10 cc. of a 10 per cent solution of barium chloride, previously diluted to 30 cc. and brought to boiling point. Allow to stand for some hours, filter, wash with hot water, ignite and weigh as barium sulphate. This weight multiplied by 0.13732 and the product divided by the weight of the sample gives the per cent of sulphur in the pigment.

Specific Gravity

Employ a 50 cc. pycnometer. Insert an accurately weighed portion of sample, fill half full with water, boil gently to remove any air, cool under the tap to room temperature. Fill to the mark with fresh distilled water; after noting the temperature, weigh. Call this weight *C*. Empty flask, clean and refill with distilled water to the mark. The temperature of this test should be identical to the first procedure. Again weigh and call this weight *P*. Let *W* equal weight of dry sample.

Computation: Sp. Gr. $= \dfrac{W}{P + W - C}$

Note: More finely divided pigments which have a tendency to form a film on the water seem to work better when some other liquid, lighter than water is used. Kerosene gives excellent results.)

Computation: Sp. Gr. $= \dfrac{W \times G}{P + W - C}$ where *G* equals the Sp. Gr. of the liquid used.

Determination of Chromium Oxide[1]

Solutions: Sodium thiosulphate—tenth normal—24.82 grams per liter ($Na_2S_2O_3 . 5\ H_8O$).

Potassium hydrogen sulphate—136 grams per liter ($KHSO_4$) (approx. normal)

Sulphuric acid—one part acid—one part water.

Starch solution—Make 2 grams soluble starch into a thin paste with cold water. Pour into 200 cc. boiling water.

[1]See Scott's Standard Methods of Analysis.

Standard permanganate—about 4 grams per liter. Same as used for iron. *Determination:* Heat gently 0.3 gram sample with about 3 grams sodium peroxide (Na_2O_2) in a covered porcelain or Vitreosil crucible.[2] The crucible furnace should be just below redness. Heat for 15 minutes after fusion is liquid.

Cool and place crucible in 400 cc. beaker. Dissolve melt in about 100 cc. cold water, adding some hot water to hasten solution. Boil 10 minutes. If $Fe(OH)_3$ separates out in appreciable quantity it must be filtered off. See Scott's Standard Methods of Analysis. Make nearly acid (litmus) with sulphuric acid. (The solution darkens.) Then add 15-20 cc. $KHSO_4$ sol. and boil for 10 minutes longer.

Cool under the tap. Make up to mark in a 250 cc. volumetric flask. Pipette 50 cc. aliquot into a 300 cc. Erlenmeyer flask. Add about 25 cc. sulphuric acid. Dilute to about 200 cc. with cold water. Add about 2 grams potassium Iodide (KI) and after a few minutes titrate with the thiosulphate solution. When the green color begins to predominate, add a few cc. starch solution and finish titration drop by drop until the blue color fades to pale green.

$$\text{Then per cent } Cr_2O_3 = \frac{\text{cc. } Na_2S_2O_3 \text{ x value 1 cc. x 500}}{0.3}$$

Standardization with Standard Permanganate

Pipette 20 cc. $KMnO_4$ into 300 cc. Erlenmeyer flask. Acidify with 20 cc. H_2SO_4. Dilute. Add about 2 grams potassium iodide and, after a few minutes, titrate with standard thiosulphate, arriving at end-point exactly as described in method.

Reactions: (a) $2\ CrO_3 + 6\ KI = Cr_2O_3 + 3K_2O + 6I$.
(b) $I_2 + 2Na_2S_2O_3 = 2\ NaI + Na_2S_4O_6$.

Calculations:

$$\text{Normality of permanganate sol.} = \frac{\text{wt. Fe equiv. to 1 cc. } KMnO_4}{0.056}$$

$$\text{Normality of thiosulphate sol.} = \frac{\text{cc. } KMnO_4 \text{ x 20 x normality } KMnO_4}{\text{cc. } Na_2S_2O_3}$$

$Fe_2O_3 \times 0.6994 = Fe$; then 1 cc. N. $Na_2S_2O_3 . 5\ H_2O$ should
$= .056$ Gr. Fe $= .01733$ grams Cr.
therefore: 1 cc. thiosulphate sol. $= 0.0253$ grams Cr_2O_3 x norm.

Determination of Cobalt

The cobalt is determined after the removal of the lead manganese (iron and zinc) by precipitating with ammonia and ammonium sulphide as cobaltous sulphide; dissolving this precipitate in nitric acid, adding H_2SO_4 taking down nearly to dryness, then diluting with water, making almost neutral with ammonia, and precipitating with a boiling hot concentrated solution of ammonium hydrogen phosphate.

The precipitate is washed, dried and weighed as $CoNH_4PO_4$.

[2]Weight of sample may be varied.

DISCUSSION

BY M. R. RUST*

Introduction—Dust coats are productive of unsatisfactory results and are only a method for the cheap installation of color with resultant inferior wearing surfaces. There are no happy mediums—a job, on completion, is either good or else no good. Dust coats must definitely result in the latter. It is practically impossible to obtain a floor, dust coated, which will be uniform in either color or the mix of the dusting materials. Furthermore, it is well-nigh impossible to find a floor, prior to dusting, which would have a uniform degree of moisture to hydrate the cement uniformly in the dust mix. Even in the hands of skilled workmen, dust coats will be found satisfactory on only a small portion of their work.

General requirements for pigments—Synthetic and natural pigments are satisfactory, according to the heading, if they meet the qualifications enumerated—and the 4th qualification set forth is "fast to intense sunlight." I have yet to find my first natural color which will meet this requirement, in fact, I might add that I have yet to find one which will closely approach such performance.

It seems a hardship on the contractor to determine whether he is adding only enough natural color to make sure that he does not produce a finish subject to wear. On the same subject, who desires a dull colored concrete surface? The object of using color is to avoid dull monotony and obtain rich decorative beauty. I have encountered comparatively few requests for dull colors and as a manufacturer, we eliminate any thought of such a result from all literature and recommendations. Even the layman appreciates that if it is possible permanently to color concrete to rich intense tones, it is logically possible to produce a dull effect. To criticise the endorsement of natural colors for dull color effects, further, I wish to point out that if a job were completed with the desired dull effect, using a natural color, it would within a few weeks fade to a most unsatisfactory effect.†

*Member Committee 408.

†Without presuming to "take sides" as between synthetic and natural pigment admixtures, may the Editor interpose as a mere suggestion that dull (*un*brilliant) tones are not infrequently desirable in garden landscapes where concrete may be called upon to play a part in naturalistic effects in which brilliant tones would "scream" at nature.—EDITOR

Selection of pigments—I definitely oppose the endorsement of natural colors wherever listed under this heading. As regards the last color, blue, I must confess myself straddling the fence for the good reason that I cannot deny the more stable qualities of Cobalt compared with Ultra-marine—but on the other hand, I fail to see why Ultra-marine is not the more logical choice. Cobalt is unquestionably expensive—almost prohibitive in its pure form whereas Ultra-marines, of the finest preparation, are reasonable and for all practical purposes, will answer most satisfactorily. Despite opinion to the contrary, our experience has been without fault in the sale of such a blue. Admittedly, there are Ultra-marines of most questionable quality and some determination might be made between desirable and undesirable Ultra-marines. It seems that again we come to the same question for debate and that is whether to endorse something for the general good of the industry or to make our recommendations, in the final analysis, for the select few. My suggestion is to favor the multitude.

Methods of test—Nine pounds of pure synthetic color are ample to produce a rich and intensely colored concrete surface. Additional is only waste. Unquestionably nine pounds is more favorable to strong concrete than twelve and the only excuse for permitting the use of twelve pounds is to allow for the use of natural colors—on which I have already commented.

I am confident that our best recommendaton on the use of black is to stand entirely behind synthetic black oxide of iron. I have, personally, conducted a good many experiments to produce a black with more intensity but invariably something is lost with each gain. Not only is the mixing of the color with the concrete extremely difficult but other blacks or blends seem to produce a retarding action which would be highly objectionable and disconcerting to the unknowing contractor.

If we are to assume it true that the color present in a mix tends to dry up the mix and require more water, my suggestion of not more than nine pounds of color per sack of cement is preferable.

Blending pigments—To endorse the contractor's blending of colors is to invite more worry and grief than I care for. The contractor with a huge organization might be interested in

blending—but it is doubtful if he would care to spend the time when he can purchase the exact tone, required, from the manufacturer. Furthermore, presume that he is later required to build some addition to the original job—who possesses the formula for the blend? Here again, we are leaving ourselves wide open. It will probably be best to leave the business of blending to the maker of color with the facilities and knowledge required in blending.

Mixing pigments—Factory prepared colored cement is an excellent product in theory but it has many limitations. For the contractor to use colored cement, he must be prepared either to pay a considerably increased cost for the colored portion of the job or to anticipate less efficiency and color value in his completed work than he would receive through the purchase of the color and intelligent use on the job. Someone must pay the traffic for the machining of the color and the cement, not to mention a few other expenses involved.

Thickness of colored topping—I am again straddling the fence on this subject. I find that the bulk of the work is done with ½ in. topping and while I feel that added thickness is undoubtedly an advantage, we might wisely consider that with each ¼ in. added to thickness of the topping, the color cost is increased by a sizable sum. We may follow a rather common practice of endorsing a definite thickness with the expectation that we are to receive at least 50 per cent of that on completion—but on the other hand, contractors of the Jerry Builder type are hardly likely to follow even that reduction. If we specify ¾ in. and they are accustomed to laying ¼ in.—I strongly believe they will continue to lay just ¼ in. My thought is this, that if we can safely specify the use of ½-in. topping for, say two course monolithic work and ¾ in. for set slab construction, we might do better to adopt such thicknesses.

I am strongly inclined to believe that in attempting to recomment the sand, we are perhaps only adding confusion for the contractor. If nine pounds of synthetic color are used per sack of cement, and the sand is of a grading which will produce good, strong concrete, the finished color will be satisfactory and the slight variation of local sands would produce but very little

difference in the result. Simplicity, to me, is highly desirable in connection with endorsements to be made, widespread, to the contracting fraternity and I am confident that elimination of all trifles or incidentals will aid in getting what we, after all, desire most and that is something bordering on intelligent use of color in concrete.

Surface treatments—My experience with muriatic acid as a cleansing agent has been most unsatisfactory and I should, at no time, care to recommend it other than as an extreme measure. I am most doubtful of it being used successfully by a contractor without etching the finish and such a finish is hardly an attractive one to examine. We do not feel too kindly toward the use of steel wool as it tends to dull the finish but we do strongly favor the finish being rubbed with the mixture of about one-half paraffin oil and one-half naphtha. I agree that we should include after-treatments but I feel that acids should be recommended with restrictions.

I am entirely confident that whatever form our recommendations take in their final stages, we should make every effort to eliminate all trivial matters pertaining to the use of color and seek maximum efficiency in simplicity. I am confident that the bulk of the color used in concrete will be used by the smaller contractor and for this reason, I feel it wise to direct our efforts toward him. For every large colored job, there will be countless small ones and the small jobs will greatly govern the continued patronage of the public in colored concrete.

It would seem that much of the success of colored concrete must revert to some extent to the manufacturer of the color. If he, selfishly, sells an inferior color for the sole purpose of making a sale, he is, indirectly, destroying his own market.

Publishing standard methods of testing or determining colors will make an interesting file for a very limited few but just where shall we find the contractor who will utilize such information? Would it not be better for the Institute to adopt standards and issue these standards to the various color makers with the request that they brand their product, viz.: "This color conforms fully with the standards of the American Concrete Institute for purity and composition?" The manufacturer who would wilfully

misbrand a product would leave himself open to redress on the part of the public.

Uniformity seems a desirable feature in connection with color. We adopted the first step toward simplicity, almost three years ago, by recommending the use of nine pounds of our color per sack of cement—regardless of which of the 12 standards we manufacture. We later pioneered another step by packing all colors in sacks, each containing nine pounds, with the sole recommendation to use one sack of color for each sack of cement used in the topping. Other manufacturers might wisely follow this policy to the ultimate benefit of the industry and more particularly to the benefit of the smaller contractor—who, for some time to come, appears to be our largest and most important factor to consider. He is the man who will make or break colored concrete and while he may be partly lacking in appreciation of architecture, he is our one important objective.

CONVENTION DISCUSSION

Austin Crabbs—Mr. Allan dwelt on the importance of getting just the right amount of color in each batch. It might be interesting, in that connection, to know that one color manufacturer is prepared this year, on request, to furnish color in individual packages having the right amount of color to use in one sack of cement.

Mr. Allan—That indicates an excellent tendency; several manufacturers are doing that now. But suppose the company sends a package to you and a like package to somebody in the northern part of Iowa, and both of you use it; you will get different colors. You take the one pound package of color and use it with your local cement and develop colors that are practically the same within very, very narrow limits, from time to time, but they will be different colors from those in other parts of the state.

Mr. Crabbs—Perhaps I did not make myself quite clear. One color may be seven pounds to the package, another 10 pounds—furnished this way only upon request. He will not furnish those individual packages unless you tell him what your proportions are, how much cement you are going to use and how much fine

aggregate and how much coarse aggregate, and I think that is helping the contractor considerably.

CHAIRMAN COLLINS—In other words, it would enable you or the other manufacturer that Mr. Allan spoke about in the northern part of the state, always to have the same color, although his might differ from yours.

JOHN W. LOWELL—We have given a good deal of study to color in concrete, and one of the most baffling problems is the machinery for mixing cement and color. I was going to ask Mr. Allan if, in their investigations, they have developed any information along that line?

MR. ALLAN—Nothing beyond what you already know, recommending that the color be mixed for a minimum of ten minutes in a regular color mixer, not a ball mill, and we suggest that a small amount of that material be troweled to see if there are any streaks under a steel trowel. That would determine how much more than ten minutes is required. I think a definite effort is made not to reduce the fineness of the material, that is not to grind it as we have sometimes done in the ball mill, but thoroughly mix it in small paddle mills.

NORMAN M. STINEMAN—I believe the members would be interested in a series of articles published in *Concrete* in August, 1928, May, June, November and December, 1930 and January of this year. While these articles cover the manufacture of colors, the author, E. T. Ellis, gives at the end of each article the formula for different shades. For instance, these six articles cover yellows, reds, blacks, greens, blues and browns, and at the end of each article he gives the formula in the form of so many pounds of cement and so many pounds of different colors for a light shade of that particular color, or for a medium or a dark shade.

A. L. ASHER—In Mr. Allan's report there are two very important points—first and most important of all is the classification of mineral pigments. There are few people who know anything about the classification of mineral pigments. I feel that the manufacturer of each pigment should state on his container exactly what the material is, whether it is a chemically pure oxide, a

commercial oxide, reduced color, or natural pigment. That is one thing that I think should be absolutely standardized. The next point is the matter of mixing, inasmuch as the only mineral pigments we can use are those which are insoluble in water. The problem is to get a uniform distribution of color throughout the mortar. I think that the logical thing is to have the color ground with the cement. Even with a ball mill, I feel that the additional fineness you get there will be of no disadvantage at all, and you do get an almost perfect distribution of color throughout the cement, which means uniformity in the cement paste. When the color is brought on the job it must be measured. You cannot measure a material uniformly that runs 90 to 98 per cent through a 325 mesh. If the contractor knew that four bags of a colored cement would lay a hundred square feet of floor one inch thick, it would eliminate a lot of his troubles in figuring his costs and doing the work on the job.

H. F. Hedderick—Mr. Allan recommended a blade type color mixer. Several months ago we were interested in trying to find a color mixer and the Portland Cement Association recommended the pebble mill type. We were able to find those without much trouble, but their cost is extremely high. We tried to find a machine of the blade type, made especially for mixing colors. The only one we could find took half a bag to a bag of cement at the time, not large enough for our work. I wonder if the machines Mr. Allan recommends are on the market in the size to take five or six bags?

Mr. Allan—For such quantities you would have to use a regular stucco mixer. We were figuring on one sack batches and I think the regular stucco mixers would be best for the large batches you mention.

Nolan Browne—I should like to call attention to the use, in color work, of mineral pigments with an integral accelerator and hardener. We find that the advantage is threefold; first, their use accelerates the mixture and necessitates that the mechanic get off the job a lot quicker, thereby getting more work done; secondly, a thinner coat will wear the same length of time as a thicker coat, due to the hardening effect; and third, it reduces efflorescence on account of the waterproofing quality of

the admixture. There is a small amount of efflorescence when the material is first cured because the water does bring a certain amount of salt to the surface during the setting-up process; but when once cleaned, it has been our experience that efflorescence does not reappear; whereas, without a waterproofer, dampness is present and efflorescence may recur time and time again. I think it would be a good thing for the committee to give some consideration to this. In our own experience we have reduced the slump on the colored product to one and a half inches. Now that does make a very hard mixture to handle unless the mechanics are quite familiar with it, but it surely does get the results.

A MEMBER—I'd like to ask a question about blue color. Several years ago we used an ultramarine blue and applied it as a face on roofing tile. We used about ten pounds of color to a bag of cement; cured it in a steam room for about a week and put it on the roof and in about three months the blue color had faded entirely into a gray white. We took that roof off and made a mix of about ten pounds of blue color to the bag of cement and made a creamy mixture and blew it on the tile with a gun, about $\frac{1}{16}$ to $\frac{1}{8}$ in. thick. We put that tile back on the roof, and the roofing tile is a rich blue color. I would like to know why the color failed in the first instance and why it stood up when blown on with the gun.

MR. LOWELL—Are you sure that the tile color had not faded by the time you took it out of the curing room?

A MEMBER—No, it did not fade until we got it on the roof.

MR. LOWELL—I know that blue will fade under sufficiently high temperature.

ROY L. PECK—I'd like to ask Mr. Allan if he has any recommendation to make as to the use of color in surfaces of outdoor swimming pools to eliminate the use of color throughout the wall?

MR. ALLAN—We have limited this report to troweled surfaces.

MR. ASHER—The gentleman asked a question as to fading of ultramarine blue. There are two definite ultramarine blues. One is ultramarine blue that is absolutely a reliable blue and made for the concrete industry. The other ultramarine blue is

made for the paint industry. My conclusion is he was using a commercial ultramarine blue and got an excessive action of alkali. Using it with the gun after the concrete had hardened, he did not get that excessive action of alkali.

Benjamin Wilk—It seems to me that much would depend on the fact that, mixing it integrally the particles were not coated as thoroughly as in the thick surface application. In our experience, with a lean mixture and about six pounds of color to the sack of cement, we found that the trouble was in the color washing off the surface of the aggregate. There was not enough thickness of the color.

Mr. Asher—Well, the color in both cases was applied to the facing; we used the same amount of color in each instance.

Readers are referred to the Journal *for October, 1931 (Vol. 28) for further discussion which may develop. Such discussion should reach the Secretary by Sept. 1, 1931.*

Proposed Recommended Practice for the Manufacture of Concrete Building Block and Tile

*Report of Committee 708**

P. M. WOODWORTH, AUTHOR-CHAIRMAN

FOREWORD

These recommendations are intended to aid manufacturers of concrete building block and tile to make products that meet standard specifications of the American Concrete Institute[1] and to produce them economically. In addition to recent developments in the manufacturing procedure and in the use of porous aggregates, considerable attention is given to plant layout. This recommended practice is intended particularly for plants with an average daily production of 500 or more units. Much of the material will be of value for smaller plants.

A. PLANT LAYOUT

1. General Considerations

The economical production of concrete masonry units starts with the design of the plant which should be based on the probable volume of sales that will be developed during the succeeding three to four years. The plant layout should be such that new producing units can be added as the volume of sales makes it imperative without rearranging or disrupting the initial layout. Most manufacturers of concrete products machinery have plant layouts which are well adapted to their equipment. However, a layout fitted to one particular set of machines may not be entirely

*This report, by Mr. Woodworth, Author-Chairman of the committee has been submitted for preliminary advice and suggestion to the members of the committee: E. W. Dienhart, C. J. Herzog, M. I. McCarty, Eugene F. Olsen, W. P. Stanton and Stanton Walker and presented at the 27th Annual Convention, Milwaukee, Feb. 24-26, 1931, for discussion. It is published with convention discussion (which was all too brief) for further consideration and is open for general discussion scheduled for publication in the JOURNAL for Oct. 1931 (Vol. 28)—available to the Secretary by Sept. 1, 1931.

[1]American Concrete Institute Standard Specification P-1-A-29 is an appendix to this report.

suitable for another, consequently the type of equipment should be selected before the plant layout is definitely settled. There are a number of general considerations regarding plant layout which are common to most types of equipment.

Discussion—In establishing a concrete building block or tile plant a carefully prepared market analysis is the first step. The total volume of sales that will be developed during the next three to four years will determine the size of the plant that should be built. Many manufacturers have definitely precluded any chance of economical manufacture by building plants that are too large and over capitalized. Unwarranted optimism regarding volume of business seems to be the rule in starting a concrete building units plant. An important percentage of the high-fixed-capital plants established during the past five years have not been profitable. This should not be interpreted as meaning that small, poorly equipped plants are profitable but that to be profitable the size of the plant should be in proportion to the business that will be developed with an aggressive sales organization.

2. Elevation, Grading and Drainage

Raw materials and finished products should be handled by gravity wherever possible. The elevation of the plant floor should be sufficient to provide drainage away from the plant in all directions and a slope of about one-eighth in. per foot away from the machine to the end of the runways.

Discussion—In general the block or tile machine is at the highest point on the plant floor to provide sufficient slope from the machine through the curing rooms and out to the far end of the yard whether industrial cars, lift truck or gravity conveyors are used. The yard should be graded slightly below the concrete runways or the level of the industrial tracks because the yard tends to fill up with loose pieces of concrete, sand, gravel, etc. causing pebbles to collect on the runways, making operation of cars or trucks difficult.

In laying out a products plant, grade stakes for the yard, curing room and main factory floor should be carefully set first. Frequently a few loads of material used to build up the elevation to the proper grade in the beginning will save a manufacturer a great deal of trouble and expense a year or so after the plant is in operation.

3. Conveying Equipment

The use of conveying equipment other than that ordinarily provided with the machine is advisable if the labor saved more than offsets the interest on and depreciation of the additional equipment. Whether or not lift trucks, industrial cars, elevators, belt or roller conveyors, batch cars or other conveying equipment should be installed depends on the amount of reduction in the cost of manufacture obtained with this equipment.

4. Arrangement of Equipment

The more compact the arrangement of the plant and still provide for freedom of movement of men and equipment, the lower the labor cost. Aggregate storage and cement supply should be placed as near mixers as possible.

Discussion—The tendency to limit the amount of space at the side and in front of machines so that lift trucks or cars cannot be manipulated easily to and from the machines should be avoided. While it is important to save all possible extra steps, these should not be saved at the expense of cramping the movement of material through the plant.

Provision for ample skylights and artificial illumination is important. Painting the inside of the plant a light color is desirable.

5. Cement Handling

Cement storage facilities should be provided to keep the cement dry whether it is handled in bulk or in sacks. Bulk cement, due to the tendency to "fluff," should be measured by weight.

6. Aggregate Proportioning Equipment

Accurate equipment for proportioning aggregate either by weight or by volume is essential. Such devices should work quickly and easily. Overhead bins with the other necessary equipment for handling will usually prove economical for plants regularly producing 500 or more units daily.

Discussion—Several efficient weight batching devices are on the market and are to be recommended over volume measurements. No corrections have to be made for bulking of materials due to moisture. The only correction necessary is for the variations in moisture content in different shipments of aggregate.

7. Curing Room Construction

After units are molded, the quicker they are placed in favorable curing conditions the better the quality of the concrete. Curing rooms must be relatively tight to prevent air currents and loss of heat. They should have insulated roofs. The rooms are usually made wide enough to accommodate 2 racks, allowing 6 inches between radiation and the rack on each side and 10 to 12 inches in the middle. Tight enclosures should be used at both ends of the tunnel. The enclosures may be either moving doors made of well painted wood or light weight metal. Tight fitting canvas curtains are sometimes used on the plant end of

the rooms. Usually the doors are hinged at the top or slide in vertical guides which are made tight to prevent loss of heat and moisture. Curing rooms should be painted white on the inside to aid visibility.

Discussion—The tendency has been to build curing rooms too high. A temperature of 125 to 135 deg. F. is common against the roof, while at the floor it is not more than 70 to 75 deg. F. The heat should be kept down as low as possible and building the room no higher than is absolutely necessary to clear the top row of block is desirable. This will require workmen to stoop slightly while moving products into and out of the rooms but is no hardship.

If the layout of the plant makes it necessary to build the tunnels longer than can be filled in a half day's run, dividing curtains, usually of canvas, should be provided in the tunnel so that a run of 3 to 4 hours can be enclosed and curing started. This arrangement requires dividing the curing equipment so that each section can be regulated independently. In determining the length of curing tunnels, a minimum of 6 in. should be allowed between the ends of racks. The space between the radiation and the racks and between the racks in the center is to facilitate the movement of racks and the circulation of heat and moisture in the rooms.

8. *Types of Curing Systems*

There are six common methods used to provide satisfactory curing conditions for the freshly molded units. Refer to Figs. 1, 1A and 2.

Type "A" provides radiation and steam moisture control independent of each other. A header is placed within 6 in. of the

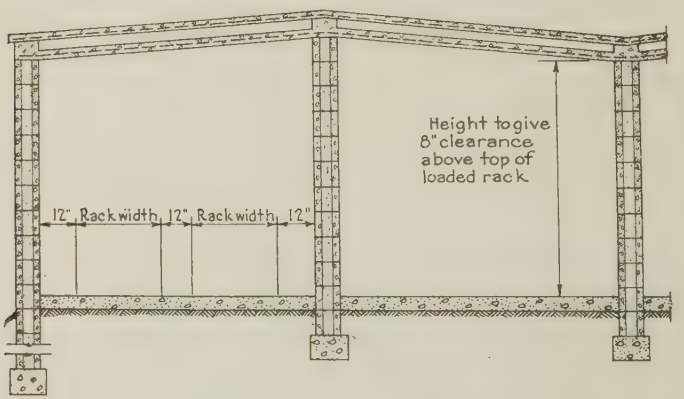

FIG. 1—TYPICAL LOW PRESSURE STEAM CURING ROOM

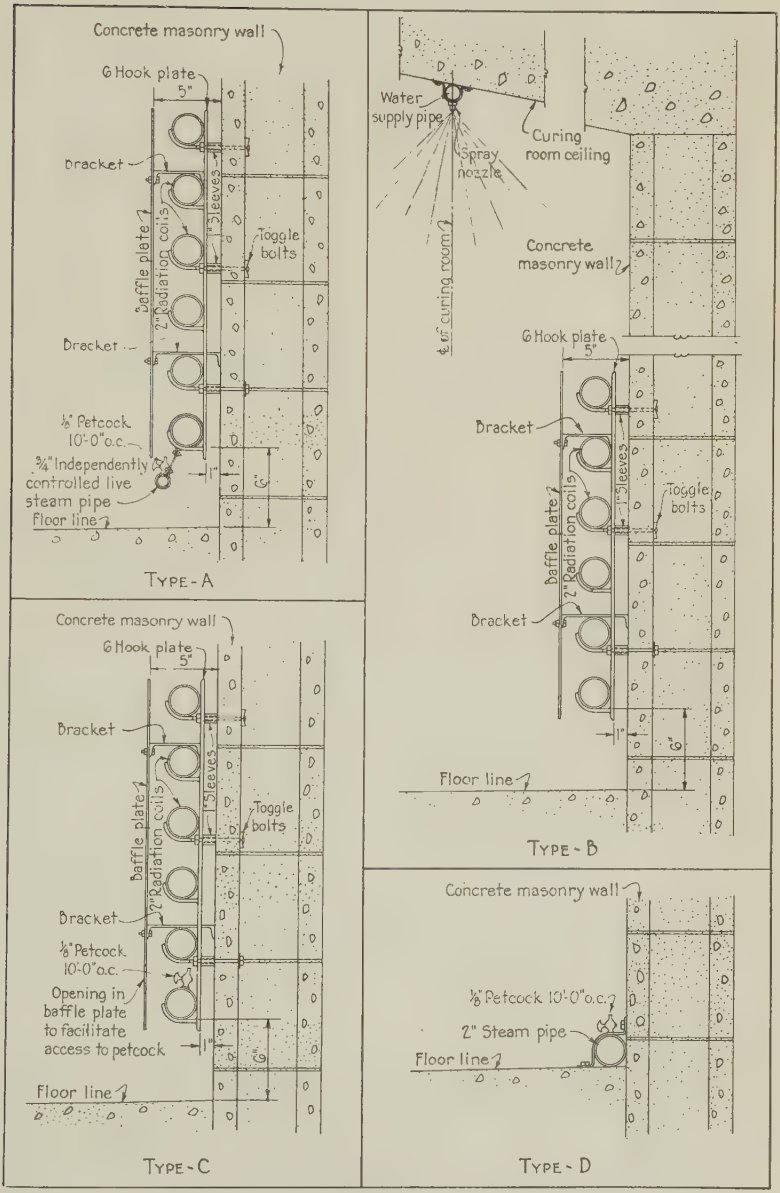

FIG. 1A—PRINCIPAL TYPES OF LOW PRESSURE STEAM CURING INSTALLATIONS

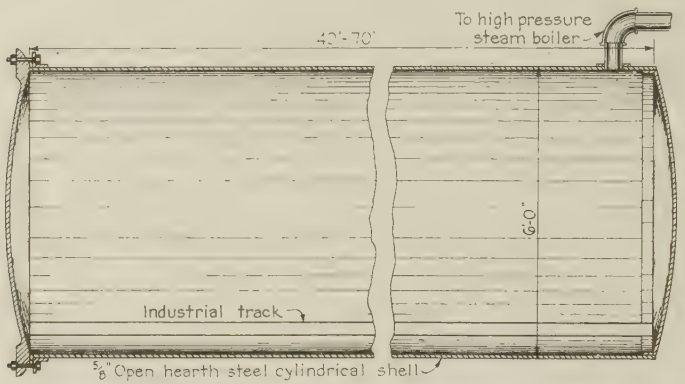

FIG. 2—HIGH PRESSURE STEAM CURING CYLINDER

floor at both ends and on both sides of the curing tunnel. Two-in. pipe connects these headers. Usually six pipes are required on each side in the northern sections of the United States if masonry walls and insulated roofs are used and if the rooms are of 2-rack width. The headers should be provided with three or four extra plugs so that additional radiation can be tapped in if the temperatures obtained are not high enough. The moisture is provided by steam through a ¾-in. pipe running just below the bottom pipe of the radiation system. This pipe is fitted with ⅛-in. petcocks on 10 foot centers staggered with those on the opposite wall. The petcocks should be directed upwards and at a slight angle toward the wall so that the steam is forced up through the radiation coils. Radiation and moisture are controlled by separate valves outside of the room. Cement-asbestos or galvanized iron baffle sheets are suspended 2 in. in front of the radiation coils. The bottom of the baffle sheet is placed even with the bottom pipe of the radiation. This acts as a jacket and causes a circulation of heat and moisture in the tunnel and prevents block directly opposite the pipes from becoming dry.

Type "B" provides independent steam coil radiation with moisture supplied through fog nozzles attached to the ceiling of the room. These fog nozzles are operated at water pressures of 30 pounds or more per square inch. If connected with the

regular water system, a heating coil should be provided so that the fog is of a temperature of at least 100 deg. F. when it enters the room. Baffle plates should be used in front of the radiation coil the same as is described for Type "A."

Type "C" provides radiation and steam moisture combined. The construction is the same as in Type "A," except that the bottom return pipe on the radiation coil is fitted with ⅛-in. petcocks on 10-ft. centers staggered with those on the opposite wall.

Type "D" provides for heat and moisture by exhausting live steam into the room through a single pipe placed within 6 in. of the floor on both sides of the room. This pipe is either drilled with ⅛-in. holes or fitted with ⅛-in. petcocks.

Type "E" provides for the curing of products in cylinders where the pressures vary from 100 to 125 lb. per sq. in. Special equipment is required similar to that used in the manufacture of sand-lime brick. While this method is not common at present, it seems to have good possibilities.

Type "F" is the least that can be expected in the way of curing equipment. It provides for rooms or sheds that are reasonably tight to prevent excessive air currents. They are equipped with fog nozzles to provide moisture. Usually this system is used where temperatures do not fall below freezing.

Discussion—Of the first four methods described, Type "A" seems to be best, because it enables the manufacturer to control independently the heat and moisture. In freezing weather or where it is necessary to get units on the job in a relatively dry condition, the mositure can be shut off after a period of moist curing and the products dried considerably by radiation. Type "A" also has the advantage of giving more thorough circulation of heat and moisture, thus tending to even the temperature and moisture conditions in the top and bottom of the curing room.

Type "B" is nearly as satisfactory as Type "A" but is slightly deficient in obtaining circulation in the curing room.

Type "C" provides ample radiation and moisture content. The drawback to this method is that the heat and moisture are controlled together. With this system it is nearly impossible to provide just heat, which is necessary sometimes for drying units after the moist curing.

Type "D," while commonly used, is not nearly so satisfactory because in order to get sufficient heat in the tunnel it is necessary to exhaust too large an amount of steam into it. Such an excess nearly always results in moisture

getting into the manufacturing part of the plant, causing unhealthy working conditions and deterioration of equipment, buildings and cement.

Type "E" should be thoroughly investigated by products manufacturers designing new plants because present indications are that the units can be cured in from 8 to 12 hours and have a strength at least equivalent to the 28-day strength under normal curing conditions. In addition, the units seem to be quite thoroughly dry and ready for immediate delivery when they come from the pressure cylinders. This makes for prompt delivery and reduces stock piles.

9. Summary of Plant Layout

Discussion—Fig. 3 shows a conventional layout embodying many of the above suggestions. In this plan the overhead bin (1) may be filled by any type of elevating equipment. The advice of the machinery manufacturer will be valuable in deciding on the type of elevating equipment to be used. The size of the bin is determined by the capacity of the plant and the regularity with which the material can be obtained. Generally not less than a three days' supply should be provided for. Opening (2) should be fitted with a measuring device, preferably weighing equipment for proportioning materials. A chute, weighing lorry or dump car (4) may be used for carrying aggregate to mixer.

The stock of cement should be piled on platform (3) close to mixer. Water tank (5) should be placed above mixer and out of the way of charging equipment. It should be provided with an automatic valve and water gauge for filling and with a perforated pipe for discharging. Space (6) under platform may be used for storing pallets, extra equipment, also a portion may be used for boiler room.

Mixer (7) on the raised platform discharges directly into agitating feeder from which concrete is elevated from machine hopper by conveyor (8). It is generally more satisfactory to have one mixer for each machine. (9)

A modification of the layout at this point is in common use. The overhead storage is elevated sufficiently so that the measuring equipment and mixer can be placed on a platform high enough to discharge directly into the hopper of the machine. Which of these two methods is better depends on the cost under local conditions. The cost of providing the extra height of storage space and elevating equipment should be measured against the cost of the agitating feeder and machine elevator. There is also a loss of floor space and more equipment to be cleaned in the first arrangement.

Concrete floor and yard runways slope from front of machine to far end of storage yard, usually ⅛ of an inch to the foot. Lift trucks (10), industrial cars or conveyors carry units to the curing room. Inside doorway (11) should be closed with vertically hinged or sliding doors or canvas curtains. Moisture in curing room is supplied as described under Section 8, "Types of Curing Systems" through coil (12) or by spray nozzles (13). Allow at least 6 in. between ends of racks (14). Outside doorway (15) should be closed with vertical hinged or sliding doors. Concrete runways (16) should be at least 1 in. above yard level and 18 in. wider than the racks or cars. Sufficient turn-

ing radius for the cars at runway intersections should be provided. For ordinary equipment sufficient turning radius is provided by placing at each corner of intersection a triangular section of paving extending 6 ft., back from the corner in both directions. This may seem like a small point in making the original layout but it is very important and unless it is provided for will lead to endless difficulty and waste of time later.

B. MATERIALS

10. Cement

Cement should meet the requirements of the current standard specifications for portland cement of the American Society for Testing Materials. It should be stored where it is completely protected against moisture.

11. Aggregates—General Requirements

Aggregates should consist of sand, pebbles, crushed stone, slag, burned shale, cinders or other approved inert materials or combinations thereof. Dense aggregates, such as sand, pebbles, crushed stone, crushed slag should be sound and durable and free from excessive amounts of dust, soft or flaky particles or shale or other deleterious materials.

Porous aggregates, either natural or manufactured should be free from injurious amounts of acid or alkali or compounds forming acids or alkalis, industrial wastes and, in the case of cinders, combustible matter in excess of 35 per cent of the weight of the aggregate. They should be of such strength as to produce units meeting the A. C. I. specifications. All aggregates should be free from frost or lumps of frozen material. Where stationary aggregate bins are provided, a coil of steam pipe should be arranged around the outlet of the bin so that the aggregates can be heated to remove frost and frozen lumps. Such heating will aid in the early hardening of concrete in cold weather. The use of crusher-run or bank-run material where the proportion of fine to coarse varies is usually unsatisfactory. The aggregates should be screened into fine and coarse particles and stored in separate bins.

12. Fine Aggregate

Fine aggregate should be considered as material passing a screen with four meshes per linear inch. It should have at least 15 per cent retained on a No. 8 screen.

13. Coarse Aggregate

Coarse aggregate should be considered as material retained on a screen having four meshes per linear inch. Maximum size of coarse aggregate should not exceed one-third the thickness of the thinnest web of the units to be manufactured.

Discussion—Storage bins should be designed to minimize segregation of aggregates. This segregation is limited to some extent by separating the materials into fine and coarse.

14. Water

Mixing water should be free from injurious amounts of oils, acids, organic material or other harmful matter. Water fit to drink is usually satisfactory.

15. Proportions

In the selection and combination of fine and coarse aggregate and in the proportioning of total aggregate to cement, the manufacturer has control to a large extent over the properties of the resulting concrete.

Discussion—The combination of fine and coarse aggregates which will develop the maximum strength may lead to units that have too rough a texture and edges that are too uneven to make the product saleable. The grading that might result in the maximum fire resistance might not be best for maximum strength or minimum absorption. For this reason, the combination of aggregates and the proportion of aggregate to cement are usually a compromise which will produce to the highest degree all of the desirable characteristics in the finished product.

16. Strength

The aggregate and the cement should be proportioned in such a way that the finished units will meet the American Concrete Institute Specifications or local building code requirements when made under local plant conditions. The only reliable way that the Committee knows for establishing definitely the proper proportions of fine to coarse aggregate and total aggregate to cement to obtain the required strength is through strength tests made in a properly equipped testing laboratory. These tests should be run frequently before the plant gets into regular commercial production and after that only often enough for checking.

In general, the coarser the grading of the aggregate, the greater the strength of the unit for any given cement content, provided there are sufficient fines in the aggregate to make the mix work-

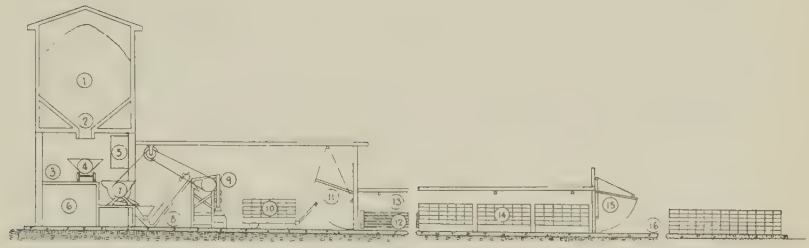

FIG. 3—TYPICAL DIAGRAMMATIC LAYOUT OF PRODUCTS PLANT

able with the given type of molding equipment. However, the grading must not be too coarse or there will be breakage in handling the units from the machine and the surfaces and edges may be too rough and irregular for a saleable product.

With the fine aggregate all passing a No. 4 sieve and the coarse aggregate graded from ¼ to ⅜ in., the maximum proportion of coarse material that can be used to advantage is about 50 per cent of the total aggregate used in the mix. Generally not more than 40 per cent of coarse material gives the desired combination and in very few instances will only 25 per cent of coarse aggregate produce a unit which has the greatest strength for a given amount of cement. The proportions of cement to be used for any given combination of fine and coarse aggregates can only be determined by trial. Trial mixes containing 25, 35, 45 and 55 per cent of coarse aggregate graded from No. 4 to ⅜ in., mixed with the fine aggregate should be made with different proportions of cement to total aggregate 1:6, 1:7, 1:8, 1:9, 1:10 and 1:11 by damp loose volume of mixed aggregate.

The first indication of the suitability of aggregate combination and cement-aggregate proportions is determined at the block machine. If the appearance of the surface and edges is satisfactory, and if the block can be handled easily and quickly without broken webs or corners, the mix is suitable with regard to appearance and handling.

After setting aside the first two and last two block from each of these trial mixes, three block from each mix should be selected

and cured according to ordinary plant practice and kept for testing at 28 days by recognized testing laboratory. From this original group of tests the manufacturer can tell within a relatively narrow margin the proportions of aggregate to cement that are necessary to produce the strength required by the A. C. I. specifications or the local code.

Uniformity of grading of aggregates is important. If the aggregate is obtained from well established commercial plants usually little difficulty is encountered. However, if the grading is irregular, it may be necessary for the manufacturer to find a different source of supply or install a set of screens to divide the material into fine and coarse and to eliminate the over-size particles.

A screen analysis of the aggregates finally selected for producing the desired units should be made and checked occasionally to determine that the grading has not varied appreciably. If it does vary adjustments in the fine and coarse aggregate proportions or in the total aggregate proportions to cement will have to be made.

It is well for a manufacturer to aim at from 75 to 100 lb. per sq. in. of gross area more strength than minimum requirements.

Discussion—In washed fine aggregate it frequently happens that too much of the very fine sand is washed away. This is particularly true of the sizes passing a 28-mesh sieve. A close distinction should be made between silt and a fine sand.

In order to obtain proper workability with dense aggregates the fine aggregate should have not less than 3 per cent nor more than 10 per cent of the material passing a 100-mesh sieve, provided the fine aggregate is well graded between the 100-mesh and ¼-in. screens. If the units in the trial batches break easily when being handled from the machine to the rack and from the rack into the curing room, the probability is that the fine aggregate is deficient in fines. A screen analysis should be run. If deficient in fines, the addition of small amounts of fine sand, stone screenings or other finely divided aggregate will aid in making the concrete workable and easily handled.

By following the suggestion above to make trial batches and have tests made the plant can get into operation on a satisfactory basis in a short time. If it is necessary to get in production in less than 28 days, block can be made and cured in the regular way and tested at 7 days. The 7 day strength can be assumed to be about 70 per cent of the 28-day strength. This is only an approximation and should be checked at 28 days.

Fine material generally cuts down the strength of the concrete and results in higher costs. Very fine material should be limited to the bare requirements

to make a block that can be handled away from the machine without cracking or breakage.

Manufacturers who use the Inspection and Certificate Service of the Underwriters' Laboratories[2] have a positive guarantee that their product will meet the A. C. I. specifications. This Service usually eliminates the necessity of further commercial tests.

17. Absorption

In combining the aggregates and in proportioning the total aggregates to cement to obtain units which meet the absorption requirements of the specification, but little difficulty is encountered if the aggregate does not contain too much or too little fines. Generally the mix that gives the maximum strength will tend to give the minimum absorption. If the absorption is too high a study of the aggregates giving particular attention to the fines will generally show what is necessary to make the correction.

18. Surface Texture

The requirements for surface texture will be controlled largely by local market conditions. Rough textures are usually desired for partition units and those that are to receive stucco or plaster. A close texture is desired for exposed ashlar and other exposed units.

Discussion—With regard to surface texture there is a wide variation in what is considered saleable in different markets. For example, in one market a very coarse textured block is acceptable to the architects and contractors even for exposed work, whereas in another market less than 100 miles away a coarse texture will not be permitted in the backing of a faced block. Keeping this in mind, the manufacturer should educate the builders from the beginning to use relatively coarse textured units.

19. Density

With the use of dense aggregates the proportions which will produce the densest products are generally those which contain the maximum amount of coarse aggregate and still contain enough fine aggregate to produce a smooth surface. With porous aggregates used in the production of light weight units, the amount of material in the mix passing a 50-mesh sieve is generally limited and in addition more of the coarse aggregate is used to produce a unit of less density and lower weight. This is generally

[2]Underwriters' Laboratories, 207 East Ohio Street, Chicago, Illinois.

desirable for light weight units except where fire resistance or water tightness are important.

20. Consistency

Concrete units made from dense aggregates on tamp or pressure machines should be mixed as wet as practicable and still prevent appreciable sagging or distortion of units. Generally a slight water web should show on the surface of the unit next to the mold box. With the pressure method a slight excess of moisture should be forced from the unit when the full pressure is applied. When vibration is used to consolidate the material the mix should be as dry as practicable to completely fill the molds and produce a pronounced water web on the surface without slumping or sagging. Where the wet cast method is used the water content should be reduced to a minimum and vibration and spading used to facilitate getting the concrete into the molds without forming aggregate pockets.

With porous aggregates, mixes somewhat drier than those used for dense aggregates are generally recommended for tamp or pressure method as this will produce a fairly coarse texture which is desired for the direct application of plaster or stucco. If porous aggregates are used in the vibration of cast methods, the surface appearance will be nearly the same as when dense aggregates are used.

21. Mixing

In dense aggregate concrete the cement and aggregate should be mixed for one minute or until the mass is uniform in color before the addition of the mixing water. All materials should be mixed from three to six minutes after the addition of the water. The longer mixing time increases the strength, density and workability. The mixer should be of such capacity that the concrete can be mixed for the time recommended without retarding production. Excessively long mixing periods, for example, from 10 to 15 minutes, while somewhat beneficial, are not generally recommended or considered economical. With porous aggregates, due to their relatively high absorption, one-half to two-thirds of the total mixing water required should be mixed with the aggregates for 2 to 3 minutes prior to the addition of the cement. Then the cement and the remaining mixing water should be added and the mixing continued for 2 to 3 minutes.

Discussion—For several years it has been considered that a batch mixer of sufficient size to keep the block making machine running at capacity with one batch every 10 minutes was necessary. The Committee recognizes that thoroughness of the mix and not time of mix is the important consideration. If, through the use of continuous mixers or other mixing methods, concrete of equal or superior strength can be obtained in less time than it has indicated, such methods should be thoroughly satisfactory.

22. Curing

Concrete hardens in the presence of moisture and heat. If moisture is not present the chemical reactions in the cement stop. If the temperature falls below 40 deg. F. these reactions practically stop. Consequently, in the absence of moisture or heat above 40 deg. F. there is little if any hardening of the concrete.

From a manufacturing standpoint it is important that units be made available for market as soon as possible. This requires that special attention be given to providing moisture and heat. The curing room should be provided with equipment that will keep the moisture in the room slightly above the saturation point at any temperatures used. Methods for obtaining this moisture were discussed in section 8.

The higher the temperature of the curing room above 40 deg. F. the more rapidly the concrete hardens, provided there is always a slight excess of moisture in the room. Means of providing artificial heat for curing were discussed in section 8. The units should be put into a curing room and protected against draft immediately after they are molded. If they are to be steam cured, the heat and moisture should be turned on as soon as possible. Proper curing conditions during the first 48 hours after the block are molded are particularly important in producing strength and density.

Discussion—In curing rooms except where high pressure steam is used it is difficult to get the temperatures much above 140 deg. F. because of heat losses. Temperatures in high pressure steam curing vary from 325 to 400 deg. F.

It has been common practice to provide a substantial excess of moisture in curing rooms. This can be eliminated because only a slight excess of moisture is required. The right amount can be determined easily by the appearance of a light fog in the curing runnel when the temperature is at its high point. Adjusting the petcocks to permit the right amount of moisture should be done when the plant is first started and little if any further adjustment will be required.

23. Length of Time of Damp Curing

With artificial heat and moisture provided as discussed in Types A., B, C and D in section 8, 24 hours of curing is considered the minimum. With high pressure steam curing, such information as is available indicates that 12 hours of curing is ample. Where only sprinkling is used the units should be protected from temperatures lower than 50 deg. F. and kept wet for not less than 3 days.

If the units are cured as described, they may be stacked in the yard and kept damp until they develop the strength and absorption requirements of the specification.

24. Dry Curing

Then the sprinkling should stop and the units should be allowed to dry. It is desirable that a covered yard or some other method be provided to keep rain and other precipitation away from the block.

Discussion—It must be recognized that the drying after wet curing is just as much a part of satisfactory manufacturing as mixing, tamping or wet curing. Several recent specifications require that when units are delivered on the job they shall not contain more than 30 to 40 per cent of the amount of moisture they hold when totally saturated. Stacking units close together in large piles prevents them from proper drying and even in the middle of the summer, units a few courses in from the outside of the pile remain damp for several months. For this reason the piles should be made narrower and it has been suggested that the block be stacked in the pile with cells horizontal and opposite so that there will be direct air currents through the pile. Some manufacturers have suggested that raising the lower course of block a few inches off the ground on small sills and then stacking the block with cells vertical and opposite will cause a chimney action to occur which will aid in drying the block. Which of these two methods is better has not been determined but either of them will aid in drying the units.

25. Faced Units

Concrete masonry units with special facing material made from selected aggregates, colored cement or other materials should be made in the following manner: The facing material should be screened to pass a $\frac{1}{8}$ in. screen and all retained on a 100-mesh screen. A mixture of 1 part of cement to $2\frac{1}{2}$ or 3 parts of aggregate will give best results. Mixes richer than these are likely to produce crazing. Mixes leaner are likely to be too absorbent. If special aggregates are used in the facing material,

as soon as the block are molded the surface is treated with a fine water fog spray to remove the surface film of cement and the units are put in the curing room and handled the same as other units.

Appendix

Report of Committee 708, February 1931

Standard Specifications for Concrete Building Block and Concrete Building Tile—(P-1-A-29)

GENERAL

1. The purpose of these specifications is to define the requirements for concrete building block and concrete building tile to be used in construction.

2. The word "concrete" shall be understood to mean portland cement concrete.

3. The average compressive strength of 3 or more concrete block or concrete building tile in lb. per sq. in. of gross cross-sectional area as laid in the wall shall not be less than 700 lb., no one unit falling below 600 lb. 28 days after being manufactured or when shipped.

Wherever concrete block or building tile are used to carry unusual heavy loads, the average compressive strength of 3 or more of these units 28 days after being manufactured or when shipped in lb. per sq. in. of gross cross-sectional area as laid in the wall shall be at least 10 times the figured superimposed load to be applied.

Non-load-bearing concrete block and concrete tile shall have sufficient strength necessary to prevent excessive breakage during delivery and handling.

4. The gross cross-sectional area of a one-piece concrete block or tile shall be considered as the product of the length times the width of the unit as laid in the wall. No allowance shall be made for air spaces in hollow units. The gross cross-sectional area of each unit of a two-piece block or tile shall be considered the product of the length of the unit times one-half the thickness of the wall for which the two-piece block or tile is intended.

5. The compressive strength of the concrete in units of all classifications except "non-load bearing block" shall be at least 1,000 lb. per sq. in., when calculated on the minimum cross-sectional area in bearing.

Absorption Requirements

6. Concrete building block and tile to be exposed to soil or weather in the finished work (without stucco, plaster or other suitable protective covering) shall meet the requirements of the absorption test.

7. All concrete building block and tile not covered by Paragraph 6 need not meet an absorption requirement.

8. Concrete block and tile shall not absorb more than 10 per cent of the dry weight of the unit when tested as hereinafter specified, except when it is made of concrete weighing less than 140 lb. per cu. ft. For block or tile made with concrete weighing less than 140 lb. per cu. ft. the absorption in per cent by weight shall not be more than 10 multiplied by 140 and divided by the unit weight in pounds per cubic foot of the concrete under consideration.

Sampling

9. Specimens for tests shall be representative of the commercial product of the plant.

10. Not less than three and preferably five specimens shall be required for each test.

11. The specimens used in the absorption test may be used for the strength test.

METHODS OF TESTING

Absorption Test

12. The specimens shall be immersed in clean water at approximately 70 deg. F. for a period of 24 hours. They shall then be removed, the surface water wiped off, and the specimens weighed. Specimens shall be dried to a constant weight at a temperature of from 212 deg. to 250 deg. F. and re-weighed. Absorption is the difference in weight divided by the weight of the dry specimens and multiplied by 100.

Weight of Concrete

13. The weight per cubic foot of the concrete in a block or tile is the weight of the unit in pounds, divided by its volume in cubic feet. To obtain the volume of the unit fill a vessel with enough water to immerse the specimen. The greatest accuracy will be obtained with the smallest vessel in which the specimen can be immersed with its length vertical. Mark the level of the water, then immerse the saturated specimen and weigh the vessel. Draw the water down to its original level and weigh the vessel again. The difference between the two weights divided by 62.5 equals the volume of the specimen in cubic feet.

Strength Test.

14. Specimens for the strength test shall be dried to constant weight at a temperature of from 212 deg. to 250 deg. F.

15. The specimens to be tested shall be carefully measured for overall dimensions of length, width and height.

16. Bearing surfaces shall be made plane by capping with plaster of paris or a mixture of ½ portland cement and ½ plaster of paris, which shall be allowed thoroughly to harden (from 3 to 6 hours) before the test. No point on the surface shall deviate from the plane more than 0.003 in. The cap shall not be thicker than ⅛-in. It shall be formed by means of an accurately machined metal plate or a heavy plate glass having a true surface.

17. Specimens shall be accurately centered in the testing machine.

18. The load shall be applied through a spherical bearing block placed on top of the specimen. The rate of loading after 50 per cent of the ultimate load has been applied shall not be greater than that which will produce a shortening of the specimen of 0.02 in. per minute.

19. When testing other than rectangular block or tile care must be taken to see that the load is applied through the center of gravity of the specimen.

20. Machined-steel or cast-iron plates of sufficient thickness to prevent appreciable bending shall be placed between the spherical bearing block and

the specimen. In no case shall the distance between the edge of the spherical bearing block and the end of the bearing plate be greater than twice the thickness of the plate. Where a number of thin plates are used, in no case shall the plates be less than one inch thick nor shall any plate extend beyond the one immediately above it a greater distance than twice the thickness of the plate.

21. The specimen shall be loaded to failure.

22. The compressive strength in pounds per square inch of gross cross-sectional area is the total applied load in pounds divided by the gross cross-sectional area in square inches.

CONVENTION DISCUSSION

W. D. M. Allan—I should like to call attention to the importance of the last point Mr. Woodworth made regarding the drying of the units after they have been cured. A unit 28 days old or 90 days old may not be any drier than one three or four days old. Several products manufacturers and others have had an opportunity in the last few weeks to criticize the master specifications of the federal government covering concrete masonry units. That specification requires that a unit shall not have more than 40 per cent of the total saturated weight of moisture when delivered on the job. That means, for instance, that a cinder concrete block with an absorption of 16 per cent when saturated, would be cut down to two-fifths of that—about 6.4 per cent, when delivered on the job. Even in the middle of the year, taking block out of the center of a large stock pile that has been rained on a month before, block will rarely meet that requirement, so we have got to add to our manufacturing processes another step that is as important as anything we have been considering in the past, and that is drying the units after they have been wet-cured. It is as certain as can be that after all the discussion on volume change and this specification covering moisture content when units are delivered, it will be a matter of only six months or a year when many specifications will have a limit of that kind. The tendency is in that direction, and every manufacturer is going to have to recognize it if he is going to get important work.

Benjamin Wilk—There are just a very few points, I think, to be considered. In view of the fact that this curing condition is so essential, it will be desirable to consider the use of paved yards entirely. We found over a considerable area of our place that a three inch paving was satisfactory. We have had such

pavement in use now for five years and it is saving us a whole lot of money. The maintenance of a gravel or cinderized yard is considerable, especially with trucks running across it, and we put in three inches of concrete which has stood up very nicely. It saves in the cost of piling. Instead of having driveways alone and instead of carrying block say, six feet, you can take your truck and bring your blocks up to the exact point where you want to pile it, and the man can take the block off the truck and pile it on to the regular pile. It will also in many cases, make a better pile, for it will often be difficult to pile block nine or ten high on cinders, gravel etc., if you want to separate them in piling. Under ordinary conditions one tier of blocks will support the next tier, but if you separate them it will be necessary to have a very even footing, and a paved yard would eliminate the trouble from block falling over.

It seems to me that consideration should be given to the fact that in using lift trucks wider curing rooms are necessary, especially in view of the fact that the pipes are on the inside. I notice it was twelve inches from the edge of the rack. A block may overhang about four inches and you only have left about eight inches. Four inches of that space may be used up with your piping and you have but four inches left for clearance. It is very difficult for the man operating the lift trucks to set the racks in such a way that he can have easy access. As far as piling block is concerned, you must take into consideration the difference between using block or tile for back up, and block or tile used for exteriors. A block piled horizontally will generally be scraped as the men place the block horizontally and as they are taking it from the pile, they naturally pull them. You may tell them a thousand times to lift them, but they won't do it, and as they pull them, little particles of sand will start scratches on the block.

Readers are referred to the JOURNAL *for October, 1931 (Vol. 28) for further discussion which may develop. Such discussion should reach the Secretary by Sept. 1, 1931.*

Discussion of Paper by C. A. Hughes and A. S. Levens:

"Strength and Shrinkage of Mortars Made with Blends of Portland Cement and Pozzuolanic Materials"*

BY LEWIS H. TUTHILL†

Several years association with the problems of mass concrete have strengthened the conclusion that plain portland cement concrete has serious deficiencies when used in this manner. More than two years ago this led to a beginning of studies of the effects of pozzuolanic co-mixtures with portland cements. About the same time contemporary work was started in three other field and industrial laboratories in California.

In many ways the paper was an excellent check on our work with Fresno pumicite, (mentioned as F in the paper under discussion) but the conclusions enumerated, although correct in the light of several independent series of similar tests, do not bring out the importance of the possibilities of the use of this and similar pozzuolanic material with portland cement—particularly in mass concrete. It is also felt that certain of the tests were over too short a period to demonstrate the ultimate action of a slow working material of this kind. This applies particularly to the strength tests, and to the shrinkage tests which were terminated just at the point where there was a decided indication that time and age materially reduced the tendency toward volume change in these concretes. In a concrete dam, for instance, it is not only what may happen in the concrete the first few months that is important, but also, its probable behavior through the first few hundred years.

*A. C. I. Journal, December 1930; *Proceedings*, Vol. 27. p. 317.

†Concrete Technologist, Los Angeles, Calif. (Exchequer, Melones, Pardee and Calaveras dams).

The use of the visual test tube method was an excellent independent check upon our method of proving the material under consideration to be a true pozzuolana. Our method was to make a water paste of two parts of pumicite to one part of hydrated lime and cast 2 x 4 in. cylinders. These specimens attained a strength of 400 lb. per sq. in. in a month while pastes of the individual ingredients mixed separately remained soft. Both of these methods and results satisfy the requirements of the accepted definition: "A substance is said to be pozzuolanic when, while not necessarily cementatious by itself, it possesses constituents which will combine with hydrated lime at ordinary temperatures in the presence of moisture to form stable insoluble compounds of cementatious value."

Compression tests of concrete made by the writer are submitted to show the effect at one year. The early lag and later catching up in strength is the same for the concretes as for the mortars discussed in the paper. Richer and drier concretes, and concretes of lower fineness modulus, show the same trend of strength increase but with an increasing period (from six months to two years) before the equivalent of the concrete in which no pumicite is substituted for cement is reached. This lag in strength is not a matter for concern where high early strength is no object as long as its ultimate attainment is assured—and it is assured, for pozzuolanic concretes show far more consistent and uniform time increase strength ratios than do the plain cement concretes. As long as the practical minimum strength necessary safely to sustain early loads is attained, the delay in reaching equivalent or usually superior ultimate strength is unimportant compared with the advantages of pozzuolanic concretes in reduction of heat liberated on setting, in fixing in an insoluble form the usually soluble lime compounds, and, particularly, in consequent durability and permanence of the structure.

Aside from establishing the fact that concretes, in which the pumicite is substituted for a portion of the cement, will attain the same or greater strength than the plain concretes with greater uniformity and without retrogression, it is submitted that in the above tests is an indication of the pozzuolanic char-

EFFECT ON COMPRESSIVE STRENGTH AT VARIOUS INTERVALS OF SUBSTITUTING FRESNO PUMICITE FOR CEMENT BY VOLUME

*In addition to water here indicated, water was added for absorption of the aggregates and an amount equivalent to 60 per cent of the weight of the pumicite.

†Each strength value is the average of two 8 x 16 in. specimens, each from a different batch assembly. One specimen for each period was made from each batch. Aggregate 3 in. maximum.

NOTE: It was plainly noticeable, particularly in this wet consistency, that as the amount of pumicite substituted increased, the mixture became harsher as to workability. This is believed due to the lower absolute volume and mass in an equivalent volume compared with cement which reduces the lubrication. In order that workability be maintained, particularly where the remaining cement is less than 1 bbl. per cu. yd., substitution by weight is recommended.

acter: combination of lime and silica to form the strength giving (as well as insoluble) calcium silicates. For instance, in the first series the ratio of increase, 28 days to 6 months, for plain concrete is 1.22; for 30 per cent substituted pumicite it is 1.78—an increase of .56. Where does this extra margin of strength come from? Certainly not from the aggregate. The cement has gone its limit at 1.22. Free lime and soluble silica are present. Cement chemists generally agree that calcium silicates are the strength giving elements of cement. It would seem evident that some such combination of these two ingredients had been formed.

As a matter of fact all contemporary work on this subject has uniformly and consistently proven the characteristic pozzuolanic reaction with free lime of this pumicite and other available American materials. The existence of a percentage of free lime in all cements—varying in amount from brand to brand—and

Tests									

*The percentage of pumicite is the percentage of the cement plus pumicite.

NOTE: In all the series AD two year specimens were made. Tests will be made on these at the proper time in the fall of 1931.

the disastrous effect of its solubility in the dissolution and decay of hydraulic and sea water structures in apparently recognized in this country as evidenced by numerous articles and references on this phenomenon. But so far, indirect rather than fundamental measures have been generally taken to combat these results. We must confess that the Europeans are somewhat in the lead of us in the solution of this problem by the recognition of the effect of using pozzuolanic co-mixtures with their portland cements. Some quotations from European publications and statements in limited circulation are believed to be pertinent and instructive.

From Paper No. 693—"Scientific Researches on Pozzuolana Substances," by A. M. Manonilov, Director of the Mechanical Laboratory of the Moscow Institute of Transport Engineers:

The scope of the question may easily be gaged from the fact that 14 papers, bearing on the decay of portland cement in water, were delivered in English, Swedish, Danish, Dutch, Belgian, French, Spanish and Japanese experts during the last International Congress on Navigation held in London in 1923.

All these numerous scientific labors in investigating the decay of portland cement in water have definitely shown that the cause of this decay is not to be assigned to faulty work in building concrete structures; nor to faulty portland cement used in the cases in question; but is inherent to the very nature of portland cement, whose process of setting involves the formation of a quantity of hydrate of CaO (which is $Ca(OH)_2$ easily subject to solution in water and to gradual alkalization. These researches have conclusively shown that it is to this particular process of alkalization of the $Ca(OH)_2$ that the weakening of concrete and its subsequent decay is due. In the presence of sulphates, usually found in sea water, the process of decay of portland cement is considerably accelerated owing to the additional chemical reactions tending to form lime sulpho-aluminate: 3Ca) Al_2O3 3Ca SO_4 $3OH_2O$. This formation of lime sulpho-aluminate results in huge increase in volume which in turn is followed by the formation of numerous cracks increasing the permeability of concrete to water and contributing to a quicker alkalization of $Ca(OH)_2$. In the presence of magnesial salts in water soluble calcium salts are formed which can be easily washed away by water.

Thus, since the law of decay of portland cement in water was established, the question naturally arose of finding means to prevent this process of destruction.

* * *

After extensive scientific investigations had been started, all the countries concerned soon came to the conclusion that the best, the simplest and cheapest method of preventing the decay of portland cement in water was that of introducing pozzuolana aggregates into the concrete, the "active silica SiO_2

being the main component of the above aggregate. The prevention of decay of portland cement in this case consists of the active silica SiO_2 binding the hydrate of calcium oxide $Ca(OH)_2$ and thus creating the combination $CaO\ SiO_2\ 2\frac{1}{2}H_2O$ which is next to insoluble in water. Another favorable factor in that the possible formation of destructive lime sulpho-aluminate $3CaO\ Al_2O_3\ 3Ca\ SO_4\ 30H_2O$ is altogether eliminated provided only a sufficient quantity of active silica SiO_2 is available.

* * *

Port structures at Odessa, Yalta, Feodossia, Novorossijsk, Poti, Batum and Petrovsk were inspected, and so also were the dry docks in Sebastopol and Baku. The piers in these ports were built after the Marseilles type. Standard portland cement was made use of in all these structures, excepting only those of Odessa and Poti where Roman pozzuolana and Teil lime were employed along with portland cement. The results obtained from the inspection of concrete structures in South Russian ports of the Black and Caspian seas led to the same conclusions with regard to the decay of portland cement in sea water which at that time had already been arrived at abroad. The inspection showed that visible symptoms of decay could be already observed seven years after immersion; a considerable degree of decay was observable in the course of 13-14 years, and complete destruction took place in 25-30 years. (where only portland cement was used).

Two pertinent conclusions were:

(1) Extensive scientific analytical work was carried out in tracing the true cause of this decay and resulted in the same conclusions which were also arrived at by scientists of other countries. The research resulted in raising full scale the question of the tremendous value of pozzuolana substances.

(2) In connection with the scientific and industrial conclusions obtained as to the expediency of applying pozzuolana substances, the question has been given these last ten years such great attention in the USSR that pozzuolana substances are incorporated in the official Matrice Standards as a substantial item thereof.

[Mr. Tuthill also refers to "Building Research Bulletin No. 2—Pozzolanas" of the Department of Scientific and Industrial Research, England, and to discussion by Prof. Lingi Luiggi, (Italy) of a paper by J. B. Lippincott describing the successful use of pozzuolanic material ground with cement in construction of the Los Angeles aqueduct, *Transactions* of the *American Society of Civil Engineers*, 1913, Vol. LXXVI, pp. 567-9.—Editor]

So it would appear from international research, experience and opinion (including our own), which conforms so well from one source to another, that it is true that:

1. Portland cement concrete is improved by the inclusion of an intimately mixed pozzuolana by reason of its combination with otherwise free and soluble lime to form insoluble and enduring compounds.

2. From centuries of experience of the durability of lime-pozzuolana compound mortars and concretes, it may be taken for certain today that there will be certainly no decrease, and most likely an increase in the durability and permanence of concretes in which some pozzuolana of proven reaction with lime is used as a co-mixture with portland cement.

3. Available American materials are equal or superior to similar materials used so widely abroad with profit and success, and otherwise unusually permanent results.

All that has been accomplished to date in volume change studies is a classification of causes and effects, and a recognition of the factors increasing and those decreasing this unpleasant phenomenon in concrete—particularly in massive work.

It is evident that with present day materials and the best of practice, volume change cannot be eliminated. Fortunately the best practice to other ends results in minimum volume change (avoidance of excess water and fines, and thorough curing). It should be admitted that volume change is a property of concrete which must be recognized and provided for in design the same as its strength or its weight.

In this light, any slight variation more or less in volume changes caused by the use of any particular ingredient is not important. It is a property that should be otherwise recognized and properly taken care of in design, and if this is properly done, variations of a few per cent would be of no actual importance—especially when attended by such important improvements in the other characteristics of the concrete as described above. Although Fresno pumicite (like any other extremely fine ingredient) slightly increases shrinkage on drying, structures in which this pozzuolana was used show less cracking than other structures in similar circumstances but made with plain concrete. This may be because pozzuolanic concrete is enough more elastic to offset any increment of increased shrinkage factor. Experiments have shown a ten per cent reduction of modulus of elasticity for such concretes.

BY F. M. LEA*

Messrs. Hughes and Levens refer to the method of the Building Research Board for estimation of the activity of pozzuolanas.

*In charge of research on pozzuolanic materials, Building Research Station, Garston, Watford, England.

This method has now been replaced by a more accurate quantitative method.[1] The pozzuolana is ground to pass a 180 mesh to the inch sieve and its rate of reaction at 25 deg. C. with a N/30 $Ca(OH)_2$ solution, when mixed in the proportion of 0.5 gm. solid to 125 cc. solution, measured by an electrical conductivity method. Initially an adsorption of $Ca(OH)_2$ takes place, but this adsorption bears no relation to the pozzuolanic activity of the material. It is followed by a steady combination reaction between lime and pozzuolana and the mean rate of this action between the twentieth and forty-fifth hours after mixing is defined as the activity of the material. The activity figure so obtained is a good index of the pozzuolanic properties of the material at early ages up to about 28 days, but it does not afford any measure of, for instance, the strength which will be developed at longer ages.

Some typical activity figures are shown in the following table.

RELATIVE ACTIVITIES OF POZZUOLANAS AT 25 DEG. C.

Pozzuolana	*Activity.* (mgm. $Ca(OH)_2$ removed per 1000 mins. by 0.5 gm. pozzuolana from 125 cc. $Ca(OH)_2$ solution).
Burnt clay A	7.2
B	10.5
C	6.0
D	3.3
Scottish spent oil shale A	7.5
B	6.0
C	5.0
Trass A	2.9
B	1.2
C	4.7
Santorin earth A	2.9
B	1.1
Italian pozzuolana	2.4
Granulated blast furnace slags	0–3

The two naturally occurring volcanic rocks F and P studied by Hughes and Levens appear from their results not to differ widely from the European naturally occurring pozzuolanas such as trass and Santorin earth. Extensive studies on the production and properties of pozzuolanas which have been in progress for some years at this Station have shown that artificial pozzuolanas

[1] c. f. Annual Reports of the Building Research Board, 1926-1929.

can be produced which are markedly superior to the naturally occurring materials. Such materials are selected clays burnt at predetermined and controlled temperatures, and the spent oil shale of the Scottish shale oil industry. These materials are ground to a residue of a few per cent on a 180 mesh to the inch sieve for use as pozzuolanas. It is doubtful if granulated blast furnace slag is to be regarded as a pozzuolana in the strict sense of the term since this material does not combine very appreciably with free lime in set mortars or concretes.

The properties of a pozzuolana may be determined and compared in a number of ways, but the most useful are initially an activity test by the conductivity method mentioned above followed by tensile strength tests on lime-pozzuolana-sand briquettes stored under carbon dioxide-free conditions. These tests can then be followed, if results warrant it, by tensile strength tests on cement-pozzuolana-sand mortars and compressive strength and other tests on concretes. Measurement of the free lime present in set cement-pozzuolana mortars and concretes is another important and valuable method for assessing the value of pozzuolanas. Suitable methods for these determinations have been developed.[2] The substitution of 40 per cent cement by an active pozzuolana of the spent oil shale or burnt clay type reduces the free lime content of a water stored 1:3 cement-sand mortar from about 2.0 per cent to 0.8 per cent at 7 days, from 2.3 per cent to 1.0 per cent at 28 days and to about 0.7 per cent at 6 months.

The suggestion made by Hughes and Levens that prolonged moist air or water curing is necessary for the satisfactory utilization of pozzuolanas seems to apply more to the naturally occurring materials than to the artificial products. This is well illustrated by some data on the tensile strength of 1:1:6 pozzuolana-hydrated lime-standard sand mortars. The briquettes were similar to those specified in the British standard specification for portland cement except that mechanical methods of mixing and ramming were employed. This substitution of mechanical for hand methods has no very marked effect on strength. Results are the mean of six briquettes tested in the same conditions as stored.

[2]A general account of these methods will appear in Building Research Special Report No. 17 to be published shortly.

TENSILE STRENGTH 1:1:6 POZZUOLANA : HYDRATED LIME : STANDARD SAND MORTARS STORED AT 12-13 DEG. C.

Pozzuolana	Tensile Strength lb. per sq. inch									
	Dry stored					Water stored				
	7 da.	28 da.	3 mo.	6 mo.	1 yr.	7 da.	28 da.	3 mo.	6 mo.	1 yr.
Scottish spent oil shale	169	280	344	324	400	107	207	341	466	521
Burnt clay	192	296	373	391	393	155	263	337	387	400
Santorin earth	41	110	143	201	...	8	62	306	446	...

Considerably higher strengths are obtainable in lime-pozzuolana mortars in which the ratio of lime to pozzuolana is decreased while keeping constant the ratio of pozzuolana plus lime to sand. The effect of temperature on pozzuolanic activity is very large and in tests on lime-pozzuolana mortars at least careful control of storage temperatures is essential. This is particularly noticeable with the naturally occurring pozzuolana Santorin earth which gives such low strengths over short periods at 12-13 deg. C. The tensile strengths at 7 and 28 days of water stored 1:1:6 Santorin earth-hydrated lime-standard sand mortars stored at 25 deg. C. were 45 and 250 lb. per sq. inch, or some four to five times the strengths developed at 12-13 deg. C.

Hughes and Levens find large reductions in the compressive strength of 1:3 cement-sand mortars at early ages when the volcanic earths are substituted for cement. This is similar to the results found with trass. The substitution of 40 per cent cement by trass results in about 50 per cent reduction in strength at 7 days and about 40 per cent at 28 days in 1:2.6 concrete mixes at a constant slump of either ½ inch or 2 inches. In 1:5 mixes the corresponding reductions in strength are about 65 per cent at 7 days, 55 per cent at 28 days and 45 per cent at longer periods. The water:cement × pozzuolana ratio required for a given slump is increased by the substitution of trass for cement. Relatively few data are as yet available on the compressive strengths of concretes with shale and burnt clay pozzuolanas, but from preliminary results it appears that the strengths obtained are much higher than when trass is used. The tensile strength of 1:3 cement:sand mortars is slightly increased at 7 days by the substitution of 20 per cent of the cement by a spent shale or

burnt clay pozzuolana and decreased 5-15 per cent by the substitution of 40 per cent, but at 28 days the unsubstituted cement mortar strength is exceeded by 10-20 per cent in the first case and by 0-15 per cent in the second. For all amounts of substitution down to a 40 per cent cement 60 per cent pozzuolana mix the ultimate (1 year) tensile strengths of the pozzuolana-cement mortars equal or exceed those of the mortar made from unsubstituted cement.

A short account of some of the main lines of investigation on pozzuolanas that have been carried out will appear in the Annual Report of the Building Research Board for 1930.

Readers are referred to the JOURNAL *for October, 1931 (Vol. 28) for further discussion which may develop and for the authors' closure. Such discussion should reach the Secretary by Sept. 1, 1931.*

Discussion of a paper by U. T. Berg:

"Continuous Beams and Frames in Building Construction"*

AUTHOR'S CORRECTION

On page 363—Table 3

For $\frac{I_h \cdot L}{H' \cdot I} = 0$, the bracket for K_s should include P and N values, and K_d should apply to the D values only.

On page 371

$H' = H$ is incorrect for condition of loading as shown, Fig. 9B. As column moments are of constant value throughout $\phi_2 = \frac{H}{2\,E\,I}$ and consequently $H' = \frac{3}{2}\,H$.

Discussion of a paper by F. E. Richart and V. P. Jensen:

"Tests of Bonding Floor Finish to Slabs of Haydite and Gravel Concrete"*

DISCUSSION

BY JOHN G. AHLERS†

The data presented in this paper confirm experience gathered from practice in the field; that it is possible to apply cement finish to structural slabs within 24-hours and have them act as an integral part of the structure.

This paper should bring to engineers and architects the conclusion that specifications should be written so as to allow contractors to place floor finish within 24-hours of the pouring of the slab and have these considered as monolithic and part of the structural slab.

Experience in the past has shown that where careful construction methods are followed one inch finish, placed afterwards, can be made to bond thoroughly with the structural members and the data presented confirms what has been observed in practice.

As might be expected, this paper shows that there is equally good bonding between structural slabs of haydite and structural slabs of gravel-concrete.

BY M. A. TIMLIN

Messrs Richart and Jensen show definitely that there is no inherent defect in the bond of a rich floor finish to a base of Haydite concrete. It would seem at first that the bond of the Haydite concrete was better than with the gravel concrete since failure occurred in the concrete itself immediately below the bonding plane in the former and entirely in the bond in the latter. A definite conclusion to this effect can not, however, be drawn from the data available.

*A. C. I. Journal, December 1930; *Proceedings* Vol. 27, p. 339.
†Barney-Ahlers Construction Corp., N. Y. C.

It would be difficult if not impossible to evaluate the strength of the bond from these tests. In the gravel concrete and the floor finish the moduli of elasticity were nearly enough the same that the slabs would act practically as simple beams with relatively low shear stress between the finish and base course.

On the other hand, with a finish having a modulus of elasticity of 4,030,000 lbs. per sq. in. superimposed on a Haydite base course with a modulus of elasticity ranging from 920,000 to 1,860,000 lbs. per sq. in., depending on the proportions used, when the load is applied to the slab the Haydite concrete tends to compress throwing greater load into the finish course. When this occurs, for each unit of load applied, greater stress exists in the finish course and less stress in the base course than when gravel concrete was used and the moduli of elasticity were more nearly equal. This of course causes greater shear stress.

If failure of the bond had taken place before failure of the reinforcement it might be possible to compute what shear stress had existed at the time of failure. Since initial failure of the reinforcement occurred first this can not be done. As soon as such failure took place the concrete in the base course was immediately placed in tension while the finish was still in compression. Just what these two stresses were can not be determined and consequently the shear stress is an unknown quantity, but would undoubtedly be greater in the case of Haydite concrete and greater in the lean than in the richer mixes.

Since the finish on the Haydite slabs had pieces of the base course adhering to them, indicating failure in the Haydite concrete immediately below the bonding plane rather than in the bond itself, it would appear that the shear strength of the bond were greater than the shear strength of the concrete.

With the gravel concrete base, the shear strength of the concrete exceeded that of the bond.

Therefore if the shear strength of the concrete is a function of the compressive strength only, the bond to the Haydite concrete was better than to the gravel concrete since the richer Haydite mixture had higher compressive strength than the leaner gravel mixture. If however, the shear strength depends also on the

modulus of elasticity and other factors, as it probably does, this line of reasoning will not apply.

A point of particular interest brought out by Messrs. Richart and Jensen is that the finish course took a large part of the load, particularly in the slabs with lean base courses and should be figured as part of the slab thickness.

There are a number of questions which arise as to actual behavior in a floor which are not covered by these tests, but which should be given serious consideration. Probably the most important of these is the differential expansion and contraction due to differences in moisture and temperature conditions. This has long been recognized as an important factor where a rich finish is used on a lean base course of gravel concrete. Since this is so where the differences in the coefficients of expansion are low, it would be of far more importance between gravel topping and Haydite base where the differences in the coefficients of expansion are probably of greater magnitude. The importance of this point could be determined only by laboratory tests showing the differences in expansion of two types of concrete under varying conditions of moisture and temperature.

While we have no data bearing on the resistance to impact of a floor consisting of base course of Haydite and a rich gravel concrete finish, it is logical to assume that such resistance would be at least equal to that of a gravel concrete base. Concrete made with an aggregate having the characteristics of Haydite would serve as a cushion and be able to absorb impact transmitted to it through the finish course better than a more rigid material. There should, therefore, be less tendency to crack or to split off from the finish course.

The report under discussion is based on tests made to show the behavior of a slab having the rich finish course in compression as in the case of a slab between supports. It would be interesting to know what the action would be when the compression is taken entirely by the lean base course and the finish course is in tension, and the slab of course properly reinforced, as in the case of a slab passing over a beam or attached to a wall.

Durability of Concrete

A Report of Committee 801

A. E. LINDAU, CHAIRMAN

Two papers on the following pages—"Study of Defective Concrete," by F. R. McMillan and "More Lessons from Concrete Structures in Service," by Roderick B. Young—both members of Committee 801, Durability of Concrete—were presented at the 27th Annual Convention, Milwaukee, Feb. 24-26, 1931, with the following remarks by Mr. Lindau, chairman of the Committee.—Editor

It is my privilege to introduce the speakers on the assumption that I should know something about the committee work. You will notice that this number appears on the program as a Symposium by members of Committee 801, and that there are two who are "symposing," which probably reduces a symposium to its simplest terms. It was intended to be a more complex symposium than we have. There has been enough work done by the committee to fill a session; at one time the Program committee hoped that might be done, but other things intervened and we are privileged to have the two papers as here presented. The work of the committee has been going on for some time and it will probably go on for some time more. The committee has undertaken to survey structures individually and collectively. This survey has taken the members of the committee individually and in groups from, I was going to say, "Greenland's icy mountains to India's coral strands," but that is a little large; they did make a survey of structures though in what you might call the

sub-arctic regions of Canada, and continued at other times to the sub-tropical regions of our southern states, and from the Atlantic Ocean to the Pacific Ocean; so geographically they have done a big job. The committee is functioning by making these reports from time to time, as individual papers.

Readers are referred to the JOURNAL *for Nov. 1931, (Vol. 28) for discussion of the two papers which follow. Such discussion should reach the Secretary by Oct. 1, 1931.*

Study of Defective Concrete*

BY F. R. MCMILLAN†

In a survey of concrete structures representative of almost every kind of aggregate, method of construction, and condition of exposure to be found in the greater part of the United States and portions of Canada, a considerable amount of clinical material has been developed from which much can be learned both as to what to avoid and what to require to obtain more durable structures. While it is hoped later to make an extended presentation of the data from this survey, this paper will be limited to a discussion of some of the ways in which different causes of disintegration or unsatisfactory concrete are identified.

SOURCE OF INFORMATION

In a survey designed to bring out the causes of defective concrete, there are three principal sources which must be relied upon for information:

(1) Personal recollections of competent persons engaged on the work at the time of construction.
(2) Original records.
(3) The condition of the structure itself.

Personal recollections of responsible individuals are not often available and frequently none too reliable. Original records, when available, are most reliable as to the details covered, but good original construction records are very rare and seldom do they cover all the points upon which the concrete engineer of today seeks information. It is, therefore, the evidence presented by the structure itself upon which the investigator must to a large extent rely for his information. This would be somewhat discouraging if there were available for study only a few struc-

*Presented at the 27th Annual Convention, A. C. I., Milwaukee, Feb. 24-26, 1931, as part of the work of Committee 801, Durability of Concrete—see p. 1037.
†Director of Research, Portland Cement Association, Chicago.

tures representing a limited set of conditions, but as the scope of the study is extended the indications multiply rapidly until it is possible to read with considerable accuracy the causes of defective concrete in the present condition of the structure.

In reference to personal testimony, it is of interest to consider the fallibility of man's recollection as applied to details of events that transpired a dozen years before. Sometimes the personal evidence has the ring of reliability and accuracy and serves to illuminate and corroborate the evidence presented by the structure itself. Equally often the statements are not convincing and cannot be squared with findings on the ground. A desire to conceal or soften the facts is encountered sometimes. This, however, can usually be detected and the true condition revealed by a few judicious questions.

Not always is it the memory that is at fault when the recollections fail to agree with the evidence presented by the structure itself. Frequently, the memory is quite accurate as to things that were supposed to have been done, but the inexorable effect of time has disclosed that the work was not carried out as directed.

It may be pertinent to point out the desirability of making complete records of the construction operations. With a few outstanding exceptions like the structures of the Reclamation Service and the Crystal Springs Dam, it was the experience in this survey that the records available were generally disappointing.

EXAMINATION OF BOTH SOUND AND DEFECTIVE CONCRETE ESSENTIAL

In an examination of a structure, the portions which show no defects require study as well as the defective portions. The extent and position of the unaffected areas with relation to exposure and conditions of placement give important information. The general character of the surface and its variation from point to point may show conditions as they existed in the now defective portions at some previous stage. Similarly, the study of structures in which only slight defects are in evidence may provide essential information for the explanation of some other structure. The significance of these comments will be brought out in a

number of the illustrations of this discussion; as specific instances the cases of the XY building and of the Gull Lake and Pine River Dams are cited.

The XY building, not identified for obvious reasons, had shown serious spalling of the concrete jambs just inside of metal window frames and the frames were badly rusted. At the time of the inspection, the windows on the most exposed side of the building were so completely affected, that many had to be replaced and the concrete around the openings restored. Those that had not been reconditioned were in such advanced state that no explanation of the cause could be discovered. However, an examination of the sides of the building least exposed to wind and rain disclosed a number of the windows in which the development of the trouble could readily be traced through its various stages. This study showed that the trouble began from rusting of the sash on the inside at a point just above the horizontal pivot of the ventilating sash. These ventilating sash were in the upper portion of the window and when opened (top inward) permitted the rain, driven by the wind, to rebound and strike the inside of the frame. At some of the windows only the first signs of rust were showing, on others the rusting had progressed downward and upward varying distances with resulting spalling also in various degrees. Here was a complete record showing all the stages through which the other windows had passed—a record which could not have been added to by the original construction records, or by personal recollections of those engaged on the work.

Gull Lake Dam is a case where a study of a well preserved structure provides an explanation of defective conditions found elsewhere. This is one of five dams forming navigation control reservoirs in the headwaters of the Mississippi River, built by the U. S. Engineers Corps between 1902 and 1907. This is a group of structures in which the field notes spoke eloquently of the workmanship and supervision—conclusions which were later confirmed by personal discussion with the foreman in charge of the construction of all five dams.

Figs. 1 and 2 show three views of this dam which bring out both the excellent workmanship at the time of construction, and the perfect condition of the structure today. The complete absence of spalling at the water line is particularly noticeable. At

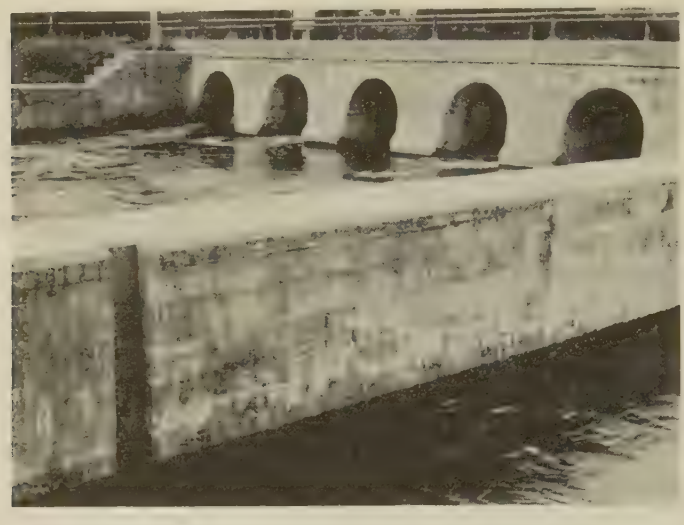

FIG. 1—GULL LAKE DAM, MINN. EXAMPLE OF GOOD CONSTRUCTION METHODS. ALMOST NO DEFECTS EVIDENT AFTER 25 YEARS

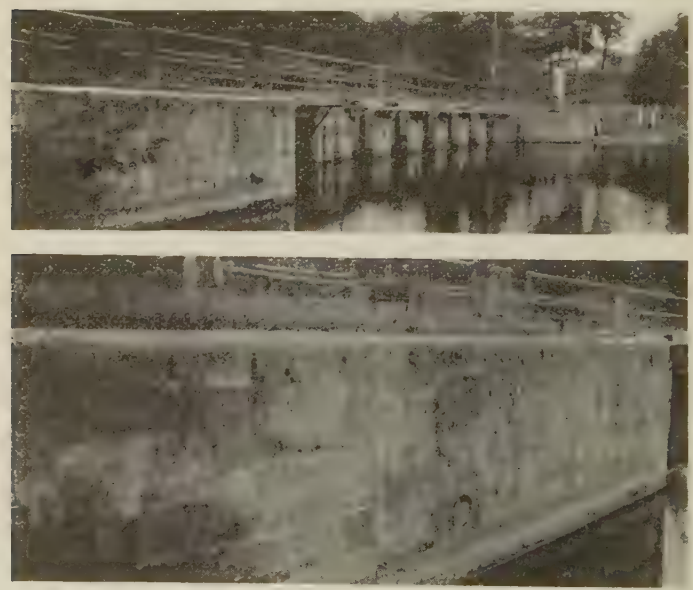

FIG. 2—DETAIL VIEWS OF GULL LAKE DAM, MINN.

the time of the inspection, it seemed important to know whether this unusual condition was due to specially good materials and workmanship, or merely to the absence of conditions which produce spalling. Such knowledge was necessary, not only to a proper understanding of this structure, but of others where such spalling is observed.

Several clearly defined water lines were in evidence (some are visible in the pictures) indicating that the reservoir level might not have been stationary long enough to produce spalling. Yet it seemed that in 22 winters in this climate some spalling would have occurred unless the concrete were unusually resistant. By close examination of the concrete below the water surface, areas were located where well-defined spalls had occurred at the corners of three of the piers. These were the characteristic V-type spalls so often found at the water surface and indicated that at some time in the past, water surface and ice conditions had been such as to produce this spalling and ravelling at the corners. The occurrence of these corner breaks at only a few places over the entire area was interpreted as showing certain defective spots in the concrete which yielded to the severe conditions, while the general excellence of the concrete was such that the disintegration was thus localized.

Another of the five dams of the Mississippi Headwaters is Pine River Dam shown in Fig. 3 in which, as in Gull Lake Dam, the presence of certain defects in an otherwise perfect structure is convincing evidence that it was the unusually good workmanship in the rest of the structure which accounts for its excellent condition after 21 years. The single defect in this dam is the calcium carbonate deposit seen in Fig. 3 on the wall of the fishway near the end where it joins the piers of the dam. This deposit shows that a slight leakage had taken place along a fill plane, forming this incrustation in exactly the same manner as similar or large deposits are formed in so many structures.

Pine River Dam has been used by the writer in a number of other discussions because it is such an outstanding example of what it is possible to obtain with careful construction methods. It was the last and noticeably the best of the group of five dams all of which were built under the supervision of Hans Olson.

FIG. 3—PINE RIVER DAM, MINN. ANOTHER STRUCTURE OF EXCELLENT RECORD DUE TO GOOD CONSTRUCTION METHODS

The method used by Mr. Olson should be made a matter of record as it is thoroughly sound in the light of our present-day knowledge of concrete mixtures, and accounts for the splendid performance which these structures have given. The proportion of sand to cement was determined by the engineer in charge by comparative tests of mortars using the available sand and standard sand. The instructions were to use with this mortar as much of the coarse aggregate as was possible and still obtain a mixture which could be worked into place, and in which there were no unfilled pockets between the coarse aggregate particles. The instructions also required placing the concrete in thin layers and thorough ramming with tampers weighing 35 lb. Only enough water was to be used to show on the surface after such thorough ramming. Mr. Olson found that the workmen were inclined to slight the tamping with these heavy tampers. By reducing these to a weight of 25 lb., he obtained much better results. He also found that he got better consolidation of the successive layers if he used somewhat more water than was intended in the instructions. When the extra water resulted in a tendency to overwetness, this was counteracted by the use of

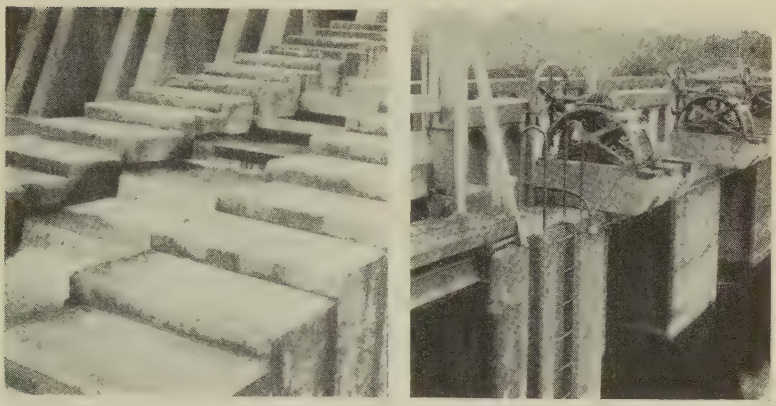

FIG. 4—DETAIL VIEWS OF PINE RIVER DAM

batches somewhat drier than the average. In this manner he obtained not only a homogeneous concrete in each layer and a thorough bonding of the layers, but avoided the undesirable accumulation of water and laitance as the placing progressed. The detail views of Pine River Dam in Fig. 4 show the excellent results from this method.

EVIDENCE OF DRY MIXES

The use of mixes too dry for proper placement or consolidation is usually quite easily detected from the appearance of the structure. The defects resulting from this cause are well illustrated in Fig. 5, which shows 2 views of the Thompson Dam near Duluth, built in 1906. This dam was described by H. C. Ash in a paper before this Institute in 1929. In the picture at the left, the failure to bond successive layers is indicated by the calcium carbonate deposits brought to the surface by water seeping along the surface between layers.

The successive layers are quite clearly marked by these incrustations. These show the irregularity which would be expected from dry mixes spread in thin layers.

The picture at the right shows two nearby sections in which the seepage between successive layers was nearly eliminated. This was accomplished by the use of a slightly wetter consistency. In the section at the left in this picture the bond between the portions

FIG. 5—THOMPSON DAM, MINN. SEE PROCEEDINGS, A. C. I., V. 25, P. 29, 1929

representing successive day's lifts was not perfect, as can be seen by the heavy incrustation of calcium carbonate below the surfaces of separation. In the section at the extreme right the bond between successive layers is perfect, and that between successive day's work is nearly so.

Mr. Ash, in his paper, makes an interesting comment on the difficulties he had in training inspectors out of the habit of insisting on too dry mixes. After the first few sections, his method, which was something like that used on Pine River Dam, was mastered and the structure completed according to his desires. The three sections to be seen in Fig. 5 show the stages in this improvement.

In considering the defects of the type illustrated in the picture at the left in Fig. 5, it must be remembered that they are principally of interest as they affect the appearance of the structure. The seepage had practically ceased years ago and the integrity of the structure has not been affected. It has been the almost universal experience in this survey of structures that where concrete placed by this dry tamped process was encountered, the structure has stood up well under all conditions even though an unsightly appearance resulted from such defects as pointed out above.

The dam shown in Fig. 6, built in northern United States in 1898, is another case where the use of dry mixtures is plainly evident. The various layers have been sharply defined by the frost action on the portion of the concrete at the lower edge of each layer. The dry, stiff mixes are difficult to work into the acute angle between the horizontal surface and the downstream face of the dam. This provides an easy point of attack from the frost action which is most pronounced at the lower edge of each layer. A lesser amount of spalling is shown at the top of each layer. The surface of this dam also shows the aggregate exposed by erosion, solvent action, and frost. Except for these surface defects this dam is in excellent condition and should continue to serve its purpose almost indefinitely.

Fig. 7 shows portions of a western dam, more than 30 years old, in a locality subject to moderate frost action. In the upper view, considerable spalling can be seen at several of the fill planes.

FIG. 6—AN EXAMPLE OF DRY TAMPED CONCRETE AFTER 30 YEARS EXPOSURE

The stiff consistency of the mixture is indicated by the steep slope of the surface marking the boundaries of successive lifts. Some undercutting where the concrete joins the rock is seen at the extreme right of the view. Aside from these defects, the entire surface is seen to be very well preserved. The discoloration is the result of a growth of moss which is quite heavy in some spots. In the lower view, the mixture was somewhat wetter as shown by the flatter slope to the fill planes, although this could not be described as a wet mix as this term is used at the present time.

It was noted above that it was the almost universal experience to find well-preserved concrete when the dry-tamped mixes were

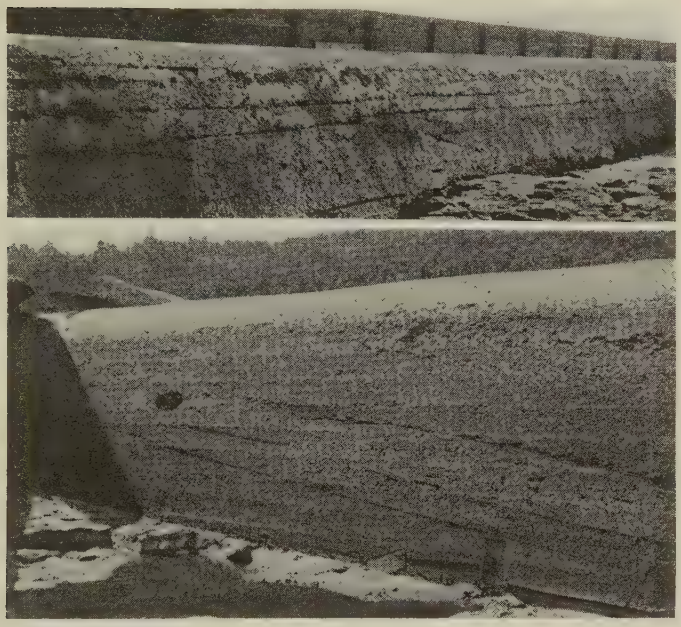

FIG. 7—ILLUSTRATING DRY AND SEMI-DRY MIXES

used. It is significant also that where mixtures of this type were used there is less confusion as to the causes of defects. It will be brought out in what follows that in certain cases it is very difficult to determine the factors primarily responsible for the condition of the structure, but this is not the common case where the dry tamped mixes were used. This rather clearly indicates that the better concrete which is likely with the dry mixes, combined with the freedom from serious segregation obtained by this method of placing, serves to protect against deterioration from other causes such as poorly graded or dirty aggregates, or even aggregate that in less durable concrete would clearly show unsound.

Fig. 8 shows another structure in which the dry tamped concrete is evident from the irregularity of the surfaces of contact and lack of bond between successive layers. This is a Lake Michigan breakwater built about 30 years ago. In the view at the bottom, the surfaces separating the successive layers are discernible through the thin mortar protection though not so

FIG. 8—A LAKE MICHIGAN BREAKWATER AFTER 30 YEARS OF SERVICE. NOTE GOOD CONDITION OF THE DRY TAMPED MIXES

readily as in the view at the top in which this thin coating is completely weathered away. Both these views show the general character of the construction resulting from this method of placing and its generally good condition after 30 years of about the severest kind of exposure.

On the horizontal surface in the lower view of Fig. 8, board marks are clearly visible. Such use of boards to protect the top surfaces of walls has been frequently encountered in structures of the period of this breakwater. Incidentally, this structure also provides a good illustration of the inaccuracy of the personal recollections of individuals in regard to details of the work. In this case the carpenter foreman who built the forms for this

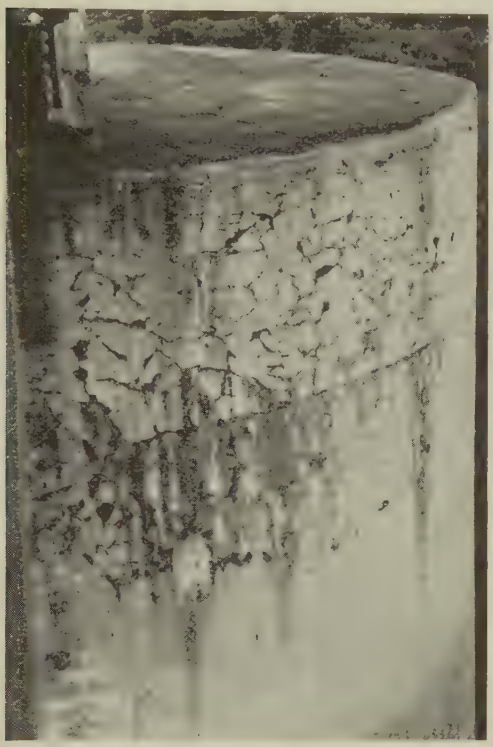

FIG. 9—AN EXAMPLE OF DISINTEGRATION DUE TO UNSOUND AGGREGATE

breakwater was interviewed and stated with some positiveness that the concrete mixtures were very wet. This recollection seems to have been based on the fact that the men wore rubber boots when distributing the concrete in the form, but it is not supported by the evidence of the structure itself.

EVIDENCE OF UNSOUND AGGREGATE

Fig. 9 shows a railway pier in which a fairly advanced state of disintegration due to unsound aggregates is illustrated. It is not obvious on first sight that the appearance of the surface in this picture is indicative of coarse aggregate disintegration. As can be seen in this picture, the lower part of the pier is still in very good condition and it is only in the upper 3 ft. that disintegration has begun. In this respect conditions are similar to those in which

FIG. 10—EXAMPLE OF AN EXCELLENT STRUCTURE MARRED BY SEEPAGE AT A FEW JOINTS

overwet mixes resulting in "water gain" are responsible for the disintegration. In fact, it is quite probable that some effect of "water gain" is responsible for the conditions in this pier. As pointed out previously it often happens that several factors are responsible for conditions observed in structures and, that in many cases, poor aggregates are well preserved which in either more exposed conditions, or more permeable or porous concrete would have shown early signs of deterioration.

A condition which makes it difficult to determine how much of the disintegration in the pier in Fig. 9 is due to water gain is that the disintegration of the aggregate itself proceeds more rapidly where the contact with water is most frequent. Thus, the rain falling on top of the pier starts disintegration at this point. As the expansion and disruption of the aggregate proceeds the concrete becomes more porous and the water finds its way through this porous mass to the layers below. The process is continuous from the top down in exactly the same manner as that resulting entirely from water gain.

BONDING SUCCESSIVE LAYERS

Fig. 10 presents a characteristic defect that is easily recognized. In this structure can be seen the incrustation of calcium car-

FIG. 11—STRUCTURAL DEFECT DUE TO INADEQUATE DRAINAGE

bonate which had its origin in water seeping through the joints between the successive layers. Such deposits are seen both on the intrados of the arch and on the one pier in the immediate foreground of the picture. This structure was built in 1905 and it appears from the present condition that the deposits seen in Fig. 10 have not increased materially in recent years. This means that either the joints have thoroughly sealed themselves, which is a very common condition, or that water can no longer find its way to the open seam.

Fig. 11 shows one of the arches in this structure which has

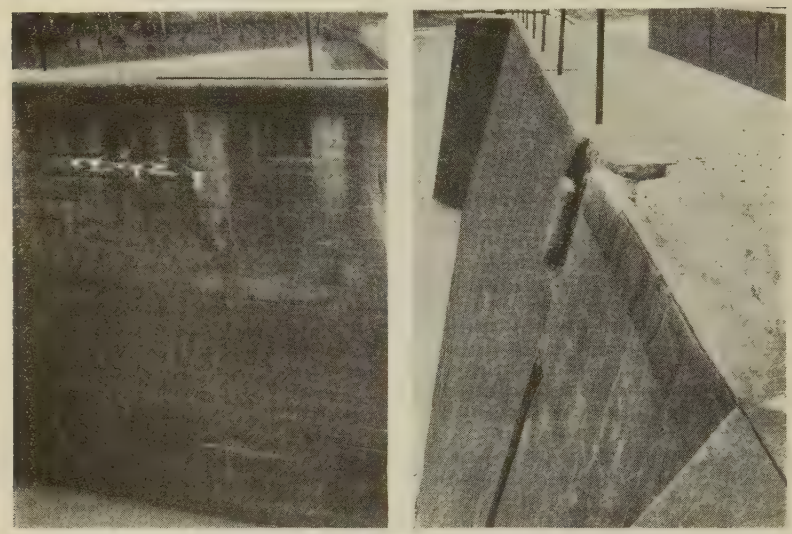

FIG. 12—A LOCKWALL WITH CORE OF LEAN CONCRETE AND FACING OF A RICHER MIX

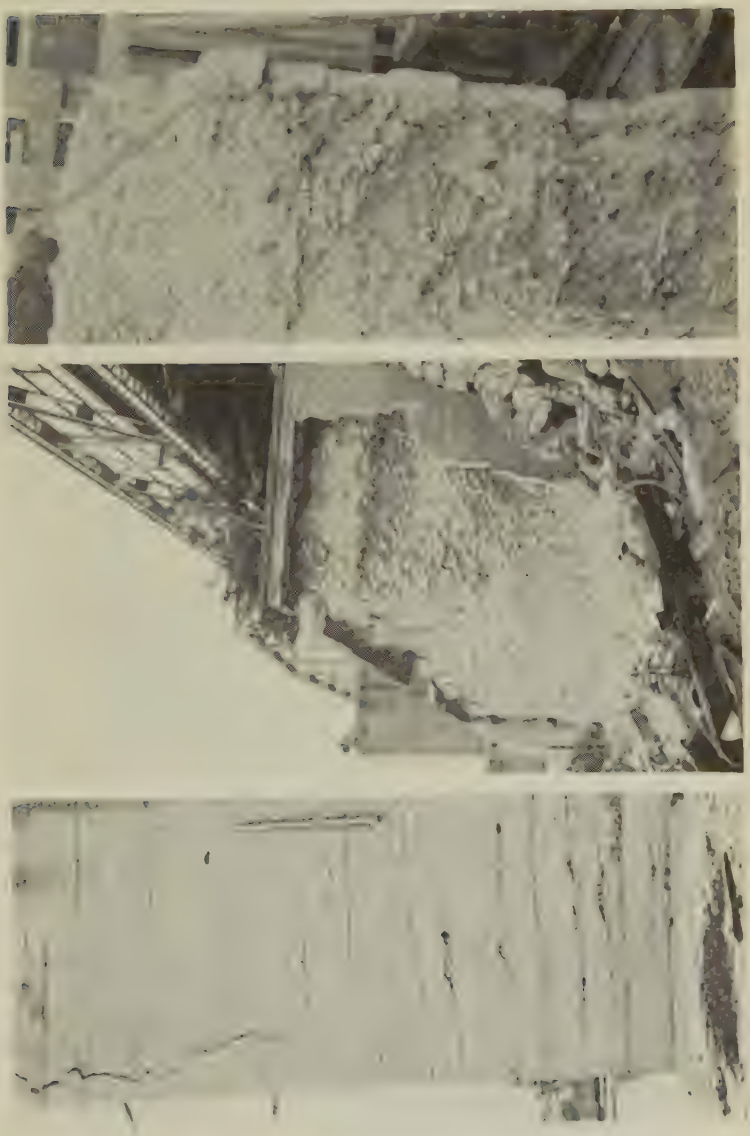
cracked longitudinally for a portion of its length. It appears that this crack has been produced either by the hydrostatic pressure or freezing of the saturated spandrel fill. This indicates the necessity for proper drainage in this spandrel space. The fact that it has been confined to only a few of the arches in this long structure indicates that, in general, the provisions in this respect were successful. Similarly, the complete freedom from seepage at most of the other joints in the structure indicates that the methods employed for obtaining the proper bond through successive layers were generally successful.

STRUCTURES FACED WITH A RICHER MIXTURE

A condition frequently encountered is where a concrete structure is faced with a somewhat richer mixture to provide greater resistance to the weather. In some of the earlier structures this type of construction was very common. While there are successful structures of this type there are cases where the outer shell has cracked badly and separated from the interior. In such failures of this type as have been encountered, the outer shell has been relatively thin and of concrete very much richer than the inner mass.



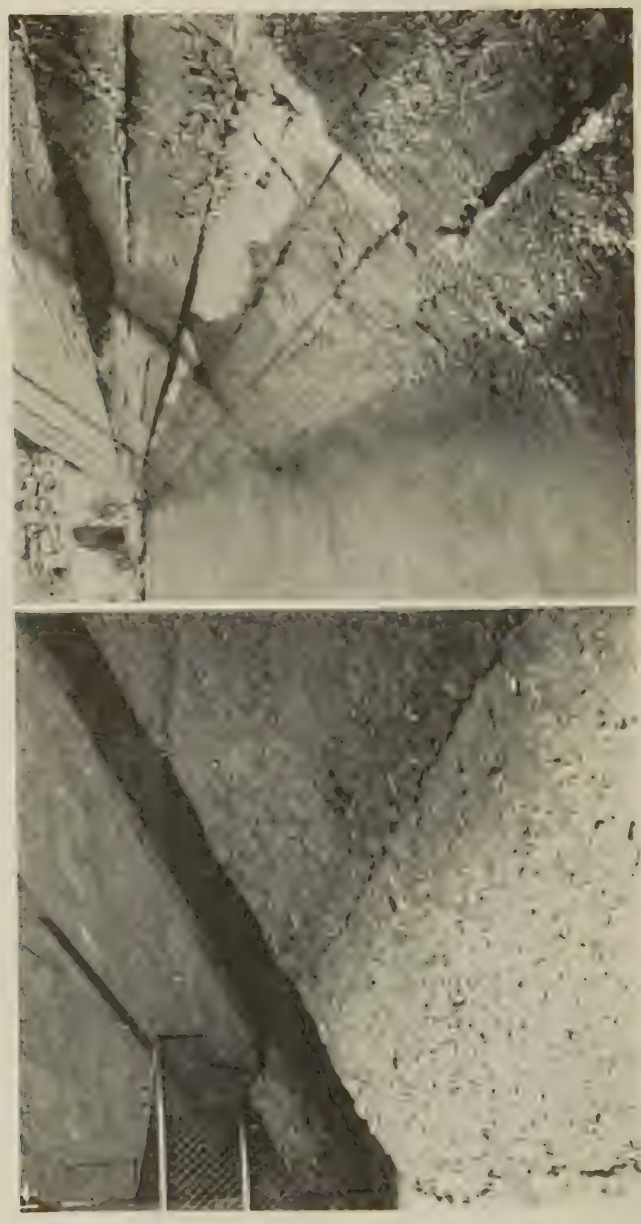


FIG. 13—EXAMPLE OF LEAN CONCRETE FACED WITH A RICHER MIXTURE

FIGS. 14 AND 15—TWO VIEWS OF A DAM OF VERY LEAN MIXTURE IN MILD CLIMATE.

Figs. 12 and 13 show two prominent examples of this type of construction. Fig. 12 is a lock wall built in 1904 and 1905. Except for the very prominent cracking which is clearly seen in the two views, the exterior concrete is in excellent condition. In the view at the right, small portions of this outer shell have been broken away. Fig. 13 shows three views of another lock wall built between 1895 and 1899. In the view at the left a portion of the outer wall is seen in which the shell is badly cracked but still in position on the wall. In the central view is seen a section of the wall where the outer shell has completely broken away and the mass concrete within badly weathered. The view at the right shows a point where a section of the wall has been cut away to provide for extensions to the structure. The extremely lean character of the mass concrete and the dense character of the outer shell is brought out very well in this view.

The feature it is particularly desired to emphasize in Fig. 13 is the character of the cracking shown in the picture at the left. The large spacing between the cracks, their large size and regularity of occurrence is typical of incipient failure in this type of construction.

QUANTITY OF CEMENT

Evidence as to the quantity of cement used in the mixture is the most difficult to obtain from an examination of the structure. An extremely lean mix gives a weak and porous concrete that is readily attacked by the weathering agencies. Such a result is also produced by inadequate curing. When evidence from sources other than the examination of the structure indicates a deficiency of cement, it is usually found that the defective concrete is more or less general over the structure unless there is some point of local attack such as the water line. This would naturally be the case also where curing had been neglected. The lean concrete in the wall at the center in Fig. 13 is a typical case of gross deficiency of cement. It is seen that this concrete was badly disintegrated over the whole surface once the protecting shell of rich concrete was removed. While curing may have been involved to some extent in this wall, the extreme leanness of the mix is very evident.

Another example of a lean mixture is shown in Fig. 14 and 15. These show portions of the downstream face of a dam in which a

FIG. 16—ANOTHER VIEW OF THE DAM IN FIG. 14

so-called sand cement was used. This cement was made by grinding portland cement with approximately equal parts of sand or crushed granite. The concrete was mixed in about the usual proportions for structures of this kind using the ground mixture as the cement portion, thus the actual cement content was about ½ bbl. per cu. yd. The views in Fig. 14 and 15 are typical of the worst portions of the downstream face. Fig. 16 shows most of the downstream side of this dam. From this it can be seen that there is some scaling here and there over the entire surface.

While the scaling due to these lean mixtures is quite evident, it is very much less than would be expected for the usual conditions. The two factors which account for the limited scaling for such lean mixes are the careful methods followed in placing the concrete and the mild climate to which it is exposed. This dam is in the arid region of the southwest where both rain and frost are rare occurrences.

A fairly complete construction report on this dam shows that every care was taken to secure proper bonding of new and old work and specially to compact the concrete between the plum stones and against the forms. One inspector was employed with

FIG. 17—BUTTRESS WALL BUILT IN 1908, SHOWING EFFECT OF "WATER-GAIN"

each of the placing gangs. Concrete was delivered in bottom dump buckets and plum stones were deposited immediately upon the freshly dumped concrete. This report shows also that some attention was given to the curing. The concrete was kept wet for a period of two weeks, which was none too much for exposure to the hot dry air of this region.

The success of this careful placing is shown by the fact that there has been practically no seepage into the inspection gallery, nor along the construction joints or fill planes. The complete absence of seepage on the downstream face, as shown by the photograph in Fig. 16 is a rare condition for structures of that period (1913-1916).

CONSISTENCY AND PLACING

Defects due to careless or wrong methods of placing and over-wet mixtures are the most common to be found in concrete structures. As suggested in a previous paragraph, other causes

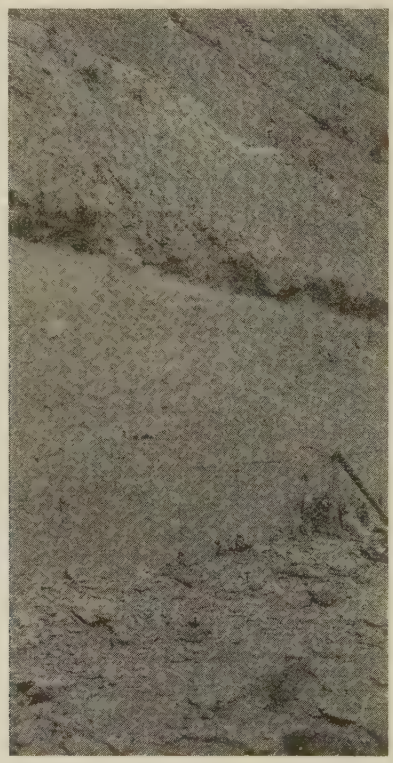

FIG. 18—PORTION OF A DAM IN SEVERE CLIMATE, ILLUSTRATING POOR CONSTRUCTION METHODS

of defects may be completely obscured by sloppy mixtures or improper placing. Evidences of "water-gain," segregation, and honeycombing are everywhere to be seen and easily identified. Closely allied with these are the cases where successive layers of concrete fail to bond properly. Sometimes these defects occur in structures where the mixtures are suitable and placing methods are otherwise satisfactory. More commonly, however, they are associated with a general carelessness in other respects. A few illustrations will suffice.

Fig. 17 shows a very common case. The stepped buttress wall, which is part of a dam in Michigan, built in 1908, provides a good

FIG. 19—ANOTHER PORTION OF THE DAM SHOWN IN FIG. 18

opportunity for water and fine material to collect during placing. The usual method is to deposit concrete in the body of the structure which allows the lighter portions of the mix to flow outward to the more distant points. The ease with which the rain and snow can collect on the steps hastens the disintegration through frost attacking the porous concrete.

Fig. 18, which shows portions of a dam in a very severe climate, is another illustration of poor construction methods. Improper mixes and segregation, due to excess water were everywhere evident on this structure. Curing also may have been neglected. The slope of the inclined fill plane to be seen just above the handle of the pick at the extreme right of the picture shows a somewhat stiffer consistency than was evident in other parts of the structure. This concrete of stiffer consistency shows much better resistance than the wetter layer just above. Fig. 19 shows another portion of this dam. In this view also the concrete of stiff consistency shown immediately above the badly honeycombed area, is re-

Fig. 20—Two-ft. laitance bed resulting from placing concrete through water

Fig. 21—Dam in northern climate. Note good condition of spillway in contrast with abutment wall

FIG. 22—CRYSTAL SPRINGS DAM, CAL. A DRY TAMPED CONCRETE PLACED IN 1886-1888

sisting the weather much better than the layer immediately below. This lower layer is almost devoid of coarse aggregate for a considerable depth below the top. This dam was about 13 years old when this picture was taken.

Fig. 20 shows a 2-ft. bed of laitance resulting from placing concrete through 14 ft. of water. Fig. 21 shows a dam in a severe climate in which the concrete in the spillway was placed with extreme care, while in the abutment there is evidence of water gain and laitance with consequent seepage at the fill planes.

These illustrations could be multiplied indefinitely with each case showing some major or minor defect resulting from the manner in which the work was carried out. It is fitting to close this discussion with an example of concrete which is well preserved because it was well placed. Crystal Springs Dam, shown in Fig. 22, is such a structure. This dam was built between 1886 and 1888 by Herman Schussler, chief engineer of the Spring Valley Water Co., of San Francisco. It is a masterpiece of good construction using the dry tamped method. Every detail of preparing the materials, measuring the quantities (including the water), mixing, placing, ramming, and curing were carried out in accordance with carefully prepared instructions. It stands as a monument to Mr. Schussler and his careful methods of construction.

Readers are referred to the next paper and to discussion of both which follow it and are referred further to the JOURNAL *for Nov., 1931, (Vol. 28) for discussion which may develop. Such discussion should reach the Secretary by Oct. 1, 1931.*

More Lessons from Concrete Structures in Service*

BY RODERICK B. YOUNG†

Any public utility, railroad or government has such a considerable investment in concrete structures that their behavior in service is a question about which they must needs be concerned. Realizing this, the Hydro Electric Power Commission decided, some years ago, to systematically study the behavior of their many concrete structures, with a view to learning not only their existing condition, but their probable condition in years to come. The examinations thus made disclosed so many interesting points in connection with the behavior of concrete in service, that it was extended to include other concrete structures in different parts of Canada and the United States, until the number of inspections now made have reached a total of several hundred. This paper is an attempt to set down briefly some of the conclusions that have been reached as a result of these examinations.

Very few concrete structures are entirely free from disintegration of some kind or other, and their defects are usually so much more conspicuous than serious that they lead the casual observer to condemn concrete as a building material, forthwith and forever. Even the critical observer is apt to become despondent by the seeming prevalence of defective concrete, and some of our well-known engineers are still in this mental condition as a result of their examinations.

However, this is not a fair view to take of the behavior of concrete in service. While defective places can be found in most concrete structures, they are usually of very limited extent

*Presented at the 27th Annual Convention, A. C. I., Milwaukee, Feb. 24-26, 1931 as part of the work of Committee 801, Durability of Concrete, see p. 1037.

†Testing Engineer, Hydro Electric Power Commission of Ontario.

FIG. 1—LIFT LOCK AT PETERBOROUGH, ONTARIO, 26,000 CU. YD. OF ALMOST PERFECT CONCRETE WHICH HAS BEEN IN SERVICE SINCE 1904

and of minor importance. After any serious and wide-spread examination of concrete structures, one can hardly come to any other conclusion than that the greater part of the concrete in service today is in good shape and will remain so for many years to come.

One frequently finds old concrete structures in most excellent condition, resisting the destructive forces of nature, as well or better than any other material that could have been used. If anyone doubts the truth of this statement let him visit the Trenton Dam near Rome, N. Y. or the Hinckley Dam nearby, the Lift Locks at Peterborough, Ontario, the Crystal Lake Dam near San Francisco, Calif.[1] or the Thomson[2] and Pine River dams in Northern Minnesota, for these structures offer convincing proof that concrete when properly made is a durable material.

On the other hand, one occasionally meets with a structure in which the greater part of the concrete is disintegrating, but even in these cases it is the rare exception to find one so poorly made that there is not a considerable part of it in first-class shape. Even such a horrible case as that shown in Fig. 3 has its good

[1]References are listed at the end of this paper.—EDITOR

FIG. 2.—SIDE WALL OF PETERBOROUGH LIFT LOCK, WHICH IS UNDER WATER PRESSURE. NOTE ALMOST PERFECT CONDITION OF CONCRETE AFTER 27 YEARS' EXPOSURE TO SEVERE NORTHERN CLIMATE

points, and I think I can safely say, after the examination of a great many concrete structures, that not one per cent can really be classed as failures in the sense that the concrete has deteriorated or will in the near future, deteriorate to such an extent that early replacement will be required.

In any extended examination of deteriorated concrete the observer is struck with the fact that there is a marked similarity in the appearance of many of the affected areas and in the manner

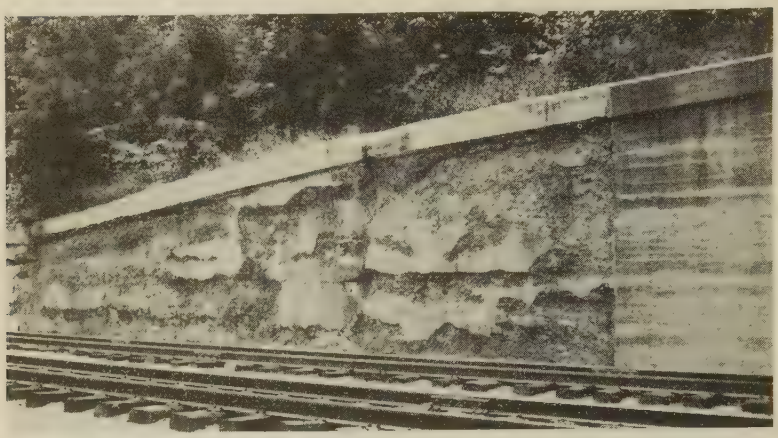

FIG. 3—EVEN SUCH A HORRIBLE EXAMPLE OF POOR CONCRETE AS THIS HAS AREAS WHICH ARE IN FIRST-CLASS CONDITION. THIS RETAINING WALL IS APPROXIMATELY 20 YEARS OLD

of their occurrence. One comes gradually to classifying them by type, and in the majority of cases finds, from the evidence offered by the concrete itself, that the circumstances surrounding the cases of a common type are similar.

By far the greater number of cases of deterioration are due to the segregation of the concrete mixture before or during its deposition. The author, in a previous paper[3] before the Institute, gave numerous examples of typical defects due to this cause and explained the manner in which they occurred. Briefly, it was shown there that the principal causes of segregation are the use of over-wet mixtures, improper methods of handling and placing, and over-manipulation of the deposited concrete.

The evils of excess water manifest themselves in water-gain and the formation of laitance at the top of "lifts" and in the accumulation of mortar and fine material in corners, at vertical joints, and under sloping forms. Improper handling and placing cause, not only the familiar honeycombed areas of gross segregation, but the even more dangerous sections of concrete that are not noticeably segregated but are sufficiently so as to be porous and permeable. Over-manipulation is frequently the result of an

FIG. 4—DEFECTIVE HORIZONTAL JOINT CAUSED BY CARELESS CONSTRUCTION. CORROSION OF THE CONCRETE ADJACENT TO THE JOINT HAS NECESSITATED REPAIRS

attempt to obtain good surfaces with poorly proportioned and harsh-working concrete mixtures, by excessive puddling and spading of the surfaces. But whatever the cause of segregation, the result is failure of the affected concrete, if the exposure to which it is subsequently subjected is sufficiently severe.

If segregation is also the most common cause of deterioration, it is also the one for which there is the least excuse, and it may be well to point out here, as will be done later, that segregation is almost entirely preventable by a little ordinary care and forethought.

FIG. 5—DETERIORATION ADJACENT TO A VERTICAL JOINT. A POROUS CONCRETE MADE FROM PIT-RUN GRAVEL PLACED WET

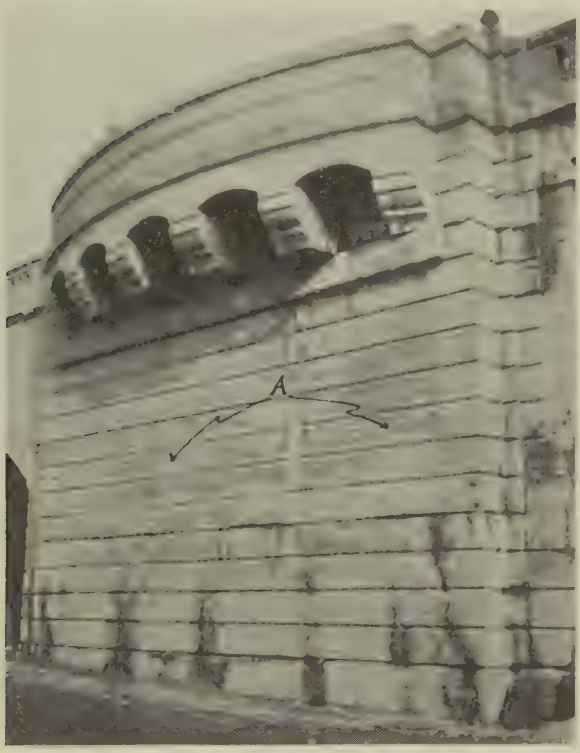

FIG. 6—POOR DRAINAGE NECESSITATED THE REPAIR OF THIS BRIDGE PIER AT "A." NOTE THE DETERIORATION OCCURRING ADJACENT TO LIME ENCRUSTATIONS

After segregation, probably the next most common type of deterioration is caused by joints, either vertical or horizontal, which are not water-tight. With these might also be classed cracks due to shrinkage or structural movements, through which water seeps. Where the concrete adjacent to the joint or crack is of poor quality, due to segregation or other causes, the deterioration may become serious. Where the concrete is good, the effect of the presence of water is likely to cause only an unsightly blemish and so the potential danger of the situation is overlooked. That there is a very real danger in the continued passage of water

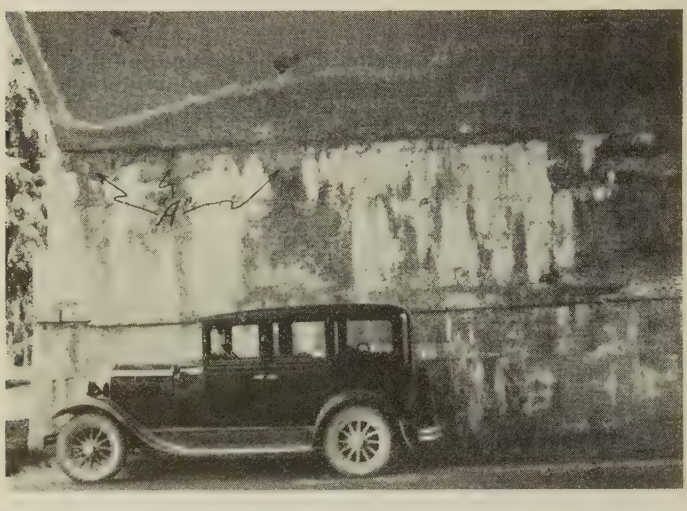

FIG. 7—ANOTHER EXAMPLE OF THE DETERIORATION OF A BRIDGE PIER CAUSED BY LACK OF DRAINAGE. NOTE AGAIN THE PRESENCE OF LIME ENCRUSTATIONS AND THE PATCHING AT "A"

through concrete is evident if one realizes that practically all its cementitious material is water-soluble and may be removed by solution if enough water is available.[4] The presence of calcium carbonate deposits, sometimes in great quantity, wherever seepage occurs is proof, if other proof is needed, of this statement.

Trouble of this kind is particularly likely to occur in hydraulic structures such as dams and conduits, but is also commonly found is retaining walls and bridges. In the majority of hydraulic structures there is no other corrective except to make the joints water-tight, which can be done by exercising the greatest care in their construction, and by the use of waterstops where, for any reason, movement of the joint may occur. In the case of retaining walls and bridges, much may be done by water-proofing and drainage. Engineers designing reinforced concrete bridges should give a great deal of thought to these points for one finds many very fine structures which would not be in their present unsightly condition if they had been properly drained.

Another very frequent cause of deterioration, especially along the sea coasts, is the corrosion of the embedded reinforcing steel.

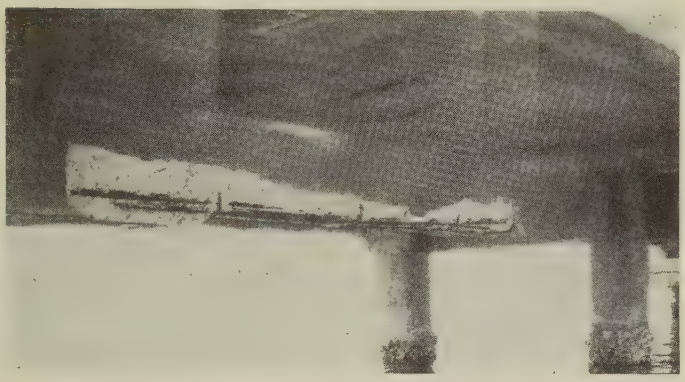

FIG. 8—ONLY 10 YEARS OLD, BUT THIS BRIDGE HAS HAD TO BE ABANDONED DUE TO THE PREVALENCE OF SIMILAR CONDITIONS

The oxides of iron, which form in the presence of moisture and oxygen from the corrosion of steel, occupy roughly two to three times the space of the original steel they replace, and consequently a reinforcing bar, if allowed to rust, will crack or spall the concrete surrounding it.

This type of deterioration is very prevalent along the sea coasts, although it is by no means confined to those localities. In the southern parts of the continent where frost action is absent, it is by far the most serious form of deterioration and the most common. It is serious because in many cases any considerable spalling of the concrete endangers the safety of the structure and may even cause its failure.

Since there seems to be no practical method of rust-proofing the reinforcement, the obvious remedy is to embed the bars in dense impermeable concrete to a depth sufficient to protect them from moisture and air. Seemingly this should not be difficult to do, as one can discover instances where as little as one-half inch of concrete or mortar gave complete protection to the steel. The present excellent condition of most of the concrete ships built during the war is proof of this, and other examples such as that illustrated in Fig. 9 are not uncommon.

However, even if the engineer designs his structure to provide sufficient embedment of the reinforcement and specifies and

FIG. 9—ONE-HALF-INCH OF DENSE, IMPERMEABLE CONCRETE HAS PROTECTED THIS STEEL FOR SIX YEARS

obtains a dense durable concrete with which to cover it, he has not done his complete duty until he designs his reinforced concrete members in such a way that the quality concrete that he has provided can be placed properly around the reinforcing steel. If the bars are so concentrated and spaced that it is impossible to get concrete around and through them without the use of excess water or over-manipulation, one can hardly blame the concrete or the workmanship for any deterioration that subsequently occurs. In the case illustrated in Fig. 9, a covering of one-half inch of the concrete had protected the steel for six years. The concrete here had the hardness and appearance of one that would test 3500 lb. per sq. in. or better, and apparently had been well cured. However, the beams made of this same concrete repeatedly show cracking along the line of the tension reinforcement, and as far as one could determine, the probable cause was the difficulty of properly placing the concrete in the bottom of the beam below and alongside of the steel.

Certain localities are blessed with very fine aggregates and in these, deterioration of the concrete due to unsound aggregate is practically non-existent. In other localities, not so blessed, cases of deterioration due to the failure of the aggregate are fairly common. The author has had the opportunity to observe con-

crete structures in several of both types of localities and while there is no question but that the quality of the aggregates has an important influence on the condition of the structures, unsoundness of the aggregate alone is seldom the primary cause of disintegration, although it is usually a contributory factor where other detrimental conditions exist.

This statement is probably more nearly true for the coarse aggregate than for the fine. In most of the cases that the author has examined where the coarse aggregate was unsound, it seemed probable that if the mortar surrounding the coarse aggregate had been of better quality, the unsound aggregate alone would not have been able to cause disintegration of the concrete. It is not at all uncommon to see evidence, such as in Fig. 13, where a great deal of unsound coarse aggregates has been used and still the concrete was generally in good condition. On the other hand, where unsound coarse aggregate is to blame for the disintegration of the concrete, the failure is usually distinctive and complete.

Unsound coarse aggregate may be protected by being surrounded by a durable mortar, but if the mortar itself is made up of unsound fine aggregate, the concrete is doomed. In such cases, the failure is a true disintegration and takes place relatively rapidly, usually manifesting itself within a very few years by a general deterioration and softening of the concrete.

There is a belief, in some quarters, that unsound cement is the cause of most of the deterioration of concrete, while others argue to the contrary. One occasionally meets with a clear-cut case of disintegration where all the evidence points to the cement as the cause, but these cases are rare. The author has made a careful examination of some dozens of deteriorated structures, the condition of which was blamed on the cement, and found therein so much evidence that other factors such as those already discussed, were mainly responsible for the present condition of these structures, that he has been forced to the conclusion, that whereas there may be cements which, although passing all the usual recognized tests, are still unstable in concrete, yet they do not have any important deleterious effect until other improper conditions are permitted to exist. The reasonable conclusion is, therefore, that if a cement meeting the present accepted standard

FIG. 10—BOW OF THE CONCRETE SHIP "FAITH" BUILT IN 1918.
NO DETERIORATION HERE

specifications is used in a structure, future deterioration caused by the cement alone is extremely unlikely.

Any discussion of the behavior of concrete in service is hardly complete without reference to the agencies that bring about their deterioration. It should always be remembered that concrete structures are exposed to the same weathering conditions which, through the ages, have levelled whole mountain ranges and totally changed the aspect of continents. It should also be remembered that the same weathering agencies are proving destructive to stone masonry and to brickwork, and that only the complete protection of iron and steel structures save them from being

destroyed in a very short time. The following little couplet appearing in the *Engineering-News Record*[5] expresses this thought os aptly as to be worth repeating:

> "Bricks will break and rocks will fall,
> Paint will peel, and concrete spall,
> Wood will rot, and steel will rust,
> Ashes to ashes, and dust to dust."

Concrete has many enemies in nature, but by far the most important is the combined action of water and frost. One has only to make a tour from north to south, examining concrete along the way, to discover the part that frost plays in the deterioration of concrete. Below the frost belt, even the poorest concrete will give service for years without appreciable deterioration, and only when used in a reinforced concrete structure where corrosion of the embedded steel causes spalling, will its poor quality become conspicuous. One finds many structures in Florida and along the Gulf of Mexico that are ten or more years old and in first-class condition, which if north of the Ohio River would, in the same period, have required extensive repairs or replacement.

It should be remembered in dealing with the action of frost that it is not the freezing of the concrete itself that is harmful, but the freezing of water that is present in the concrete. Dry concrete, no matter what its quality, is not destroyed by alternate freezing and thawing, but let the pores of that concrete be filled with water to such an extent that no space is available to take care of the expansion that inevitably takes place when water changes to ice, and disruption must occur unless the concrete is strong enough to resist the large stresses set up. If one considers that concrete is relatively weak in tension, one sees the reason why, in making concrete resistant to frost action, impermeability is so much more important than strength.

It should also be remembered that while concrete may resist one freezing or several when saturated with water, yet the continued repetition of this action will in time destroy it. Further, disintegration due to frost proceeds from the surface inward and only a few degrees of frost are required to cause freezing of the contained moisture in the surface layer. It would seem, therefore, that the effects of frost should be more severe in those sections of the continent that have the greatest number of alternate

FIG. 11—DETAIL OF BOW OF S. S. "FAITH." NOTE FREEDOM FROM STEEL CORROSION, ALTHOUGH SOME OF THE REINFORCEMENT IS ONLY EMBEDDED ONE-HALF INCH

freezings and thawings, and while this is not subject to statistical proof, it seems to be borne out in a general way by observation. It certainly is a fact that as soon as one enters those sections having more than a very few annual frosts, the evidence of frost action is almost as common and as conspicuous as in districts further north, so that it behooves the engineer in those sections having mild winters to remember that his concrete structures are subject to as severe, and possibly more severe exposure than those in more rigorous climates.

If frost is not a destructive agent except in the presence of water, then it might truthfully be said that water is concrete's worst enemy. As already mentioned, water alone will destroy concrete through its solvent action, but more important, water is the medium through which most of the other enemies of concrete carry on their attack. Sea water, sulphate-bearing waters, and bog waters are merely waters carrying impurities that render their destructive action more severe, and all act through the intimate contact that the water has with the concrete through absorption in its pores.

Perhaps the author is inclined to over-rate the importance of water as a destructive agent due to his long contact with hydraulic structures, but it is also possible that others, differently situated and not having had the same chance to observe the

FIG. 12—UNSOUND AGGREGATE CAUSED THE CONDITION OF THE CONCRETE AT THE RIGHT. THE CONCRETE AT THE LEFT IS SIMILAR IN ALL RESPECTS, EXCEPT THAT A DIFFERENT COARSE AGGREGATE WAS USED

destructive effects of water, under-rate its possibilities instead.

Research tells us that, given the opportunity, any water will, in time, completely remove the binding material which is formed in concrete by the hydration of cement[4,6,7] and a few cases of the kind have been reported in the technical press[6,8,9,10,11]. However, for the most part, engineers are inclined to think of such action as a remote possibility, but in this, they are wrong, for it is a quite common occurrence around hydraulic structures, although its true nature is often obscured by being combined with frost action.

Mention has already been made of the solvent action of water adjacent to leaking joints or cracks, but it is by no means confined to these places. Porous concrete, where totally submerged is water, will have the cementitious material dissolved therefrom in a few years, even when the water in contact with it is hard. The author has had three cases of this kind requiring major repairs, occur in his work in as many years, besides two others where the solvent action of water was the primary destructive agent, but was assisted by the surface action of frost.

FIG. 13—SPALLING DUE TO UNSOUND COARSE AGGREGATE. THE EFFECT OF THE UNSOUND AGGREGATE IS CONFINED TO THE SURFACES

Another manifestation of the solvent action of water is regularly found wherever concrete has been in contact with soft pure waters for any length of time. In such cases, the water dissolves the surface coating of cement mortar, exposing the underlying aggregate. This action takes place relatively rapidly at first, until the aggregate has been exposed, after which the action becomes very slow for then the only cement in contact with the water is that between the aggregates. The author has examined concrete structures less than two years old that have been etched in this way, and others from ten to thirty years old that had a deeper etch, but still no unravelling of the affected surfaces. In hard water this etching action is very slow.

Examples of the solvent action of water may often be found where drainage conditions are such that rain water runs over the surface of concrete. The same phenomenon will be found also on the tops of cornices, handrails, sills, and the treads of steps, and along the lower edges of the same cornices, handrails and sills, where water collects during rains.

None of these surface manifestations of the corrosive action of water are serious, but give a quantity of that same water a

chance to penetrate the concrete and the results may be very dangerous.

A study of the characteristics of those waters that have proved most corrosive to concrete, reveals the interesting fact that, whereas the hydration products of cement are soluble in any water, those that are most destructive are relatively pure waters carrying so little CaO in solution that they are lime hungry and having an acid reaction as indicated by a hydrogen-ion concentration below 7.00. These observations have been confirmed by investigations recently reported in Germany.[12]

The addition of certain salts to a water will increase its destructive properties. Sea water and the sulphate-bearing waters of the west are both cases in point, and in both, the salts involved are principally the sulphates of magnesium, sodium and calcium. The action of these compounds on the concrete appears to be both chemical and mechanical, the chemical being partly a corrosive action and partly an interference with the normal processes of hydration,[6,13] the mechanical due to the disruptive effects of the by-products of the chemical reactions, which forming compounds within the cementing matrix of the concrete require more space than the materials they replace.

A great many natural waters, both ground and river, contain one or all of the sulphate salts in solution, but unless the quantity is considerable, their presence is unimportant. However, in some parts of both western Canada and the United States, there are localities where the ground waters contain dangerous concentrations of these sulphate salts and where sulphate action becomes a matter of major importance to engineers, but generally speaking, sulphate determination is a local, rather than a continent-wide problem. On the other hand, it is found elsewhere occasionally and the engineer asked to diagnose a case of disintegrated concrete and prescribe for its treatment should not overlook that fact. Its manifestations are usually, but not always, distinctive and may easily be obscured by frost action. Where there is any suspicion of sulphate action, a chemical analysis of the disintegrated concrete will show whether or not one's suspicions are justified.[14]

All sea water structures are liable to sulphate action due to the presence of these salts in the ocean. However, while the

FIG. 14—A POROUS CONCRETE 20 YEARS OLD WHICH WOULD HAVE RAPIDLY DISINTEGRATED IF SUBJECTED TO FROST. MADE OF FINELY-GRADED SEA SAND AND SHELLS

author's observations of sea water structures have been limited, it has led him to question whether the destructive tendencies of sea water were due to the salts it contains as much as to the fact that it was water. One can duplicate in the harbors of the Great Lakes all of the types of deterioration that one sees on the North Atlantic seaboard. Along the southern coasts below the range of frost, there is little evidence of chemical deterioration of the concrete, other than the surface etching met with in fresh water where it is of a corrosive type. There is a great deal of spalling due to corrosion of the embedded steel, and while this type of action will naturally be more severe in the presence of salty moist air, it is by no means confined to the seacoast, but is quite common elsewhere. There is the further fact that sea water does not contain high concentrations of the sulphate salts. The author, therefore, is inclined to believe that most of the deterioration of concrete in sea water is due to the same factors which cause it elsewhere and not, as usually claimed, to the presence of sulphates.

We have now considered both the effects brought about by the deterioration of concrete and the principal agencies that have acted to bring these effects into being. We have also considered,

FIG. 15—ANOTHER SOUTHERN WALL OF VERY POOR CONCRETE, WHICH EXCEPT FOR LOCAL SPALLING DUE TO AGGREGATE, IS IN FAIR SHAPE

though rather briefly, some of the faults of workmanship that usually accompany deterioration. Can we not now deduce from the information thus obtained, what property of the concrete renders it susceptible to attack?

The answer to this is neither difficult nor new; the author pointed it out some years back,[15] and others have done likewise. The fundamental condition which is common to almost every disintegrated concrete is that it is porous in the sense that it is absorptive or permeable to water. Prevent the penetration of water into concrete and at once it becomes a building material highly resistant to all ordinary destructive agencies. Even in the case of those waters which will destroy any concrete in time, such as concentrated sulphate waters, the rate of deterioration is greatly reduced where it is confined entirely to the exposed surfaces, as it must be if the concrete is impermeable.

If one accepts this conclusion, as one almost must after a critical review of the evidence offered by concrete everywhere, then the problem of durable concrete becomes the problem of making it dense and non-porous, or speaking in terms of measureable properties, impermeable and non-absorptive. Reduced to these terms, the problem is theoretically easy of solution for the fundamental factors in the making of a dense, water-tight, high-

strength concrete have long been known and are generally well understood. Practically, the problem is more difficult, for the degree of skill and care used in handling and placing concrete is of paramount importance in making it durable, and proper workmanship in these particulars is not always easy to obtain.

No attempt will be made here to consider the factors necessary to produce a dense, impermeable and strong concrete. If the reader is not already familiar with them he has only to consult the recent technical literature[16,17] to find them discussed in full, but it might be useful for the author to consider briefly here a few points that his observations have led him to believe are important in any concrete which is to be subjected to severe exposures.

One of the conditions that frequently give difficulty is the use of harsh, unworkable mixtures. A concrete mixture deficient in mortar is not only more likely to segregate in handling, but even if this is prevented, it requires a great deal of spading to give presentable surfaces, which, in turn, causes scaling. Mixtures of this type are also inherently porous, because their harshness is usually due to a lack of mortar or to a mortar which is itself harsh from a deficiency in the grading of the fine aggregate. In addition to these drawbacks, a harsh mixture is more apt to segregate in handling, and because of its lack of workability, there is much more chance that some well-intentioned individual will attempt to overcome its deficiencies by the addition of water.

Another frequent cause of disintegration is the use of over-lean mixtures. Cement plays a dual role in concrete; in combination with water, it forms the glue that binds the aggregates together, but it and its products of hydration also fill and seal the smaller spaces in the aggregate mass. Any reduction in cement content beyond a certain amount is accompanied by an increase in porosity until a point is reached where, if the exposure is severe, disintegration is almost inevitable.

Instances of disintegration due to lack of cement are by no means uncommon and several have been reported to the Institute. The matter is one that every engineer would do well to remember when he specifies concrete in terms of its compressive strength. With the modern cements, it is now taking less cement to obtain concrete of a given 28-day compressive strength than it did eight or ten years ago, and the result is that quality as measured by

FIG. 16—POCKETS OF SEGREGATED CONCRETE FROM WHICH CEMENT WAS TOTALLY REMOVED BY SOLUTION. NOTE POSITION OF WATER LINE AT "A" AND SLIGHT ETCHING OF SURFACE, WHERE WATER IN CONTACT WITH IT IS HARD. COMPARE WITH FIG. 18

strength is not the same today as then. As an example, take the experience of the Hydro Electric Power Commission of Ontario. In 1920 the Commission built a hydro-electric plant and used approximately seven sacks of cement per cu. yd. to produce a concrete testing 2500 lb. per sq. in. at 28 days. In 1930 they built another plant a few miles away on the same river with aggregate and cement from the same source and using five and three-quarter sacks per cu. yd. obtained concrete testing 3500 lb. per sq. in. at 28 days. Concrete of the same strength as that made in 1920 could have been produced with about four and one-quarter sacks per cu. yd., but the latter, while as strong, would not have been as impermeable, and hence as durable and so in this case the governing feature in the choice of the cement content was durability and not strength.

Strength can never safely be taken as a measure of impermeability in a concrete, for while it is true that for a given set of conditions, the greater the strength of a concrete the less its permeability, it is not true that a certain degree of permeability will exist in all concretes of the same strength regardless of the

FIG. 17—THE FIRST CONCRETE PUT IN UNDER WATER-CEMENT RATIO CONTROL, BUILT IN 1919

aggregate, the cement content, or the treatment that it has received. A concrete of today is probably more permeable and hence less durable than concrete of equal strength made ten years ago, and yesterday's standards of quality no longer apply to today's concrete. It is the author's opinion that the widespread adoption of the strength specification for concrete is creating a situation dangerous to the industry, for the same engineers who are now adopting the newer forms of specification are still using the old standards of strength as a measure of quality, in the belief that in meeting these they are assured of a durable weather-resistant concrete.

Segregation of every form is extremely dangerous to the permanence of concrete. Some of the consequences of segregation have already been mentioned in the beginning of this paper and the practices which most frequently cause segregation were touched upon. But, whether or not segregation is the result of excess water, improper handling, a poorly designed mixture, or over-manipulation, the fact remains that practically all segregation is easily prevented by the exercise of ordinary care and forethought, and there is no excuse for any architect, engineer or contractor to tolerate its presence in any concrete work for which he is responsible. He has a right to demand and expect

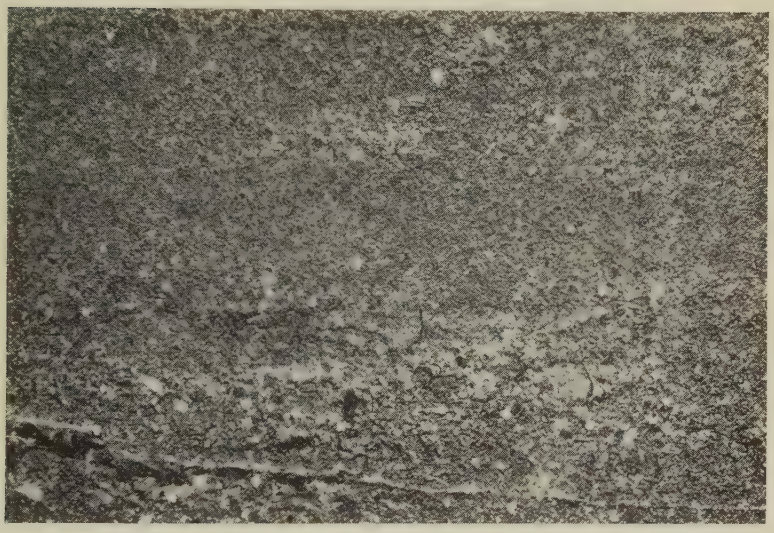

FIG. 18—CLOSE-UP OF A PART OF THE CONCRETE SHOWN IN FIG. 17 WHICH HAS BEEN ETCHED BY BEING IN CONTACT WITH A CORROSIVE WATER

good workmanship in these particulars for it costs no more to handle and place concrete without segregation than with, particularly if the effect of segregation on the cost of finishing is taken into account.

Many a concrete job falls short of perfection because of lack of the proper kind of supervision. There has to be on the job some individual with a sound knowledge of concrete armed with the proper authority, whose duty it is to see that the quality of the materials, standards of workmanship, and the after-treatment of the concrete are as they should be. The success of those outstanding cases of durable concrete mentioned in an earlier paragraph was due in no small degree to the fact that such a man was connected with the job. The Petersborough Lift Locks had Walter J. Francis; the Crystal Lake Dam, Herman Schussler; the Thomson Dam, H. C. Ash, and so on, and they are enduring monuments to these men.

Supervision of a concrete job has to be intimate and continuous to be successful. It is not enough to make a daily visit to a job as is the too common practice of many architects and engineers.

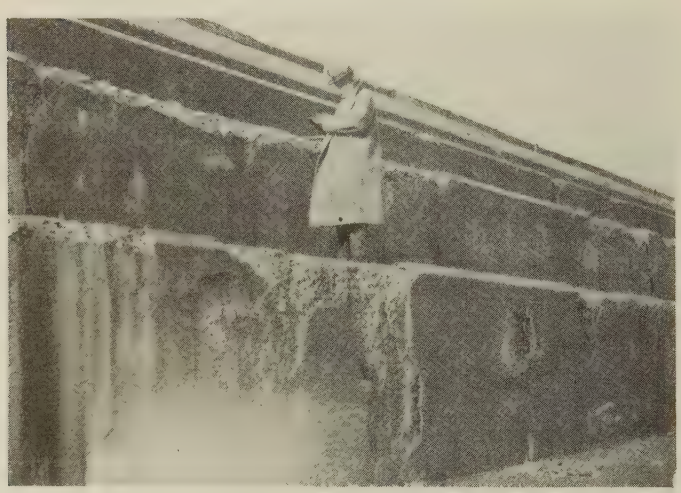

FIG. 19—SCALING AND DISINTEGRATION DUE TO HARSH WORKING CONCRETE MIXTURES AND THE CONDITIONS ARISING THEREFROM

Someone should be present immediately before and during the placing of any important concrete. Such supervision adds but little to the cost of a structure and is cheap insurance to pay for a job that will be free from future trouble. And it is the common experience of those dealing with competent inspectors that in many indirect ways they effect economies of operation that more than offset the cost of their services.

Summing up, the author has arrived at the following conclusions as a result of his experience with concrete good, bad and indifferent:

(1) Generally speaking, concrete structures are satisfactorily performing the functions for which they were built.

(2) While few concrete structures are wholly free from deterioration, the excellent condition of the greater part of even those which would be classed as examples of poor concrete, and the outstandingly good condition of others 20 or more years old, are proof that concrete is and can be made durable.

(3) Most cases of deterioration can be classified into a few types to which definite causes can be assigned.

(4) Most of the defective concrete is due to faults of workman-

ship, the use of excess water, and other causes that are strictly preventable by the exercise of reasonable care and supervision during construction.

(5) Faulty construction joints are very prevalent and under certain circumstances may start dangerous deterioration.

(6) Unsound aggregate can cause serious disintegration, but trouble of this kind is not general and usually does not become a factor in destroying concrete unless the concrete is otherwise unsatisfactory.

(7) Cement is seldom a primary cause of concrete deterioration.

(8) The principal naturally occurring destructive agents affecting concrete are frost, water, and the corrosion of embedded steel.

(9) Water, if allowed to penetrate concrete may, and often does, totally destroy it due to its solvent action on the cementitous binder.

(10) Fundamentally, most concrete deterioration is due to its being porous.

(11) The best recipe for durable concrete is to make it so dense and impermeable that water cannot enter.

(12) Harsh, unworkable concretes are prone to deteriorate.

(13) Lean concretes, no matter how strong, are not durable.

(14) Intelligent and constant supervision of concrete during construction is necessary to insure durable concrete.

DISCUSSION BY L. W. WALTER*

IN THE papers presented by Mr. McMillan and Mr. Young, the authors have brought to us some impressive lessons arising out of their experience in work directed along the lines of the activities of Committee 801. Coming as they do from men who have made it their business to acquaint themselves with the performance of concrete structures of various types under different conditions of exposure, and whose business it is to know how to overcome the deficiencies which they have observed, and which their investigations have revealed, these papers commend themselves to the careful study of all those who have been less favored by opportunity and experience.

It is brought out that, of the factors affecting the durability of concrete, the one of most concern is the action of frost on saturated concrete. It follows from this that the most important requirement of concrete, in the interest of durability, is watertightness. This requirement is essential, not only in freezing climates, but in concrete exposed to corrosive waters, and in reinforced concrete structures in or very near sea-water.

It has also been my privilege to examine many structures with which I have been familiar from a standpoint of construction and conditions of exposure, and to have accompanied the authors of these papers in a survey of many structures in a climatic range extending from Key West, where frost is unknown, through the northern part of the United States and southern Canada,

*Inspecting Engineer, Erie Railroad Co., Jersey City, N. J., Member Committee 801.

where frequent cycles of freezing and thawing have their telling effect on concrete of inferior quality, and into the north woods where a diminishing number of freezing and thawing cycles seem less severe in their toll, even though the winter temperatures are low. My conclusions from these examinations are in agreement with those of the authors of the papers presented.

There is one important matter brought out in Mr. Young's paper which I particularly desire to emphasize, namely, that strength alone is not a dependable measure of water-tightness or durability.

In the design of concrete to meet the fundamental requirements for strength, durability and economy, too little consideration is being given to the fact that, as measured by 28-day test results, present day cements carry higher strength-giving quality to the concrete than was characteristic of cements of earlier periods, but do not produce correspondingly higher ultimate water-tightness when used in like proportions.

The gradual but constant stepping up from year to year in strength-giving quality of cement, as determined by the 28-day tests, without its contributing, in a corresponding degree, to higher ultimate water-tightness of concrete, calls for extreme caution in the selection of a particular class of concrete, classified on a strength basis.

Unfortunately, many users of concrete are overlooking the basic principle of the water-cement ratio law, and, in trade practice, are depending upon strength as the sole measure of quality. With present day cements, it is possible to get relatively high 28-day strength of concrete with mixtures lean in cement and with a high water-cement ratio. Such mixtures are too porous to withstand unfavorable exposure.

In order to stop this trend in trade practice, and to safeguard against the use of these porous mixtures, it seems necessary to indicate in our specifications (separately for each class) not only the maximum allowable amount of water per bag of cement, but also the minimum allowable amount of cement per yard of concrete.

Readers are referred to the JOURNAL *for Nov. 1931, (Vol. 28) for further discussion of the two preceding papers which may develop. Such discussion should reach the Secretary by Oct. 1, 1931.*

The Permeability of Gravel Concrete*

BY PAUL T. NORTON, JR.† AND DAN H. PLETTA‡

INTRODUCTION

The research project reported in this paper was begun three years ago in the Mechanics Department at the University of Wisconsin in the hope of determining the relationship between permeability and water-cement ratio, and also the relationship between permeability and such other properties as strength, consistency, absorption, cement-voids ratio and grading of aggregate.

A number of permeability tests had previously been made in this laboratory. In none of these earlier tests was the water-cement ratio computed, although F. R. McMillan has figured the water-cement ratio for the concretes reported in University of Wisconsin Bulletin 1245 (1923) and has plotted the flow of water against these values.

The data used in establishing the results of these observations were obtained from a series of tests repeated five times in order to aid in securing accurate averages. The program included the making and testing of 34 different mixes, with each of which three or four different amounts of water were used, ranging from that required for normal consistency to 35 per cent more than that amount. The mixes were designed to cover the range from those suggested by the Fuller-Thompson curve to others which were much over-sanded. A complete series of 34 mixes was made and the series repeated five times in order to eliminate as much as possible such things as the aging of cement, the varying relative humidity, the change in temperature, the curing condition of the

At the time these tests were made Mr. Norton was Assistant Professor of Mechanics and Mr. Pletta was Instructor in Mechanics at the University of Wisconsin.

specimens, the personal equation, etc. With each permeability specimen made from a given batch, two 6 x 12-in. cylinders were molded. One of these was used to obtain the compressive strength of the concrete, and the other for absorption testing. Nearly 2000 specimens were made and tested.

This research project was made possible through the research fund of the Mechanics Department of the University of Wisconsin. The authors are grateful to the institution with which they were formerly connected for the opportunity of carrying on this work and to Prof. M. O. Withey for his careful supervision of the tests and helpful suggestions in the writing of this paper. The authors also wish to thank M. E. Basford, Azmi Jemil, Robert Greiling, Leo Janicki, M. O. Scott and the others who assisted in the tests, and also the Atlas Portland Cement Co., the Lehigh Portland Cement Co., and the Universal Portland Cement Co. for their donations of the cement.

MATERIALS

Cement—The cement used in these tests was a mixture of equal parts of Universal, Lehigh and Atlas portland cement. Twelve barrels of each were mixed and stored in bulk in a large galvanized iron bin, which was made as air tight as possible by having the seams calked with tar and the door edged with felt. About 20 lb. of each brand was removed before the mixing and used for testing the individual brands and a like amount of the mixture set aside for a similar purpose.

The results of these tests are shown in Tables 1 and 2. Table 1, showing the chemical analysis of the individual cements, represents the tests of the respective manufacturers. Table 2 outlines the physical properties of each of the cements and of their mixture as determined at the laboratories of the manufacturers and the University of Wisconsin testing laboratory. The tensile and compressive test specimens were made, stored and tested according to A. S. T. M. specifications. The loose weight per cubic foot of cement was assumed to be 94 lb.

Sand—Mixes "A" to "a" inclusive, see Table 6, were made of Janesville sand, and "b" to "k" inclusive of University sand. Janesville sand is about two-thirds quartz and one-third dolomite; University sand is almost entirely quartz. Tables 3 and 4 show

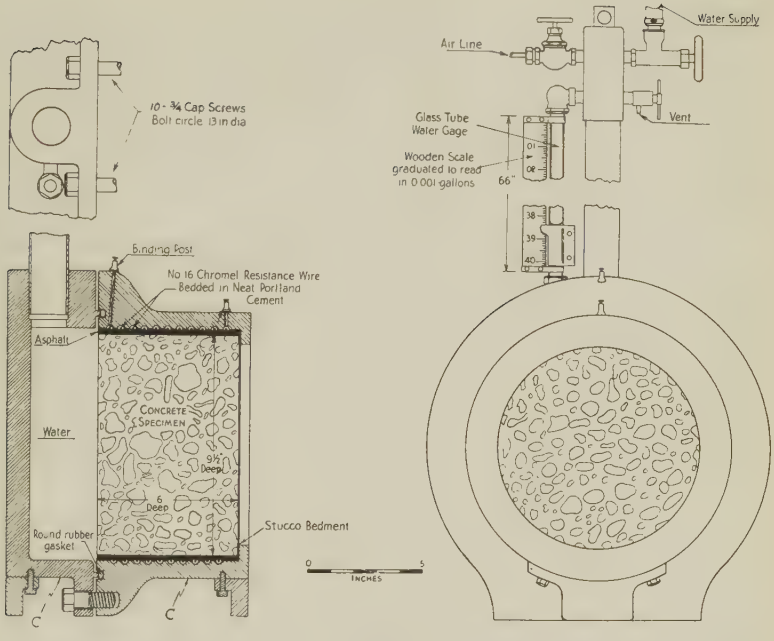

FIG. 1—APPARATUS FOR TESTING THE PERMEABILITY OF CONCRETE TO WATER

the physical properties of the two fine aggregates. All of the sand was screened through a ¼-in. sieve before it was tested or used.

Gravel—As the gravel was received it was screened into three sizes: ¼ to ⅜, ⅜ to ¾ and ¾ to 1½ in. The specific gravity and absorption of the three sizes varied somewhat, and since the individual sizes were combined to make the five different coarse aggregates used, the specific weights, specific gravities and absorptions also differed. This information is shown in Table 5. All of the material was Janesville gravel with the exception of the largest size used in the "Z" and "a" mixes. This was obtained from a gravel pit near Madison to reduce expense.

Mixed Aggregate—The sand and gravel were combined into 34 different mixes and the characteristics and proportions of materials in each are shown in Table 6.

Preparation of Materials—The sand was air dried before it was used by spreading it on the floor of the testing laboratory and

raking it occasionally for a day or two. The gravel was air dried in separate storage bins. About four hours before mixing the moisture content both of the sand and of the individual sizes of coarse aggregate to be used was determined by weighing a 500-gram sample, heating it in an oven to constant weight and then weighing it again. This information was used to determine the amount of water to be added to a particular batch so that the water-cement ratio would remain constant for individual batches throughout the series of tests. The temperature of the mixing water was kept at approximately 70 deg. F.

Weighing the Materials—The cement and aggregates for each batch were weighed on a scale sensitive to 0.05 lb. and the water on a scale sensitive to 0.01 lb. After the cement, sand and the individual sizes of coarse aggregate had been weighed separately they were weighed collectively for a check.

MAKING THE SPECIMENS

Mixing the Materials—After the materials had been weighed the sand and cement were placed on a metal mixing tray about 3 ft. 8 in. by 5 ft. 6 in., the surface of which had just been moistened. The cement and sand were first mixed to a uniform color by two men, working from opposite sides of the tray, turning the batch over twice with square pointed shovels. The coarse aggregate was then added and the mixing repeated. The water was poured into a crater formed in the aggregate and the material forming the crater was worked in toward the center. After the batch had been allowed to stand for a half minute it was mixed by turning over fourteen times.

Slump and Flow Tests—The slump and flow tests were made for each batch 10 minutes after completion of the mixing. There was a twofold purpose in the delay; it allowed the aggregate, which varied in moisture content from time to time, to absorb enough moisture so that the consistency remained almost constant for the same batches later in the series and it provided ample time to weigh materials for another batch.

Setting Up and Filling the Molds—The molds for the 6 x 12-in. cylinders used for the strength and absorption tests were set up on leveled steel plates. The molds for the permeability specimens were made of cylindrical metal sides with wooden bottoms

that had been thoroughly soaked in oil. The molds were oiled each time before they were filled.

Each batch of concrete was placed in the three molds as soon as possible after the slump and flow tests had been made. The 6 x 12-in. cylinders were filled one-third full, then tamped 25 times with a $\frac{5}{8}$-in. rod, then refilled another third, etc., and the top finally finished with a trowel. A metal plate was used as a cover to prevent evaporation. The permeability mold was filled half full and tamped 25 times, then filled completely and re-tamped, and the mold leveled off with a tamping rod. These molds were covered with wet cement sacks to retard drying.

Stripping the Molds—The molds were removed after 24 hr. The outer film of concrete on the top and bottom of the permeability specimen was removed with a wire brush and one of the other cylinders, later to be used for the absorption test, was subjected to a similar treatment on all surfaces. The other specimen was used for the strength test. The marks identifying the batches were painted directly on the specimens.

Curing the Specimens—As soon as the molds had been stripped and the specimens painted they were placed in a moist closet where they remained until 28 days old. Not more than eight batches were made at any one time, for the permeability apparatus was designed to test a maximum of eight specimens. The permeability test ran for at least 50 hr. and thus the frequency with which the eight batches could be made was also controlled.

APPARATUS

Permeability Apparatus—The apparatus for measuring the flow of water into the permeability specimens is shown in Fig. 1. The smallest divisions on the scale represent 0.001 gal., and, by use of the sliding target, readings may be interpolated to 0.0001 gal., although in this test such precision was adhered to only when reading the dummy, the readings for the test specimens being made to 0.0005 gal. The coil of high resistance wire was bedded in portland cement mortar which was mixed quite wet and cured for several days in the moist closet. The coil was used to heat the casting.

The air pressure system included two reservoirs, distribution pipe, flexible copper connecting tubes, a pressure gage and the necessary needle valves. The reservoirs were of relatively large

capacity when compared to the distributing pipe and so insured an almost constant pressure during the run.

The dummy consisted of a test unit similar to those used for the actual testing with the exception that the dummy specimen was cast on the outside of an iron plate and this bolted to a casting (c). The volume of water in the casting was the same as in the regular test units.

A wet and dry bulb thermometer and an electric fan for directing a current of air against the wick of the wet bulb were a part of the apparatus.

Heater for Absorption Specimens—The absorption cylinders were dried in a double-walled gas heater that was insulated on the top and sides with an asbestos covering. A solution of glycerine and water, mixed in such proportions that it boiled at about 220 to 240 deg. F., filled the space between the walls. The heater was large enough to dry 48 cylinders at one time.

TESTING

Length of Curing Period—Specimens were ordinarily removed from the moist closet at an age of 28 days. The permeability specimens of the first few lots were removed three or four days earlier with the expectation that they would be ready for testing on the 28th day but this was found to be impossible, and for the balance of the test specimens of all three types were removed at an age of 28 days, except for six lots which were removed at 27 days, 11 lots at 29 days and one lot at 30 days.

Compression Cylinders—Compression cylinders were broken on a 200,000-lb. testing machine the day they were removed from the moist closet. The top of the cylinders as molded was capped with neat gypsum plaster and the bottom also similarly capped in the few cases where an examination showed that this surface was not plane.

Absorption Cylinders—When the absorption cylinders were removed from the moist closet, they were first cleaned with a fiber brush, and then weighed to 0.01 lb. and left to accumulate until there was room in the heater. After they had been dried to constant weight they were immersed in water at room temperature and weighed after ½, 6, 24 and 48 hr. They were then capped on both ends and broken the same day. The weight after 48 hours in water was approximately the same as when first re-

moved from the moist closet so that the compression and absorption cylinders contained about the same amount of water when broken.

Permeability Specimens—With the exceptions noted in the first paragraph of this section permeability specimens were removed from the moist closet at an age of 28 days. They were immediately brushed to remove any loose material and weighed in air and in water to secure data from which the density of the concrete could be calculated. One coat of an asphalt priming paint was applied to the cylindrical surface to aid in securing a watertight bond. It was found that the surface of the specimen was dry enough for the priming coat after remaining in the dry air of the laboratory for about three days and that the priming coat required about 24 hr. to harden.

The first operation in the sealing process was to place the casting in a horizontal position with the circular shelf that supported the outer face of the specimen on the bottom. A small amount of neat gypsum plaster was then spread on this shelf and the specimen immediately placed and centered in the casting. The plaster bed prevented the molten asphalt from escaping during the pouring and supported the specimen rigidly in the casting when the air pressure was applied. Specimens were so placed in the casting that the flow of water was from the bottom to the top as originally molded.

After the plaster bed had dried for at least a half hour the casting was heated by passing an electric current through the resistence coil for three to five minutes. This was done for two reasons; first, to prevent the molten asphalt from being chilled before it could completely fill the space around the specimen and, second, to improve the seal by compressing the asphalt as the casting shrank upon cooling. Crystal Steep Roofing asphalt was used.

After the asphalt was poured, the casting with the specimen sealed within it was bolted to the other part of apparatus, the soft rubber gasket having first been put in place. The permeability tube was then filled with water and the copper tubing carrying the air pressure to the top of each water column attached. After the air had been applied the valves between the air reservoirs and the rest of the apparatus were closed to determine

whether there were air leaks in the tubing or connections. The actual testing was begun after any such leaks had been stopped and the air valves opened. Readings were then taken of the height of the water in the permeability tubes, of the height of the water in the dummy unit, of the air pressure and of the temperatures as read from a wet and dry bulb thermometer. All of the readings were taken every time the height of the water in the permeability tubes was read.

Ordinarily readings were taken and the face of each specimen examined at intervals of one hour or so for the first few hours and afterwards at greater intervals. In general at least three readings were taken each day during the 50-hr. test period.

Changes in air pressure and in room temperature produced changes in the height of the water column. In order to correct for such changes the dummy readings were employed. It was found, however, that the corrections for such changes were necessary only in the less permeable specimens.

The room temperature and relative humidity were not considered in calculating the data, for they appeared to have no material effect on the flow of water through the specimen, although they probably had some effect on the appearance of the face where there was enough water flowing through to make the surface appear slightly damp.

The pressure on the top of the water column was maintained as nearly as possible at 40 lb. per sq. in. except in some of the later tests where 100 lb. was used. In most cases it varied only slightly during the run. The increase in pressure on the specimen due to the height of water in the tube was not considered, for the differences in water flow due to such small changes in pressure are much less than the difference regularly found between two specimens of the same mix.

Untreated city water was used, it being considered that the test period was too short to permit clogging of the voids in the concrete by sediment in the water or by bacterial action. It should be noted that the apparatus was completely drained of water between runs and a fresh supply used with each set of specimens.

While no attempt was made to measure the water flowing from the concrete, the face of each specimen was carefully examined at

each reading and its condition noted on the data card. A defective seal could be detected by the appearance of water at the edge of the specimen. In such cases a notation was made on the card and the specimen rerun at the first opportunity. Some of the specimens were plainly defective and such specimens were not considered in calculating the data.

At the end of the test period the air valve leading to the reservoirs was closed and the casting containing the specimen removed from the apparatus. The casting was then turned so that the specimen would drop out when the asphalt was melted by passing an electric current through the heating coil imbedded in the casting. The inside of the casting was scraped to remove the asphalt and the gypsum that did not come out with the specimen and it was then ready for the next specimen.

COMPUTATIONS

Permeability—The data on the flow of water was plotted on graph paper, the flow being plotted against time, and the resultant curve corrected when necessary from readings of the dummy. The 20, 40 and 50-hr. flow was read from the curve and listed in a table. The flow for the 20 to 50 and 40 to 50-hr. intervals was thus obtained, the units being gal. per sq. ft. per hr. The values are given in Table 8. Whenever the test results for any one specimen did not conform more or less to the average of other specimens of the same mix, the data were discarded and the specimen rerun at a later time. In a few instances so much difficulty was experienced in obtaining data that only three values were used in the average, but this was true in only about 5 per cent of the cases. About 60 per cent of the results are the averages for five values and 35 per cent the average of four values.

Density—In computing the density of the individual batches the weights of the permeability specimen in air and in water were used together with the total weight of the batch, including the water, and the specific gravity of the cement, sand and gravel. The following formula was used:

$$\rho = \frac{\left[\frac{W_c}{62.5K_c} + \frac{W_s}{62.5K_s} + \frac{W_g}{62.5K_g}\right]\frac{W_p}{W_b}}{\frac{W_p - W_{pw}}{62.5}}$$

ρ —Density or absolute volume of cement, sand and gravel per unit of concrete volume.
W_c —Weight of cement used in batch.
W_s —Weight of sand used in batch.
W_g —Weight of gravel used in batch.
W_p —Weight of permeability specimen in air.
W_{pw}—Weight of permeability specimen in water.
W_b —Weight of batch including water.
K_c —Specific gravity of cement.
K_s —Specific gravity of sand.
K_g —Specific gravity of gravel.

It will be noted that the first term in the brackets gives the absolute volume of cement in the batch. The absolute volume of cement per cubic foot of concrete was obtained by dividing the absolute volume of cement in the batch by the volume of the batch. This latter value was computed from the weight of the permeability specimen and of the batch and the volume of the permeability specimen.

Absorption—The absorption was calculated for the ½, 6, 24, and 48-hr. intervals using the oven dry weight of the specimen as a basis. The results for the five specimens of any one mix and consistency were averaged and these results are listed in Table 8. In a few cases, when readings were not made exactly on schedule, the results of the individual specimens were plotted and an average curve drawn through these points. The data were then obtained from this graph.

Water-Cement Ratio—The water-cement ratio was computed for the first series and in the four succeeding ones it was kept constant, the amount of mixing water required for the batches being calculated in advance after the moisture content of the aggregate had been determined. A correction was made for the absorption of the aggregate in all of the computations. At the beginning of the second series the total absorption for the aggregate was not known exactly and so the same amount of water was used that was used in the first series. Later, when the water-cement ratios for these batches had been computed, it was found that they were almost exactly the same as those of the first series. The average values are shown in the tables.

RESULTS OF TESTS

Significance of Data from these Permeability Tests—When considering tests of this sort it should be remembered that laboratory tests on the permeability of concrete are qualitative rather than quantitative and that differences between types of apparatus, size and shape of specimens and other differences in the manner of performing the tests make it impossible to compare directly the rate of water flow through concrete of a given composition as determined by different laboratories. Also, it hardly seems possible to reproduce conditions in an actual structure with the small specimens of the laboratory but in a properly conducted laboratory it should be possible to compare the permeability of different concretes under laboratory conditions. It would seem reasonable that of two different concretes the one that showed the greater leakage in the laboratory would also show the greater leakage in an actual structure, but it should not be expected that a concrete which showed water on an exposed face in the laboratory would necessarily do so in an actual structure, or vice versa. In these tests the relative permeabilities of different concretes are compared under laboratory conditions, these conditions having been maintained as nearly constant throughout the test as was possible.

In these tests the flow of water reported represents flow into the specimen and thus includes both the water absorbed by the specimen and that flowing through the specimen. The flow curves plotted from the data cards showed a high initial rate of flow whch gradually decreased as the run continued and the specimen approached the saturation point. The absorption data reported on cylinders from the same concrete showed there was little or no increase in weight after the cylinders had been immersed in water for even 24 hr. so that it is reasonable to suppose that very little of the flow noted for the 40 to 50-hr. period represented water absorbed by the specimen. In Table 10 it can be seen that there is some difference in the flow for the 40 to 50 and 100 to 110-hr. intervals, but since this represents flow under 100 lb. per sq. in. pressure the differences are probably greater than they would be under lower pressure. None of the concrete was wholly impermeable as far as flow into it was concerned, even though the exposed face apparently was perfectly dry. In such cases the

rate of flow for the 40 to 50-hr. period was very low, being less than 0.001 gal. per sq. ft. per hr. in all cases and much less than that in most cases where there was no sign of moisture during the test. Such small amounts of water might readily evaporate on reaching the free surface. As might be expected the flow curves showed that the rate of flow was decreasing slightly even at the end of the 50-hr. period. It has been shown in other tests that the better the curing and the longer the curing continues the less permeable the concrete becomes. The curing conditions during the run were most excellent so that a continuous but very slight decrease in flow might be expected.

Table 8 gives the rate of flow for both the 20 to 50-hr. period and the 40 to 50-hr. period, but only the flow for the latter period will be considered for this report.

For various reasons it was impossible to test all specimens at the same age, but they were removed from the moist room to the dry air of the laboratory at an age of 28 days (a day earlier or later in a few cases as noted in a previous section). These tests and those reported by others indicate but little decrease in permeability after proper curing is discontinued so that the slight average differences in age at the time of testing were disregarded.

It would seem that the method used in these tests of measuring the water flowing into the concrete is superior to those methods which measure the water flowing from the concrete. Concrete of ordinary mixes and properly cured for 28 days is so impermeable that no measurable amount of water escapes from the exposed face, making it necessary to use either much leaner mixes than are ordinarily used in the field or to test the specimens at a very early age. Furthermore there is no way of differentiating between concretes which appear dry on the exposed faces or between concretes permeable enough for the exposed faces to be wet but with not enough flow for it to be measurable. With the method used in these tests any concrete may be tested at any age and the flow of water into the specimen measured.

Relation of Flow to Water-Cement Ratio—Figs. 2 and 3 show flow plotted against water-cement ratio. In Fig. 2, this relation for the 10 most impermeable mixes, is so shown that it is possible to tell at a glance whether the exposed face was dry, somewhat wet or quite wet. In some cases the mix with the lowest water-

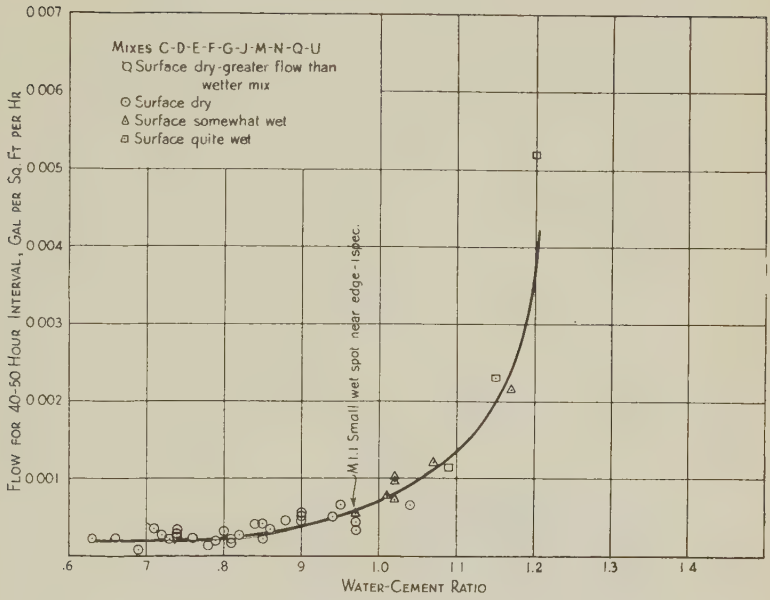

Fig. 2—Relation of flow to water-cement ratio for most impermeable mixes

cement ratio had a greater flow than the same mix with a higher water-cement ratio, although in neither case was there any indication of water on the exposed face of the specimen. Fig. 3, showing the relationship for all mixes, indicates that the correlation between water-cement ratio and flow is only general, and that such other properties as grading of aggregate, richness of mix and consistency affect this relationship to a considerable degree. For instance, of the 10 most impermeable mixes shown in Fig. 2, mixes E, F, G, M and N with 40 per cent Janesville sand and a fineness modulus of 5.5 had about the best grading of aggregate, while mixes C, D, J, Q and U were rich mixes of poorer grading, indicating that with the best grading of aggregate an impermeable concrete can be obtained with a rather lean mix, but with a poorer grading of aggregate a rather rich mix is required.

From a study of Fig. 3 and Table 8 it can be seen that for these tests the exposed face of the specimen was at least somewhat wet whenever the water-cement ratio was over 1.0 (7.5 gal. per sack of cement) with the single exception of mix F-1.2, and that with

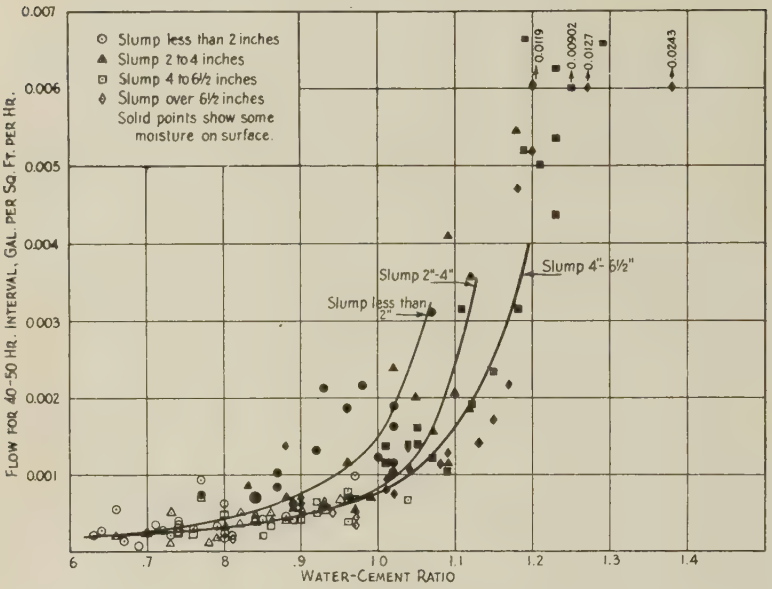

FIG. 3—EFFECT OF WATER-CEMENT RATIO AND SLUMP ON FLOW FOR ALL MIXES

such poorly graded mixes as Y-1.0 and a-1.0 the exposed face was wet although the water-cement ratio was much lower. In Fig. 3 the solid points indicate that the exposed surface was somewhat moist or wet, and their position shows that when the flow was less than 0.0005 gal. per sq. ft. per hr. the exposed face was dry for all mixes, but when the flow was 0.001 gal. per sq. ft. per hr. or more, the exposed face was at least somewhat wet for all mixes.

It might be mentioned at this point that mix R, which was the strongest concrete tested, showed up very badly in all cases where flow was plotted against water-cement ratio, strength or other variables. There was unusual variation between the flow of the different specimens of this mix but not enough to justify discarding any of them from the calculations. It would seem that the mix R (1:4 by volume) should have given at least as good results as mix Q (1:5 by volume) which had the same grading of aggregate. The densities for the two mixes were almost the same.

Relation of Flow to Consistency—This relationship is shown to a certain extent by Fig. 3 but more accurately by Fig. 4. Fig. 3

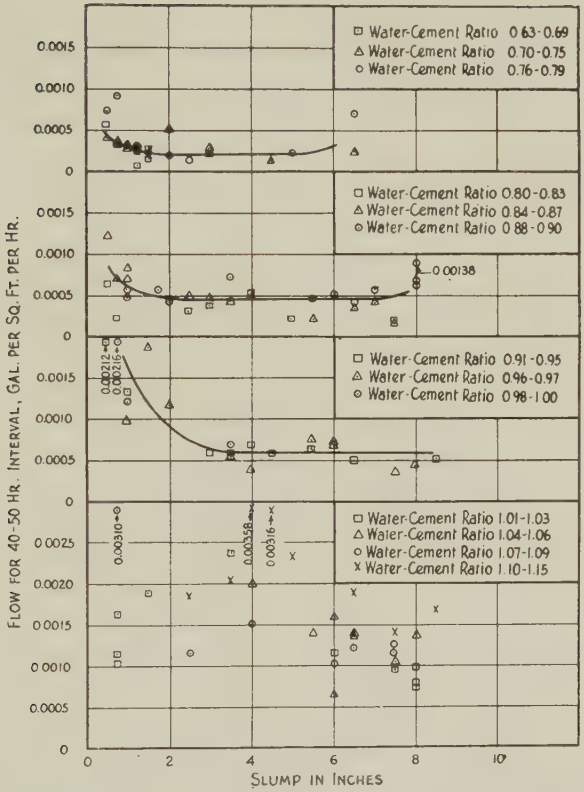

FIG. 4—EFFECT OF CONSISTENCY ON FLOW FOR MIXES OF APPROXIMATELY THE SAME WATER-CEMENT RATIO

indicates that the less permeable mixes are those with low water-cement ratios and that it is possible to have rather impermeable mixes with relatively high slump. The scattering of points made it difficult to draw accurate curves or definite conclusions from Fig. 3. Fig. 4 shows more clearly that the most impermeable mixes are obtained with low water-cement ratios when the slump is at least 2 in., that for higher values of water-cement ratios less impermeable mixes are obtained, and that to obtain the most impermeable mixes for a given water-cement ratio the minimum permissible slump must be increased with increase of water-cement ratio. For very high water-cement ratios the scattering

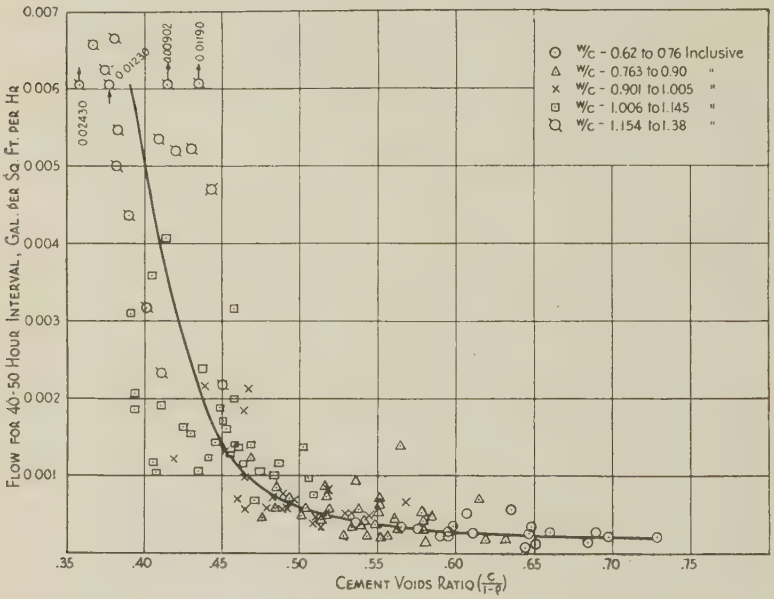

FIG. 5—EFFECT OF CEMENT-VOIDS RATIO AND WATER-CEMENT RATIO ON FLOW FOR ALL MIXES

of points indicates that definite control over the properties of the mix is lost and that, in general, high slumps are required for the most impermeable concrete. It should be remembered that all mixes used in these tests had sufficient water to make them plastic and workable and that those mixes with a slump of less than 2 in. obeyed the water-cement-strength law even though the flow of water through them was, in most cases, greater than mixes of slightly higher slump. In 15 cases the 1.1 mix showed a lesser flow than the 1.0 mix and in 9 of these mixes the average slump for the 1.1 mix was from 2 to 3 in. In 19 cases the 1.1 mix showed a greater flow than the 1.0 mix and in 12 of these the average slump was over 3 in. The water-cement ratio of the 1.1 mix was 10 per cent greater than that of the 1.0 mix, while the flow of water was less for the 1.1 mix in the majority of cases where the slump of the 1.1 mix was from 2 to 3 in. This confirms what has been found in other permeability tests; that a wetter mix is required for minimum flow than is required for maximum strength.

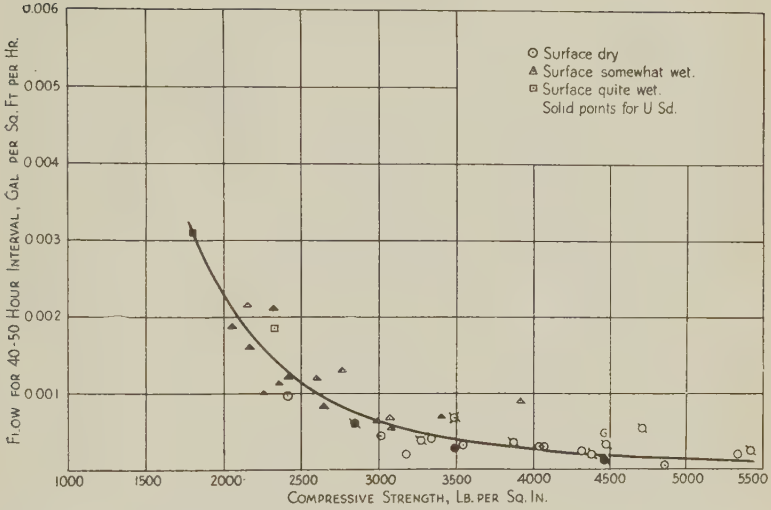

FIG. 6—RELATION OF COMPRESSIVE STRENGTH TO FLOW FOR MIXES WITH SLUMP LESS THAN 2 INCHES

Relation of Flow to Cement-Voids Ratio—Fig. 5 shows flow plotted against cement-voids ratio for all mixes, and with varying ranges of water-cement ratio. From this figure it would seem that there is a slightly more definite relationship between flow and cement-voids ratio than between flow and water-cement ratio. It is reasonable that this should be the case, for the grading of aggregate and consistency, which are important in influencing the flow affect the value of the cement-voids ratio but not the water-cement ratio. The slump, however, had some effect on the relation of flow to cement-voids ratio, for when the data were separated into four slump ranges and plotted, the curve for the 2 to 4 in. slump was farthest to the left.

Relation of Flow to Compressive Strength—Figs. 6 and 7 show flow plotted against compressive strength for two ranges in slump; the former figure for mixes with slump less than 2 in. and the latter for mixes with slump over 6½ in. Space does not permit publication of the curves for mixes with slumps from 2 to 4 in. and from 4 to 6½ in. These two curves lie within those shown in Figs. 6 and 7, with a shift to the left as the slump increases. There is apparently a somewhat closer relationship

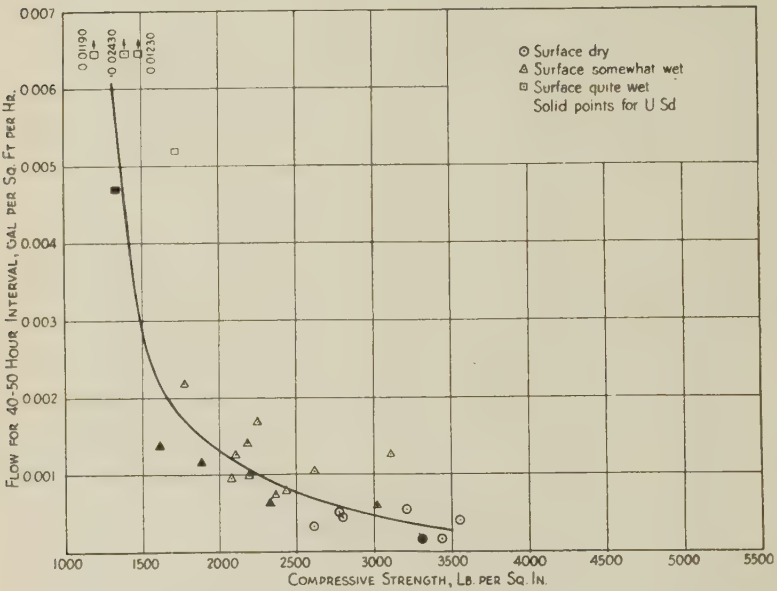

FIG. 7—RELATION OF COMPRESSIVE STRENGTH TO FLOW FOR MIXES WITH SLUMP OVER 6½ INCHES

between flow and strength than between flow and water-cement ratio. In these tests only one mix having a strength of over 3500 lb. per sq. in. showed any moisture on the exposed face, while all mixes with a strength of less than 2250 lb. per sq. in. showed some moisture on the exposed surface.

Relation of Flow to Proportion of Cement—Fig. 8 shows the cement-dry aggregate ratio (by weight) plotted against flow for mixes with a 2 to 4-in. slump. Average curves for mixes with other ranges of slump lie to the right of the one shown in the figure. They indicate that, in general, rich mixes are most impermeable.

Relation of Flow to Grading Aggregate—Fig. 9 shows flow plotted against fineness modulus for various proportions of cement and for two ranges of slump. The 1-4 and 1-5 mixes by volume agree with what has been shown already; i. e., that the more impermeable mixes are those with slumps greater than that required for normal consistency. The 1-6 mixes, however, show a marked

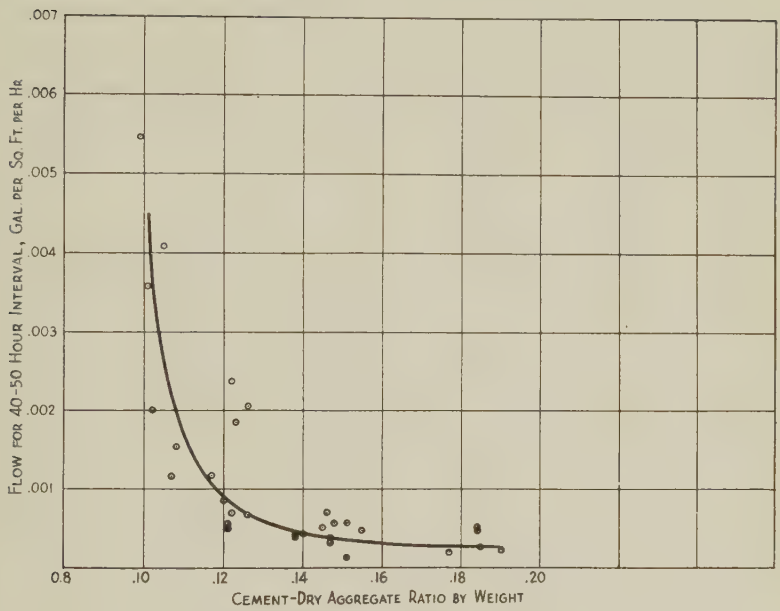

FIG. 8—RELATION OF CEMENT-DRY AGGREGATE RATIO TO FLOW FOR MIXES WITH 2 TO 4-INCH SLUMP

difference. In plotting this graph it was very difficult to obtain good curves unless the slump was restricted to narrow limits, and naturally only a few mixes could be used. This curve is not entirely irreconcilable with what is shown in Fig. 4, for it represents lean mixes of poor or fair grading, and it might be expected that for these the most impermeable concrete is that with only enough water to make it plastic. Fig. 9 indicates that as mixes become leaner, the fineness modulus must increase if minimum flow is desired. Roughly this variation is from a fineness modulus of 5.2 for a 1-4 mix to 5.8 for a 1-6 mix by volume.

The previous paragraphs indicate that a well graded aggregate is even more important from the standpoint of water tightness than it is from the standpoint of strength. A study of the grading of aggregate for the 10 most impermeable mixes shown in Fig. 2 indicate that when large sizes of coarse aggregate predominate, as for mixes C, D, E, F, G, J, M and N, rich mixes like 1-4 or 1-5 should be used when the mixes are slightly over or under sanded

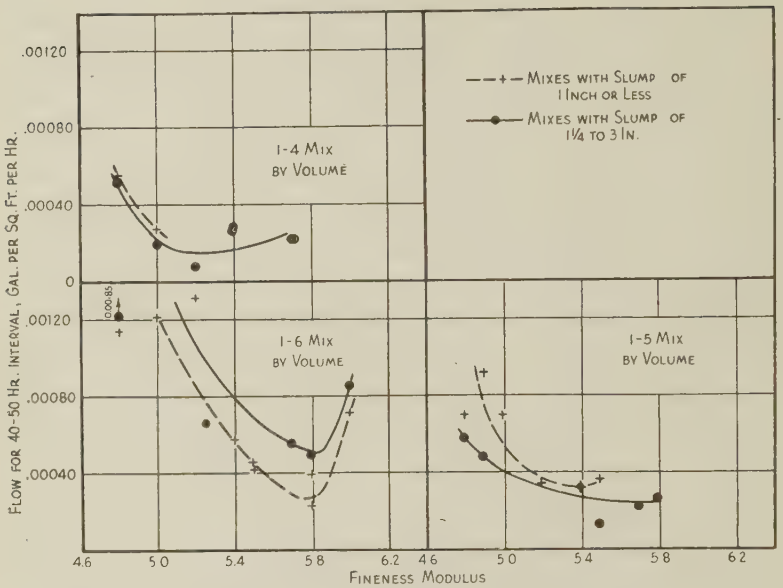

FIG. 9—RELATION OF FINENESS MODULUS TO FLOW FOR MIXES WITH SLUMP LESS THAN 3 INCHES

(50 or 35 per cent sand), but where the proportion of sand is 40 per cent by weight of the mixed aggregate the leaner mixes like 1-5 or 1-6 may be used. When the smaller sizes of coarse aggregate predominate, as in mixes Q and U, a 1-5 mix can be used with 35 per cent sand but this mix must be made richer when a greater proportion of sand is used.

Relation of Compressive Strength to Absorption—Fig. 10 shows this relationship for Janesville sand mixes. The one for University sand was similar but is not shown. In general the higher values of fineness modulus showed least absorption, but there was little difference for the best concretes.

Relation of Water-Cement Ratio to Absorption—Fig. 11 shows this relationship for mixes with a 1½ to 3-in. slump. In plotting this graph, as in some previous cases, it was necessary to restrict the consistency to narrow limits in order to obtain a satisfactory curve. As might be expected the absorption increases with an increase in water-cement ratio.

Relation of Flow to Absorption—Graphs showing this relation-

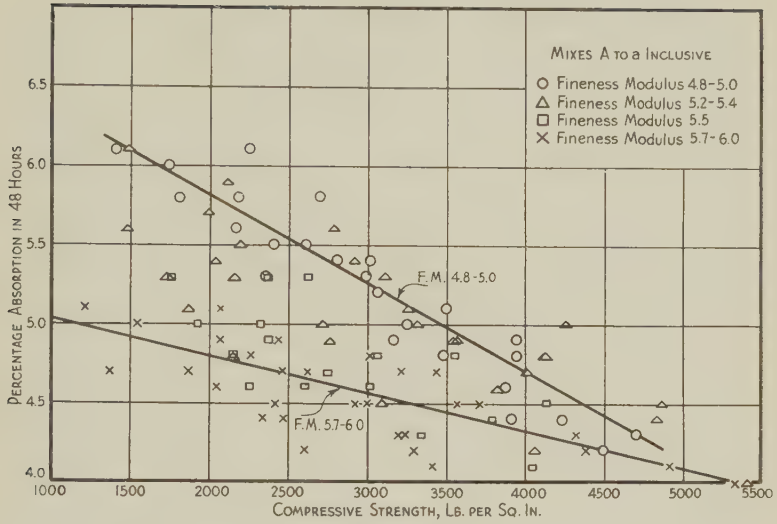

FIG. 10—RELATION OF COMPRESSIVE STRENGTH TO ABSORPTION FOR JANESVILLE SAND MIXES

ship were plotted but the individual points were spread too much to draw curves through them. Those mixes with the least flow had least absorption. This agrees with Fig. 12 which shows that mixes with greater density had least absorption.

Relation of Strength to Water-Cement Ratio—Fig. 13 shows the familiar relationship of strength to water-cement ratio. It is to be noted that the University sand mixes have less strength for given values of water-cement ratio than the Janesville sand mixes. The University sand was very fine and poorly graded, hence mixes containing it had lower strength than similar mixes of Janesville sand.

High Pressure Test Results –Some six months after the testing had been finished at the 40 lb. per sq. in. pressure 19 mixes were selected as representative ones and tested for 110 hr. at 100 lb. per sq. in. pressure. The results of these tests are shown in Table 10 and Fig. 14. The age of the specimens when first tested at the lower pressure averaged about 40 days and that of seven of these when retested about 150 days. The age when tested at the higher pressure averaged about 14 months. Fig. 14 shows, how-

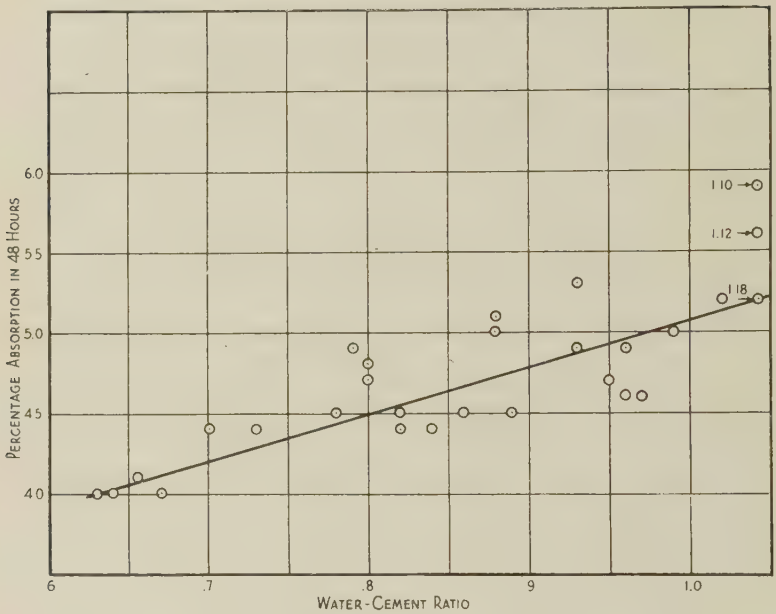

FIG. 11—RELATION OF WATER-CEMENT RATIO TO ABSORPTION FOR MIXES WITH 1½ TO 3-INCH SLUMP

ever, that the flow at the lower pressure of the 40 to 50-hr. interval is about 60 per cent of that for the higher pressure. Had this second series of tests been made at the lower pressure the two curves in the left half of the figure would more nearly coincide. It is evident, therefore, that an increase in age after 40 days has only slight effect on the watertightness. The right hand half of the figure shows the results at the higher pressure for the 100 to 110-hr. interval. It is interesting to note that this curve and the one for the low pressure in the other half of the figure are coincident up to a water-cement ratio of 0.90, and that after a water-cement ratio of 1.00 the curve for the higher pressure increases more sharply. One of the 19 mixes (X-1.35) that had shown moisture on the exposed surface in the original tests appeared dry at the higher pressure, while four of the mixes (F-1.1, G-1.1, U-1.2 and X-1.0) which had previously appeared dry now showed some moisture on the surface.

Long-Time Test Results—Fig. 15 shows flow plotted against

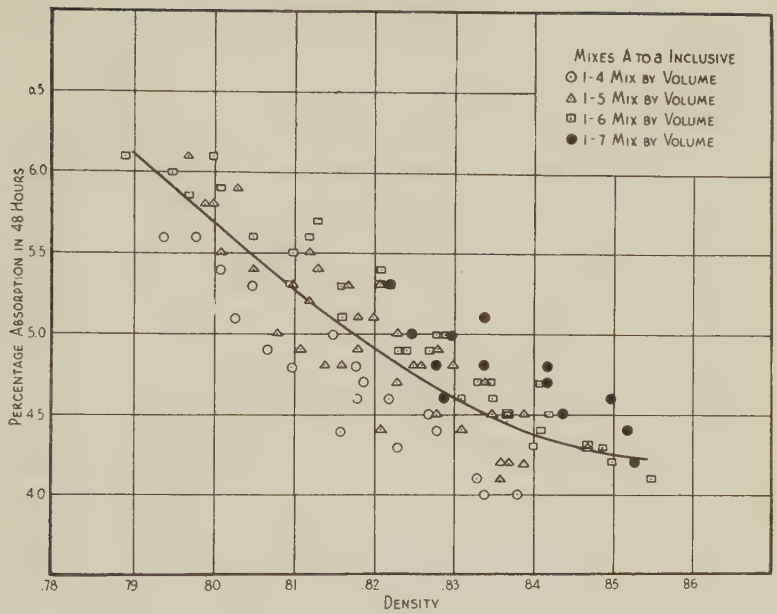

FIG. 12—RELATION OF DENSITY TO ABSORPTION FOR JANESVILLE SAND MIXES

time for several mixes. These tests were made in three installments; the first for 500 hr., the second for 1000 additional hours and the third for 3000 more hours. The dotted portions of the curves indicate these breaks in the testing. About five months elapsed between the first two runs but the specimens were not removed from the apparatus during this interval. The water remained in the casting; the air pressure was turned off. At the end of a total of 1500 testing hours various indigo dyes were added to the water in the hope of having the coloring show on the exposed surface but none was noticeable after 3000 hr., although the slopes of the curves remained constant. It may be possible that the voids in the concrete act similarly to those in charcoal and that the dyes were absorbed as are poisonous gases by the charcoal. Unfortunately the glass water tube on the casting holding the specimen 5-L1.0 was broken at the start of the run. Mix 4-X1.35 was not tested in the original 500-hr. run.

This long time testing was carried on to determine whether or not the flow of water into the specimen would continue only until

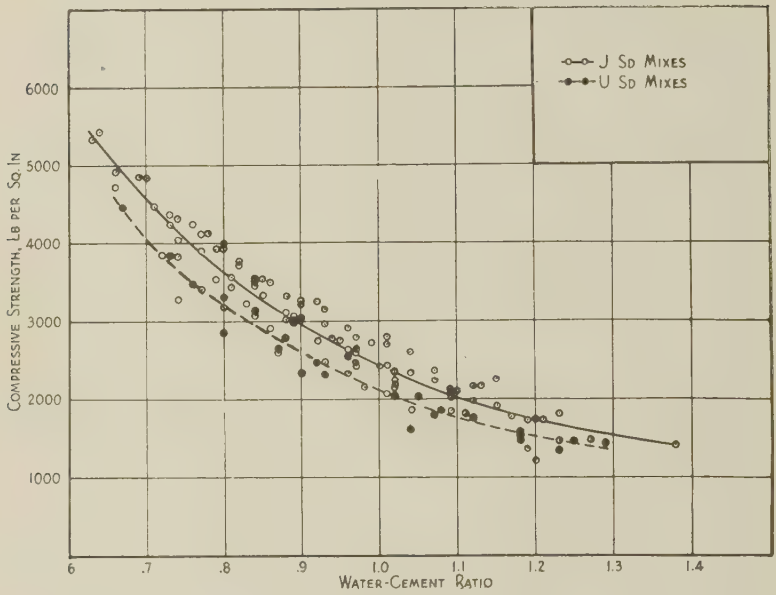

FIG. 13—RELATION OF WATER-CEMENT RATIO TO COMPRESSIVE STRENGTH FOR ALL MIXES

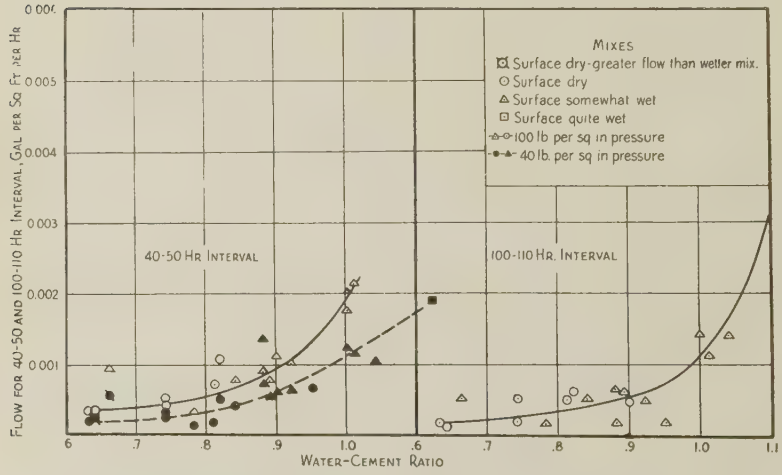

FIG. 14—EFFECT OF VARYING PRESSURE AND TIME ON THE WATER-CEMENT RATIO—FLOW RELATIONSHIP

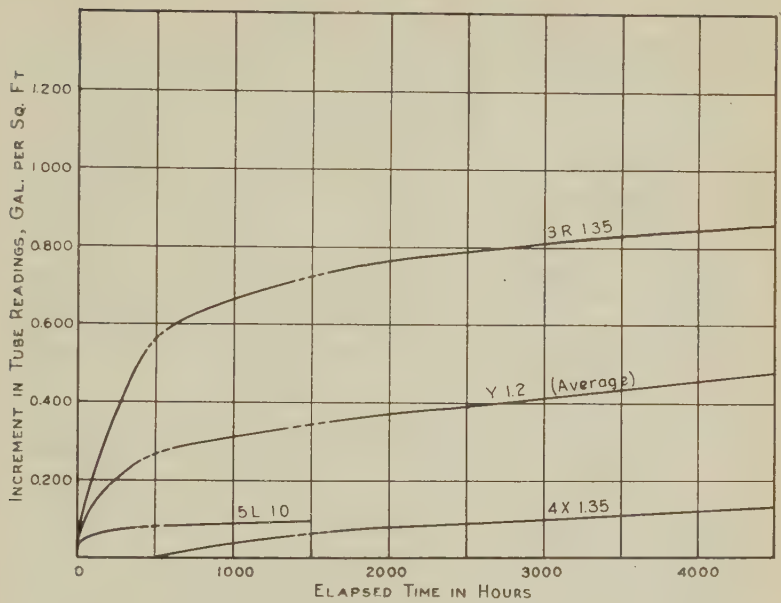

FIG. 15—TIME-FLOW CURVE FOR VARIOUS MIXES UNDER 100 LB. PER SQ. IN. PRESSURE

the voids had been completely filled, and whether the voids would become clogged by sediment or bacterial action in the water. It is evident from the figure that some clogging of the voids did take place but that it was not enough to prevent flow through the specimen at 100 lb. per sq. in. pressure.

The following calculations show the amount of water that must have passed through the specimen during the test run. Tests reported by F. R. McMillan in "Basic Principles of Concrete Making" (p. 9-11) indicated that approximately 0.20 of the volume of cement was combined water and this figure was used in the following calculations.

Mix 3-R-1.35

Permeability Specimen		Materials in Mix	
Weight	36.65 lb.	Cement	19.5 lb.
Volume	0.243 cu. ft.	Cement and Agg.	125.5 lb.
Density	0.805	Water used	12.64 lb.
		Absorption	1.35 lb.
			0.188 cu. ft.

$a + b + c = (0.805 \times 0.243) =$

$$\text{Vol. water combined } \frac{36.65}{138.1} \times \frac{19.5}{94} \times 0.20 = 0.011$$

Vol. water voids $\frac{36.65}{138.1} \times \frac{11.3}{62.5} - 0.011 = 0.037$

Abs. vol. cement, agg., combined water and water voids	0.236 cu. ft.
Vol. of water entering specimen (0.431 gal.)	0.0575
	0.2935
Vol. of specimen	0.243
Vol. of water passing through specimen in 4500 hours	0.0505 cu. ft.

Mix Y 1.2

Permeability Specimen		Materials in Mix	
Weight	36.05 lb.	Cement	19.5 lb.
Volume	0.236 cu. ft.	Cement and Agg.	126.5 lb.
Density	0.801	Water used	12.57 lb.
		Absorption	.89 lb.

Abs. vol. cement agg., combined water and water voids	0.239 cu. ft.
Vol. of water entering specimen (0.236 gal.)	0.0315
	0.2705
Vol. of specimen	0.236
Vol. of water passing through specimen in 4500 hrs.	0.0345 cu. ft.

Mix 5 L 1.0

Permeability Specimen		Materials in Mix	
Weight	38.10 lb.	Cement	15.7 lb.
Volume	0.247 cu. ft.	Cement and Agg.	124.5 lb.
Density	0.847	Water used	8.76 lb.
		Absorption	.89 lb.

Abs. vol. of cement, agg., combined water and water voids	0.244 cu. ft.
Vol. of water entering specimen	0.0066
	0.2506
Vol. of Specimen	0.247
Vol. of water passing through specimen in 1500 hrs.	0.0036 cu. ft.

Undoubtedly some water was lost in the drying of the specimens before they were tested in the later runs. During this interval they were stacked either out of doors or in the dry air of the laboratory with their cylindrical sides still covered with asphalt. It is probable that they lost about 1 per cent of moisture by weight. Tests on absorption indicate, however, that concrete will absorb approximately 1½ per cent by weight when immersed in water for a half hour (see Table 8). Since at least a half hour elapsed after the permeability tubes had been filled with water and the pressure turned on and before the readings were taken, the evaporation was counterbalanced by the absorption (under pressure) and no account of it was taken in the preceding calculations. These computations together with the constant slope of the curves of Fig. 15 indicate that water will flow through even

good concrete (5 L-1.0 mix) although the flow may be slow enough so that the surface appears dry.

SUMMARY

The results of these tests, have been analyzed in the previous section and may be summarized as follows:

1. It might be expected that the permeability would increase as the water-cement ratio increased and these tests indicate that there is such a relationship. However, this relationship is influenced considerably by the consistency and, especially with the leaner mixes, by the grading of the aggregate. More water is required for minimum permeability than for maximum strength, the permeability increasing when the water is reduced below the amount required for a slump of about 2 to 3 in.

2. Permeability decreases as strength increases and these tests indicate that this relationship may be somewhat closer than that between the water-cement ratio and permeability, although there is no apparent reason why this should be so if the relationship between water-cement ratio and strength is as fundamental as it is generally believed to be.

3. Permeability decreases as the cement-voids ratio increases and this relationship also seems to be more definite than that bebetween the water-cement ratio and permeability, apparently because of the effect that the grading of the aggregate and the consistency have on the cement-voids ratio.

4. These tests indicate that there is no relationship between permeability and absorption, except the very general one that a good concrete might be expected to be lower both in permeability and absorption than a poor concrete.

5. These tests indicate that for the comparatively small specimens used there is little change in permeability after the concrete is removed from the moist room into a dry atmosphere, and that even considerable differences in age at time of testing are immaterial, if the age at which the specimens are removed from the moist room is kept constant. In the average structure the concrete as a whole would not dry out so rapidly and the concrete might be expected to decrease in permeability for a considerable time. It may well be, however, that the concrete near the surface may be affected in the same way as the laboratory specimens, and

this would be of considerable importance if such a surface was exposed to the weather and to repeated freezings and thawings.

6. Tests at higher pressure indicate that more water will flow through the specimen, but the increased flow is not directly proportional to the added pressure. Long time tests under high pressure show that clogging of the void spaces is not enough to prevent flow through concrete although the flow may be slow enough so that the surface appears dry.

Addenda for Table 8.

Column 8—"Average Age in Days at First Testing" includes age of rerun specimens when age at retest was less than 75 days.

Column 9—"Age in Days at Retesting" includes age of rerun specimens when more than 75 days old.

Explanation of Symbols.

◌́ Surface dry, but greater flow than wetter mix.

⊙ Surface dry.

◬ Surface somewhat wet.

⊡ Surface quite wet.

Discussion of three Papers under the general heading:*

Workability and Admixtures

"A Study of the Flow Table and the Slump Test"
BY GEORGE A. SMITH AND SANFORD W. BENHAM

"A Study of Slump and Flow of Concrete"
BY INGE LYSE AND W. R. JOHNSON

"Admixtures and Workability of Concrete"
BY G. M. WILLIAMS

The discussion here presented based on three closely related and previously published papers was led by R. B. Young and J. C. Pearson, selected by the Program committee to present convention discussion, in an effort at some reconciliation of view of a moot subject. The impromptu convention discussion; the written discussion prior and subsequent to the convention, is so voluminous as to exceed available space in this Journal. *It is therefore continued to the* Journal *for November, 1931, (Vol. 28) and the publication of several interesting contributions already available is necessarily deferred.*—Editor

BY R. B. YOUNG

I understand that I was chosen to introduce this discussion on the basis that I am a disinterested party, which might be interpreted to mean that I do not know anything about it and therefore am a safe speaker. After reading the papers, I am less prejudiced than I was before because I know less about the subject than I did before. The papers are conflicting and I have been unable to comply with the specification and bring them together. The papers by Mr. Smith and Mr. Benham, and Mr. Lyse and Mr. Johnson, both report experimental comparisons of the flow table and slump as measures of workability and con-

*The three papers were discussed at the 27th Annual Convention, Milwaukee, February 24-26, subsequent to publication in this Journal: "A Study of the Flow Table and the Slump Test," by George A. Smith and Sanford W. Benham, January, 1931, Vol. 27, p. 420. "A Study of Slump and Flow of Concrete," by Inge Lyse and W. R. Johnson, January, 1931, V. 27, p. 439. "Admixtures and Workability of Concrete," by G. M. Williams, February, 1931, Vol. 27, p. 647.

sistency, using similar materials and proportions but different methods of approach. They have arrived at almost opposite conclusions as far as the main point is concerned. I have spent some time trying to bring these two papers together and I have not been very successful, because the fact remains that they record—and I am unable to find a reason why—such different conclusions. It seems to me, after studying the methods and test data obtained, that the data are unconvincing and the reasonable conclusion is that neither is the measure of the workability. Workability, as I believe most men handling concrete will agree, is that combination of the properties of concrete which allow us to handle and place it with reasonable labor and minimum segregation. Neither the slump test nor the flow test measures this property. The slump test has been used as a control test in the field for a great many years, and its widespread adoption is proof of its merit for the purpose. Smith and Benham point out that the slump test acts differently with different types of mixtures. They state this: "During the making of the tests four characteristic conditions as to general shapes of the resulting slump specimen were observed. First; specimens slumped only small amounts and retained somewhat the same shape as the molded sample. Second; specimens slumped several inches but held together, bulging out uniformly as the slump took place." That is the ideal condition when it is used as a control work. "Third; a portion of the specimen stood up on one side and the remainder fell away; not a usual condition and always checked by a second trial. Fourth; top slushed down, leaving a mound, generally of compacted aggregate in the center." That is, the concrete had begun to segregate. The observations of this paper have been quite the general experience of most users of this test. The principal value of the slump test is its use with a certain class of concrete where a uniform degree of workability is represented by a given slump. With fixed materials and a fixed combination of those materials, you can represent the workability that you are after by some slump and later you can be fairly certain that the concrete from which the sample was taken has a workability close to what you are after, if it has that same slump, but if you change the conditions, using other materials possibly, it will take another degree of slump to represent the same degree

of workability. As a control test, that idiosyncrasy of the slump is not so important. However, when it comes to measuring workability and the effect of admixtures, those little peculiarities make it difficult to interpret the result.

The flow test is almost entirely a laboratory test and is not subject to the same faults as the slump test, but is usable over a greater range of mixtures. Its principal value has been to define the approximate workability of a mix in laboratory work. There again I would say that if you find in one of these discussions, that the investigator has had a flow of 80, another laboratory worker has a good idea of what that mixture looks like, but beyond giving the other investigator an idea of what the concrete looks like, I think the test has little practical use. It is entirely too cumbersome for a practical field test.

To increase the range of mixtures, the investigators reporting in these two papers have introduced admixtures into their tests. While the purpose was to increase the range of mixtures studied, I think that one of the most likely results will be to add a good deal of discussion to the papers. In fairness to the authors, I think it should be pointed out that none of them is presenting his data to make a case for or against admixtures. These two papers present studies at workability and tests of workability, and, as I read the papers, the introduction of admixtures was more or less incidental. I think that neither the slump test nor the flow test can be safely used to determine the value of admixtures in concrete, and I, for one, would not accept any conclusions based thereon.

The paper by Professor Williams presents a new method of approach to the study of workability and the value of admixtures. In submitting his data, he made the following comments, which are worth reading. They give a little different slant to his subsequent discussion, if his viewpoint is taken into account. The author writes:

> My purpose was to outline a method of test for the rating of admixtures rather than to discuss the merits or demerits of any particular one or group. A satisfactory test should be established first. Had I intended to compare the admixtures in this manner, I would have included several others which have been used commercially, one of them approaching fairly near to No. 6 in efficiency. I included a minimum of test data in tabular form to make com-
